induced by digitalis more effectively than lidocaine.[96] Underlying atrial fibrillation and flutter typically do not convert to a normal sinus rhythm with administration of phenytoin or lidocaine. When used, phenytoin should be infused slowly IV (~50 mg/min) or in boluses of 100 mg repeated every 5 minutes until control of the dysrhythmias is achieved or a maximum of 1000 mg has been given in adults or 15–20 mg/kg in children.[9,80] Fosphenytoin has not been evaluated in this setting. Maintenance PO doses of phenytoin (300 to 400 mg/d in adults and 6–10 mg/kg/d in children) should be continued until digoxin toxicity is resolved. Lidocaine is given as a 1-1.5-mg/kg IV bolus followed by continuous infusion at 1 to 4 mg/min in adults or as a 1-1.5-mg/kg IV bolus followed by 30 to 50 µg/kg/min in children as required to control the rhythm disturbance (see Chap. 63).

Class IA antidysrhythmics are contraindicated in the setting of CAS poisoning because they may induce or worsen AV nodal block and decrease His-Purkinje conduction at slow heart rates and because their α-adrenergic receptor blockade and vagal inhibition may induce significant hypotension and tachycardia. Class IA antidysrhythmics are also prodysrhythmogenic, and their safety in the setting of CAS poisoning is unstudied. Additionally, quinidine reduces renal clearance of digoxin and digitoxin. The use of isoproterenol should be avoided in CAS-induced conduction disturbances because there may be an increased incidence of ventricular ectopic activity in the presence of toxic concentrations of CAS.

PACEMAKERS AND CARDIOVERSION

External or transvenous pacemakers have had limited indications in the management of patients with CAS poisoning. In one retrospective

study of 92 digitalis-poisoned patients, 51 patients were treated with cardiac pacing, digoxin-specific Fab, or both; the overall mortality rate was 13%.[113] Prevention of life-threatening dysrhythmias failed in 8% of patients treated with immunotherapy and 23% of patients treated with internal pacemakers. The main reasons for failure of digoxin-specific Fab were pacing-induced dysrhythmias and delayed or insufficient doses of digoxin-specific Fab. Iatrogenic complications of pacing occurred in 36% of patients. Thus, overdrive suppression with a temporary transvenous pacemaker should not be used to abolish ventricular tachydysrhythmias in the presence of CAS poisoning.[6,113] In the setting of digoxin poisoning, administration of transthoracic electrical cardioversion for atrial tachydysrhythmias has been associated with the development of potentially lethal ventricular dysrhythmias. The dysrhythmias were related to the degree of toxicity and the amount of administered current in cardioversion.[99] In CAS-poisoned patients with unstable rhythms, such as hemodynamically unstable ventricular tachycardia and ventricular fibrillation, cardioversion and defibrillation, respectively, are indicated.

■ ELECTROLYTE THERAPY

Potassium Hypokalemia and hyperkalemia may exacerbate CAS cardiotoxicity even at "therapeutic digoxin concentrations." When hypokalemia is noted in conjunction with tachydysrhythmias or bradydysrhythmias, potassium replacement should be administered with serial monitoring of the serum potassium concentration. Digoxin-specific Fab administration generally should not be used unless the hypokalemia is corrected and the patient continues to have life-threatening manifestations of CAS cardiotoxicity.

Hyperkalemia may also exacerbate CAS-induced cardiotoxicity, at "therapeutic digoxin concentrations." In this setting, therapies directed at reducing potassium concentrations should be judiciously initiated with care to avoid hypokalemia. Any exacerbation of CAS cardiotoxicity despite this correction should be treated immediately with Fab fragments.

In the presence of acute CAS toxicity, when potassium exceeds 5 mEq/L, digoxin-specific antibody fragments are indicated. When marked hyperkalemia develops in conjunction with ECG evidence of hyperkalemia and if digoxin-specific Fab is not available immediately, an attempt should be made to lower the serum potassium with IV insulin, dextrose, sodium bicarbonate, and PO administration of the ion-exchange resin sodium polystyrene sulfonate. Caution should be applied to the subsequent administration of digoxin-specific Fab because of concern for profound hypokalemia.

Calcium is beneficial in most hyperkalemic patients, but in the setting of CAS poisoning, calcium salts administration is considered to be potentially dangerous. A number of experimental studies cite the additive or synergistic actions of calcium and CAS on the heart (because intracellular hypercalcemia is already present), resulting in dysrhythmias,[37,83,104] cardiac dysfunction[61] (eg, hypercontractility, or the so-called "stone heart," hypocontractility), and cardiac arrest.[72,104,119] Although a 2004 study was unable to show an adverse effect,[43] there exist three case reports[8,64] of CAS-poisoned patients who died at various intervals after calcium administration, which supports the withholding of calcium administration in the setting of hyperkalemia.

The purported mechanism is augmented intracellular cytoplasmic Ca^{2+}, which results from an increased transmembrane concentration gradient that further inhibits calcium extrusion through the Na^+-Ca^{2+} exchange or increased intracytoplasmic stores.[59] This additional cytoplasmic calcium may result in altered contraction of myofibril organelles,[61] less negative intracellular resting potential that allows delayed afterdepolarizations to reach firing threshold,[47,59,83] altered function of the sarcoplasmic reticulum,[61,95] or increased calcium interfering with

myocardial mitochondrial function (see Chap. 22 and 23).[61] Although some investigators suspect that the rate of administration of the calcium may be a factor in the subsequent cardiac toxicity,[72,83] calcium administration should be avoided because better, safer, alternative treatments, such as digoxin-specific Fab, insulin, and sodium bicarbonate, are available for CAS-induced hyperkalemia.[8,37,64,83,104]

Magnesium Hypomagnesemia may also occur in CAS-poisoned patients secondary to the contributory factors mentioned with hypokalemia, such as long-term diuretic use to treat congestive heart failure. The theoretical benefits of magnesium therapy include blockade of the transient inward calcium current, antagonism of calcium at intracellular binding sites, decreased CAS-related ventricular irritability, and blockade of potassium egress from CAS-poisoned cells.[4,31,55,89,100,110,122] Although hypomagnesemia increases myocardial digoxin uptake and decreases cellular Na^+-K^+-ATPase activity, there is conflicting evidence on whether magnesium "reactivates" the CAS-bound Na^+-K^+-ATPase activity.[81,100,110]

The successful use of IV magnesium sulfate in the treatment of patients with ventricular tachydysrhythmias caused by digoxin toxicity has been reported, even in the presence of elevated serum magnesium concentrations.[62] The mechanism of efficacy of magnesium may be its ability to suppress delayed afterdepolarizations, prolong refractory period by decreasing calcium uptake and potassium efflux,[110] activate Na^+-K^+-ATPase as an essential metallo-coenzyme, or antagonize digoxin at the sarcolemma Na^+-K^+-ATPase pump. However, this treatment is only temporizing until digoxin-specific Fab is available for definitive therapy, and it is not advocated as first-line therapy. The precise dosing of magnesium sulfate in CAS-poisoned patients has not been established.[4,31,55,62,89,100,122] A common regimen uses 2 g of magnesium sulfate IV over 20 minutes in adults (25–50 mg/kg/dose to a maximum of 2 g in children). After stabilization, adult patients with severe hypomagnesemia may require a magnesium infusion of 1–2 g/h (25–50 mg/kg/h to a maximum of 2 g in children), with serial monitoring of serum magnesium concentrations, telemetry, respiratory rate (observing for bradypnea), deep tendon reflexes (observing for hyporeflexia), and monitoring of blood pressure. Magnesium is contraindicated in the setting of bradycardia or AV block, preexisting hypermagnesemia, and renal insufficiency or failure.

■ EXTRACORPORAL REMOVAL OF CARDIOACTIVE STEROIDS

Forced diuresis,[66] hemoperfusion,[79,120] and hemodialysis[120] are ineffective in enhancing the elimination of digoxin because of its large volume of distribution (4–10 L/kg), which makes it relatively inaccessible to these techniques. Because of its high affinity for tissue proteins, approximately 10% of the amount of digoxin is found in the serum than is found at the tissue level, and of that amount, approximately 20% to 40% is protein bound.[57]

Various investigations into new methods of extracorporeal removal are under investigation. Plasmapheresis may have a role in removing retained Fab–digoxin complexes to prevent rebound toxicity after digoxin overdose treatment in anuric patients, but its usefulness has not been clearly defined.[15,87] Additionally, there is a suggestion that hemoperfusion through a β_2-microglobulin adsorptive column might be useful as a second line measure for treating patients with acute digoxin toxicity.[55,115]

SUMMARY

Digoxin and digitoxin are the most commonly prescribed members of the drugs classified as CAS. These share common structural similarities and functions at the cellular level. CAS has a narrow

therapeutic index. Signs and symptoms of CAS toxicity range from subtle to profound. Both cardiac and noncardiac effects occur after CAS poisoning. Patients with acute toxicity often have a higher serum concentration of the drug and may present with profound nausea, vomiting, bradycardia, atrial and ventricular ectopy with block, or hyperkalemia. Patients with chronic toxicity often have a lower serum concentration of CAS and may present similarly, but more often the symptoms are more protean and include loss of appetite, headache, weakness, nausea, alteration in mental status, all of which may be combined with similar ectopic rhythms as with acute toxicity.

In addition to overt overdose, an elevation in the serum CAS concentrations and an exacerbation of the clinical drug effect leading to toxicity may occur from drug interactions or from deteriorating metabolic processes such as with declining renal function or from electrolyte abnormalities such as hypokalemia and hypomagnesemia. A systematic approach toward treating patients using basic supportive and decontamination management techniques supplemented by the early administration of digoxin-specific Fab immunotherapy may significantly reduce morbidity and mortality in these high-risk patients.

DIGOXIN-SPECIFIC ANTIBODY FRAGMENTS

Mary Ann Howland

Digoxin-specific antibody fragments (DSFab) are indicated for the management of patients with toxicity related to digoxin and digitoxin, as well as oleander, squill, and toad venom which contain other cardioactive steroids. DSFab have an excellent record of efficacy and safety, and should be administered early in both established and suspected cardioactive steroid poisoning.

HISTORY

The production of antibody fragments to treat patients poisoned with digoxin followed the development of digoxin antibodies for measuring serum digoxin concentrations by radioimmunoassay (RIA).[11] This RIA technique permitted the correlation between serum digoxin concentration and clinical digoxin toxicity.[4,18,24,57]

In 1967, Butler and Chen suggested that purified antidigoxin antibodies with a high affinity and specificity should be developed to treat digoxin toxicity in humans.[11] The digoxin molecule alone, with a molecular weight of 780 daltons, was too small to be immunogenic. But digoxin could function as a hapten when joined to an immunogenic protein carrier such as albumin. These investigators immunized sheep with this conjugate to generate antibodies.[77,79] The immunized sheep subsequently produced a mixture of antibodies that included antialbumin antibodies and antidigoxin antibodies. The antibodies were separated and highly purified to retain the digoxin antibodies, while removing the antibodies to the albumin and all other extraneous proteins. The antibodies that were developed have a high affinity for digoxin, and sufficient cross-reactivity with digitoxin and other cardioactive steroids to be clinically useful for the treatment of all cardioactive steroid poisonings.[13,69,70]

Intact IgG antidigoxin antibodies reversed digoxin toxicity in dogs.[12] Unfortunately, the urinary excretion of digoxin was delayed, and free digoxin was released after antibody degradation occurred. Furthermore, there was significant concern for developing hypersensitivity reactions. To make such antibodies both safe and effective in humans, whole IgG antidigoxin antibodies were cleaved with papain, yielding two antigen-binding fragments (Fab), with a molecular weight of 50,000 daltons each, and one Fc fragment of 50,000 daltons.[12] Affinity chromatography is used to isolate and purify the DSFab following papain digestion. Since the Fc fragment does not bind antigen and increases the potential for hypersensitivity reactions, it was eliminated. When compared with whole IgG antibodies the advantages of DSFab include a larger volume of distribution, more rapid onset of action, smaller risk of adverse immunologic effects, and more rapid elimination.[12,45,48,50] Ultimately, in 1976 Digibind was first used successfully,[78] and in 1986—it

became commercially available,[22] Digibind, a relatively pure, very safe, and extremely effective Fab product, was produced. Another commercial product, DigiFab, approved by the US Food and Drug Administration (FDA) in 2001 is also currently available.[23] It is very similar to Digibind except that it is prepared using a digoxin derivative (digoxin-dicarboxymethoxylamine) as the hapten.

PHARMACOLOGY

Immediately following intravenous (IV) administration, DSFab antibody fragments bind intravascular unbound digoxin. Uncomplexed antibodies then diffuse into the interstitial space, binding free digoxin there. A concentration gradient is then established, which facilitates movement into the interstitial or intravascular spaces of both the free intracellular digoxin and digoxin that is dissociated from its binding sites (the external surface of Na^+-K^+-adenosine triphosphatase [ATPase] enzyme) in the heart and in skeletal muscle.[71] The dissociation rate constant of digoxin for Na^+-K^+-ATPase, therefore, affects the time course for binding to DSFab and, consequently, the onset of action.[52,72]

The binding affinities of DSFab for digoxin and digitoxin are about 10^9 to 10^{11} M^{-1} and 10^8 to 10^9 M^{-1}, and are greater than the affinities of digoxin or digitoxin for the Na^+-K^+-ATPase pump receptor.[22]

PHARMACOKINETICS

The pharmacokinetics of Digibind versus DigiFab (previously named DigiTAb) were compared in human volunteers, in a study financed by Protherics.[88] Each subject received 1 mg of digoxin intravenously as a 5-minute bolus, followed 2 hours later by a 30-minute IV infusion of 76 mg (an equimolar neutralizing dose) of either Digibind or DigiFab. Free and total digoxin (free plus DSFab bound) were assayed using an ultrafiltration method over 48 hours. At 30 minutes after infusion of either DSFab, the serum free digoxin concentration was below the level of detection of the assay and remained so for several hours. A few patients in both groups had free digoxin concentrations rebound to peak concentrations of 0.5 ng/mL at approximately 18 hours and the area under the plasma drug concentration versus time curve (AUC) for 2 to 48 hours, for free digoxin, was similar for both treatment groups. The elimination half-life of total digoxin averaged 18 hours for DigiFab and 21 hours for Digibind, while the distribution half-life was 1 hour for each. The volumes of distribution were 0.3 L/kg for DigiFab versus 0.4 L/kg for Digibind.[22,23] The systemic clearance of DigiFab was higher than Digibind, accounting for the shorter elimination half-life of DigiFab (15 hours versus 23 hours).[88] Urine sampling over the first 24 hours demonstrated mostly free digoxin and very little free DSFab for both groups. The authors postulate that during renal excretion, the DSFab digoxin complex is metabolized in the kidney by the proximal tubular cells, releasing free digoxin and unmeasured DSFab metabolites.[88]

Similar findings were first described by Smith and associates in 1976, following the first clinical use of Digibind in a patient who gave a history of ingesting 90 (0.25 mg) digoxin tablets.[78] Total serum digoxin concentration, which was 17.6 ng/mL before Digibind were given, rose to 226 ng/mL 1 hour after the start of the Digibind infusion and

remained there for 11 hours, before falling off the next 44 hours, with a half-life of 20 hours.[78] Fab concentrations peaked at the end of the infusion and then apparently exhibited a biphasic or triphasic decline, probably reflecting distribution into different compartments, as well as excretion and catabolism. Free serum digoxin concentrations were undetectable for the first 9 hours, then rose to a peak of 2 ng/mL at 16 hours, and fell to 1.5 ng/mL at both 36 hours and 56 hours at which time sampling stopped. An analysis of renal elimination based on an incomplete collection suggested that digoxin was excreted only in the bound form during the first 6 hours, but by 30 hours after Fab administration all digoxin in the urine was free digoxin.

In order to better match availability of DSFab to liberated digoxin, one study compared a loading dose of DSFab followed by an infusion to the total DSFab dose infused over a short amount of time.[68] The former strategy increased the ratio of digoxin bound to uncomplexed DSFab in the plasma from 50% to 70%.[68] The authors hypothesized that a too rapid infusion regimen would result in the elimination of DSFab before the fragments could optimally bind the digoxin redistributing from tissue sites.[68]

Digoxin takes several hours to distribute from the blood to the tissue compartment. As expected, a rodent model demonstrated that DSFab were more effective when administered prior to complete distribution of digoxin.[65] Once distribution is complete, increasing the dose of DSFab improved efficacy, as measured by comparing the AUC of digoxin to that of the Fab-digoxin complex.[65]

Pharmacokinetic studies in patients with renal failure demonstrate that the half-life of DSFab is prolonged 10-fold, with no change in the apparent volume of distribution (Vd).[82] In this situation serum DSFab concentrations remain detectable for 2 to 3 weeks. Total serum digoxin concentrations generally follow DSFab. Case reports demonstrate that free digoxin concentrations reappear up to 10 days following administration of DSFab to patients with severe renal dysfunction, as compared with 12 to 24 hours in patients with normal renal function.[16,25,28,43,54,55,74,76,82–84,89] In one series of patients with end-stage renal disease, the maximum average concentration of free digoxin was 1.30 ± 0.7 ng/mL and occurred at 127 ± 40 hours.[84] The mechanism for this rebound is unclear. Following the peak, there is a slow decline that parallels the elimination of DSFab.

EFFICACY

A large study evaluating adults and children with acute and chronic digoxin toxicity established the efficacy of Digibind.[1] Of the 150 patients treated, 148 were evaluated for cardiovascular manifestations of toxicity prior to treatment: 79 patients (55%) had high-grade atrioventricular (AV) block, 68 (46%) had refractory ventricular tachycardia, 49 (33%) had ventricular fibrillation, and 56 (37%) had hyperkalemia. Ninety percent of patients had a response to DSFab within minutes to several hours of Digibind administration. Complete resolution of all signs and symptoms of digoxin toxicity occurred in 80% of cases. Partial response was observed in 10% of patients, and of the 15 patients who did not respond, 14 were moribund or later found to not be digoxin toxic. The spectacular success of DSFab for patients with digoxin toxicity is demonstrated by the fact that of the 56 patients who had cardiac arrest caused by digoxin, 54% survived hospitalization, as compared with 100% mortality before the availability of these antibody fragments for treatment.[1,5] Newborns, infants, and children have all been successfully treated with Digibind.[5,29,41,73]

ADVERSE EFFECTS AND SAFETY

DSFab are generally safe and effective. Reported adverse effects include hypokalemia as a consequence of reactivation of the Na⁺-K⁺-ATPase; withdrawal of the inotropic or atrioventricular nodal blocking effects of digoxin, leading to congestive heart failure or a rapid ventricular rate in patients with atrial fibrillation; and, rarely, allergic reactions.[22,23] In the multicenter study of 150 patients treated with Digibind, the only acute adverse clinical manifestations were hypokalemia in six patients (4%), worsening of congestive heart failure in four patients (3%), and transient apnea in a several hours old neonate.[1] There were no other reactions reported in any of the patients in this series. In a postmarketing surveillance study of Digibind that included 451 patients, two patients with a prior history of allergy to antibiotics reportedly developed rashes.[59] One of these patients developed a total body rash, facial swelling, and a flush during the infusion. The other experienced a pruritic rash. Two other reported adverse reactions were thrombocytopenia and rigors and were probably unrelated to the use of Digibind.[59] One patient received Digibind on three separate occasions over the course of 1 year for multiple suicide attempts, with no adverse effects.[8]

During the clinical trials with DigiFab, one patient developed pulmonary edema, bilateral pleural effusions, and renal failure, most likely caused by the loss of the inotropic and chronotropic digoxin effects.[23] Phlebitis and postural hypotension were related to the infusion of DigiFab in two healthy volunteers.[23]

Both products warn that patients with allergies to papain, chymopapain, or other papaya extracts may be at risk for an allergic reaction because trace amounts of these residues may remain in the DSFab.[23,50] Manufacturers of DigiFab state that because some literature suggests a resemblance between both dust mite allergens and some latex allergens with the antigenic structures of papain, patients may exhibit cross-allergenicity amongst all three. Patients with an allergy to sheep protein or those who have previously received ovine antibodies or ovine Fab may also be at risk for allergic reactions, although this is not reported.

INDICATIONS FOR DSFab

DSFab are indicated for life-threatening, or potentially life-threatening, toxicity from any cardioactive steroid.[22] Patients with known or suggestive cardioactive steroid exposure with progressive bradydysrhythmias, including symptomatic sinus bradycardia, or second- or third-degree heart block unresponsive to atropine, and patients with severe ventricular dysrhythmias, such as ventricular tachycardia or ventricular fibrillation, should also be treated with DSFab. Ventricular tachycardia with a fascicular block is likely to be a digoxin-toxic rhythm.[26,49] Any patient with a potassium concentration exceeding 5 mEq/L in the setting of an acute or chronic overdose that is attributable to a cardioactive steroid in the presence of other manifestations of digoxin toxicity should also be treated.[6] Acute ingestions greater than 4 mg in a healthy child (or more than 0.1 mg/kg), or 10 mg in a healthy adult, may require DSFab, with the threshold lower in patients with significant medical illness. Serum digoxin concentrations are not representative of myocardial concentrations until tissue distribution takes place. Following ingestion, a time delay of 4 to 6 hours is usually required for digoxin to achieve an equilibrium distribution from the serum to the myocardium. Serum concentrations of ≥10 ng/mL soon after an acute ingestion may predict the need for treatment with DSFab. Because the elderly appear to be at greatest risk of lethality, the threshold for treating patients older than 60 years of age should be lower.[7] Before the advent of DSFab, mortality in patients older than 60 years of age was 58%, as compared to 8% in patients younger than 40 years of age, and 34% in patients between 40 and 50 years of age.[7] A rapid progression of clinical signs and symptoms, such as cardiac and gastrointestinal toxicity and an elevated or rising potassium concentration, in the presence of an acute overdose, suggests a potentially life-threatening exposure and the need for DSFab.

Cardioactive steroid toxicity causes intracellular myocardial hypercalcemia, and the administration of exogenous calcium may further

exacerbate conduction abnormalities and potentially result in cardiac arrest, unresponsive to further resuscitation. Thus, in a patient with an unknown exposure who is clinically ill with characteristics suggestive of poisoning by a cardioactive steroid, a calcium channel blocker, or a β-adrenergic antagonist, DSFab should be administered early in the management, and always prior to calcium use. If digoxin or another cardioactive steroid is involved, the toxic effects can be reversed, obviating the need to administer calcium and avoiding the danger of giving calcium to a cardioactive-steroid-toxic patient. Also, as it may be difficult to distinguish clinically between digoxin poisoning and intrinsic cardiac disease, the administration of DSFab can help establish the diagnosis.

A recent computer-based simulation model compared the treatment of non–life-threatening digoxin toxicity with standard therapy. The authors concluded that treatment with DSFab could decrease length of hospitalization by 1.5 days.[21]

ONSET OF RESPONSE

In the multicenter study of 150 patients, the mean time to initial response from the completion of the Digibind infusion (accomplished over 15 minutes to 2 hours) was 19 minutes (range, 0–60 minutes), and the time to complete response was 88 minutes (range, 30–360 minutes).[17] Time to response was not affected by age, concurrent cardiac disease, or presence of chronic or acute ingestion.[1]

DOSING

The dose of DSFab depends on the total body load (TBL) of digoxin. Adults and children receiving digoxin therapeutically who develop chronic digoxin toxicity require small doses of DSFab because their total body burden of digoxin is smaller when toxicity develops. Children with acute overdoses require DSFab doses based on the amount of digoxin ingested, in a manner similar to adults with acute ingestions.

Estimates of digoxin TBL can be made in three ways: (1) estimate the quantity of digoxin acutely ingested and assume 80% bioavailability (milligrams ingested × 0.8 equals TBL); (2) obtain a serum digoxin

---

TABLE A20–1. Sample Calculation Based on History of Acute Digoxin Ingestion

Adult	Child
Weight: 70 kg	Weight: 10 kg
Ingestion: 50 (0.25-mg) digoxin tablets	Ingestion: 50 (0.25-mg) digoxin tablets

0.25 mg × 50 = 12.5 mg ingested dose	
12.5 mg × 0.80 (assume 80% bioavailability) = 10 mg (absorbed dose)	
$\dfrac{10\ mg}{0.5\ mg/vial} = 20$ vials	

---

concentration (SDC) and, using a pharmacokinetic formula, incorporate the apparent Vd of digoxin and the patient's body weight (in kilograms); or (3) use an empiric dose based on the average requirements for an acute or chronic overdose in an adult or child.

Each of these methods of estimating the dose of DSFab has limitations. History of ingestion is often unreliable, and empiric doses based on averages may overestimate or underestimate Fab requirements. Using the pharmacokinetic formula assumes a steady-state Vd of 5 L/kg. This is not accurate in the acute setting. In addition, the 5 L/kg Vd is a population average that varies both with each individual and in certain diseases, such as the decreases that occur in patients with renal disease (thought to be due to displaced tissue binding) and hypothyroidism.[87]

Sample calculations for each of these methods are shown in Tables A20–1, A20–2, and A20–3. Each vial of DSFab contains 38 mg (Digibind) or 40 mg (DigiFab) of purified DSFab that will bind

approximately 0.5 mg of digoxin or digitoxin. If the quantity of ingestion cannot be reliably estimated, it is safest to use the largest calculated estimate. The clinician should always be prepared to increase the dose, should symptom resolution be incomplete.

ADMINISTRATION

Digibind should be administered intravenously over 30 minutes via a 0.22-μm membrane filter.[22] The 38-mg vial (which binds 0.5 mg digoxin) must be reconstituted with 4 mL of sterile water for IV injection, furnishing an isoosmotic solution containing 9.5 mg/mL of DSFab. This preparation can be further diluted with sterile isotonic saline for injection (for small infants, addition of 34 mL to the 4 mL [for 38 mL total] achieves 1 mg/mL). After Digibind is reconstituted, it should be used immediately, or if refrigerated, it should be used within 4 hours.[22] Although slow IV infusion over 30 minutes is preferable, Digibind may be given by IV bolus to a critically ill patient.

Each 40-mg vial of DigiFab (which binds 0.5 mg digoxin) should be reconstituted with 4 mL of sterile water for IV injection and gently mixed to provide a solution containing 10 mg/mL of DSFab.[23] The reconstituted product should be used promptly or, if refrigerated, it should be used within 4 hours. This preparation can be further diluted with sterile isotonic saline for injection. DigiFab should be administered slowly as an IV infusion over at least 30 minutes unless the patient is critically ill, in which case the DigiFab can be given by IV bolus. If a rate-related infusion reaction occurs, the infusion should be stopped and restarted at a slower rate. For infants and small children, the manufacturer recommends diluting the 40-mg vial with 4 mL of sterile water for IV injection and administering the dose undiluted using a tuberculin syringe. For very small doses, this preparation can be further diluted with an additional 36 mL of sterile isotonic saline for injection (for a total of 40 mL) to achieve a 1 mg/mL concentration.

AVAILABILITY

DSFab are available as Digibind or DigiFab. Vials contain 38 mg or 40 mg of purified lyophilized digoxin-immune ovine immunoglobulin fragments, respectively, with each vial binding 0.5 mg digoxin.

MEASUREMENT OF SERUM DIGOXIN CONCENTRATION AFTER DSFab ADMINISTRATION

Many laboratories are not equipped to determine free serum digoxin concentrations and it is important to remember that after DSFab are administered, total serum digoxin concentrations are no longer clinically useful, because they represent free plus bound digoxin.[2,22,33,38,46,80] The type of test for total digoxin concentrations used can either result in falsely high or falsely low serum concentrations, depending on which phase (solid or supernatant) is sampled.[37,51] If the correct dose of DSFab is administered, the free serum digoxin concentrations should be near zero. Free digoxin concentrations begin to reappear 5 to 24 hours or longer after Fab administration, depending on the antibody dose, infusion technique, and the patient's renal function. Newer commercial methods, using ultrafiltration or immunoassays, make free digoxin concentration measurements easier to perform and, therefore, more clinically useful, but they remain associated with errors in the underestimation or overestimation of the free digoxin level.[32,39,56,63,81,85] Free digoxin concentrations are particularly useful in patients with severe renal dysfunction. Independent of the availability of these data, the patient's cardiac status must be carefully monitored for signs of recurrent toxicity.

Other pitfalls in the measurement and utility of serum digoxin concentrations include endogenous and exogenous factors. Endogenous digoxinlike immunoreactive substances (EDLISs) have been described in infants, in women in the third trimester of pregnancy, and in patients with renal and hepatic failure.[31,34,36,40,42,52,86,87] When EDLISs are free or weakly bound, as in these circumstances, they are measurable by the typical RIA and can account for factitiously high reported serum digoxin concentrations in the absence of digoxin treatment. The role of EDLISs in the body has not been fully elucidated, but they have an effect on both the Na^+-K^+-ATPase pump and the cardioactive steroid receptor site.[35] EDLISs are implicated as a causative factor in hypertension and renal disease.[53] Exogenous factors relate primarily to measurement techniques and interpretation.[44] Digoxin metabolites have varying degrees of cardioactivity.[47] Some metabolites cross-react and are measured by RIA, while others are not. The in vivo production of these metabolites varies in patients, and may depend on intestinal metabolism by gut flora as well as renal and liver clearance.

ROLE OF DSFab WITH OTHER CARDIOACTIVE STEROIDS

DSFab were designed to have high-affinity binding for digoxin and digitoxin. There are structural similarities, however, among all cardioactive steroids. In fact, RIA-determined digoxin concentrations have been reported in patients following poisoning with many nondigoxin cardioactive steroids,[28,49,58,64] suggesting that there is also cross-reactivity between DSFab and other cardioactive steroids. Thus, DSFab may have variable efficacy for all natural cardioactive steroid poisonings, including those unique cardioactive steroids in oleander, yellow oleander, squill, and toad venom.[3,9,10,15,27,30,66] In vitro studies also suggest the binding affinity of Digibind for cardioactive steroids.[19,20,60] One recent GlaxoSmithKline-funded in vitro study demonstrated that although both Digibind and DigiFab bound digoxin equally well, a small difference in the amount of ouabain binding to Fab subpopulations was identified with twice as much bound to Digibind as DigiFab.[61]

The successful reversal, by Digibind, of cardiotoxicity resulting from ingestion of *Nerium oleander* and *Thevetia peruviana* are reported.[14,75] One adult and one child each responded to five vials (200 mg) of Fab, but larger doses may be required in other cardioactive steroid poisonings because of the lower affinity binding of Digibind for these toxins. DigiFab is expected to have similar affinity binding toward cardioactive steroids. Both products are polyclonal, contributing to their broad spectrum of affinity for nondigoxin cardioactive steroids. Treatment decisions should be based on empirical grounds, with initial therapy consisting of 10 to 20 vials. Subsequent doses can be based on clinical response.

SUMMARY

Digoxin-specific antibody fragments have dramatically advanced the care of patients poisoned with cardioactive steroids. In the more than 30 years since the release DSFab, a lethal overdose has become manageable allowing the clinician ease in treatment with almost no risk to the patient.

CHAPTER 65

METHYLXANTHINES AND SELECTIVE β₂ ADRENERGIC AGONISTS

Robert J. Hoffman
Caffeine
(1,3,7-trimethylxanthine)
Theophylline
(1,3-dimethylxanthine)

Caffeine
MW .... = 194.19 daltons
Therapeutic serum concentration .... = 1–10 μg/mL

Theophylline
MW .... = 180.17 daltons
Therapeutic serum concentration .... = 5–15 μg/mL
.... = 10 μg/mL
.... = 55.5 μmol/L

Methylxanthines are plant-derived alkaloids that include caffeine (1,3,7 trimethylxanthine), theobromine (3,7-dimethylxanthine), and theophylline (1,3-dimethylxanthine). They are so named because they are methylated derivatives of xanthine. Members of this group have very similar pharmacologic properties and clinical effects. Methylxanthines are used ubiquitously throughout the world, most commonly in beverages imbibed for their stimulant, mood elevating, and fatigue abating effects. *Coffea arabica* and related species are used to make coffee, a beverage rich in caffeine. Cocoa and chocolate are derived from the seeds of *Theobroma cacao*, which contains theobromine and to a lesser extent caffeine. *Thea sinensis*, a bush native to China but now cultivated worldwide, produces leaves from which various teas, rich in caffeine and containing small amounts of theophylline and theobromine, are brewed. *Paullinia* spp, commonly known as guarana, is a South American plant that produces berries with a caffeine content much greater than that of coffee beans. Guarana is widely used as an additive in herbal energy drinks.

Selective β₂ adrenergic agonists (β₂AA) have been developed for the treatment of bronchoconstriction. Their selectivity has improved therapy for bronchoconstriction, allowing avoidance of the adverse effects of the previously used therapies: epinephrine, an α-and β-adrenergic agonist, as well as isoproterenol, a β₁ and β₂AA. All β₂AAs have nearly identical clinical effects; the principal differences are their pharmacokinetics. This chapter does not examine each β₂AA individually but instead discusses them as a class. The β₂AAs include albuterol, bitolterol, formoterol, pirbuterol, salmeterol, terbutaline, and ritodrine. Clenbuterol, a long-acting agonist at β₂ and β₃ adrenergic receptors, used for the purpose of treating bronchoconstriction in countries outside the United States, has emerged as an abused anabolic xenobiotic in recent years.

EPIDEMIOLOGY

The American Association of Poison Control Centers reported the following trends in methylxanthine exposures. Theophylline exposures decreased from 2609 involving 20 deaths in 1998 to 413 exposures and four deaths in 2006. Caffeine exposures decreased from 7390 exposures and no deaths in 1998 to 5696 exposures of pharmaceutical and herbal caffeine but involving seven deaths in 2006. The decrease in theophylline exposures presumably reflects continued decrease in use of theophylline in the treatment of patients with pulmonary disease. The number of caffeine exposures has essentially remained stable, reflecting steady use of caffeine, particularly caffeine in substances other than coffee, tea, and soft drinks.

There were 11,397 selective β₂AA exposures and one death in 1998 and 9564 and one death in 2006. The number of selective β₂AA exposures has remained relatively stable, presumably from consistent use of these agents, but death has remained uncommon. See Chap. 135 for a discussion of poison exposure data.

The overwhelming preponderance of caffeine consumed is in beverages, and a lesser portion is consumed in foods and tablets or capsules. Users typically seek the stimulant and psychoactive effects of caffeine. Caffeine, particularly in herbal forms such as guarana or cola nut, is also increasingly advocated for use as a weight loss agent.[76,15] The use of guarana, a plant with very high caffeine content, for weight loss and athletic performance enhancement has increased dramatically in recent years. With some scientific evidence demonstrating benefit in athletic performance, caffeine is advocated as a concentration[101,163] and "energy" booster and as an athletic performance enhancer.[34,100] Energy drinks typically containing caffeine and other stimulant ingredients are increasingly popular, particularly with adolescents and athletes.[122]

Despite the limited experience with overdose from these combination preparations, formulations containing caffeine and guarana combined with ephedrine and ma huang cause illnesses such as myocardial infarctions and death.[83] Formulations containing phenylpropanolamine and caffeine, also once marketed as an anorexiant diet aid, were removed from U.S. markets because of adverse drug events and a demonstrated lack of benefit from the inclusion of caffeine and a sympathomimetic xenobiotic for the purpose of appetite suppression.[86] (See Chap. 39 for more discussion of dietary supplements). Energy drinks are, not unexpectedly, revealing themselves as having adverse side effects.[42]

Medicinally, caffeine is used to treat neonatal apnea and bradycardia syndrome, as an analgesic adjuvant, particularly when combined with relatively mild analgesics such as acetaminophen, aspirin, and ibuprofen, and as an adjuvant treatment for headaches.

Theophylline or its water-soluble salt, aminophylline, is used to treat varied respiratory conditions, but is most well studied for its use in reversible bronchospastic airway disease, particularly asthma and chronic obstructive pulmonary disease (COPD). Theophylline was once the mainstay of therapy for such diseases, but more selective β₂aAs with fewer adverse effects, such as albuterol and other selective β₂aA, are now generally used. However, antiinflammatory and other beneficial effects of theophylline continue to be described.[107] In neonates, theophylline and aminophylline are used similarly to caffeine to

treat apnea and bradycardia syndrome. The result of such treatment is increased respiratory rate, decreased apnea, increased cardiac chronotropy and inotropy, and increased cardiac output.[32]

Caffeine toxicity is generally classified as acute, acute on chronic, or chronic in nature. Neonates receiving caffeine therapy may develop either acute or chronic caffeine toxicity.[7,17]

Chronic toxicity from caffeine is most typically described as a result of the frequent self-administration of excessive caffeine. A particular syndrome associated with chronic caffeine use consisting of headache, palpitations, tachycardia, insomnia, and delirium is termed *caffeinism*.

Theophylline toxicity results from the use of theophylline as a medicinal therapeutic agent and may develop as acute, chronic, or acute-on-chronic toxicity.

Acute-on-chronic toxicity may occur with caffeine or theophylline and is the circumstance of acute overdose in a patient already receiving chronic therapy.

Most reported cases of theobromine poisoning occur in the veterinary literature and typically result from small animals ingesting cocoa or chocolate.[57,84] Theobromine has become an ingredient of numerous "energy" drinks used for stimulation and athletic enhancement. No reports of human toxicity currently exist, but it is probable that toxicity from these sources will be reported.

Use of β₂AAs is widespread. Adverse effects are associated with both therapeutic dosing and overdose. Excessive use of β₂AAs may result in tachyphylaxis, a phenomenon in which downregulation of receptors occurs and the effects from this drug diminish as a result of excessive use.[46,96] Consequently, patients may require higher doses to achieve the same clinical effects previously experienced at lower doses, resulting in more profound systemic side effects. The most common selective β₂AA toxicity results from children ingesting oral (PO) albuterol. Toxicity of terbutaline and ritodrine are infrequent but well reported. Epidemic clenbuterol exposures have occurred in recent years, which are the result of both admixture of this substance with illicit xenobiotics as well as by intentional use for bodybuilding purposes in the United States.[53] Food poisoning by consumption of animal meat from livestock treated with clenbuterol has occurred in Europe.[18]

PHARMACOLOGY

■ METHYLXANTHINES

Methylxanthines cause the release of endogenous catecholamines, resulting in stimulation of β₁ and β₂ receptors. The resulting adrenergic agonism is important in both the therapeutic effects and of toxicity.[187] Endogenous catecholamine concentrations are extremely elevated in patients with methylxanthine poisoning.[22]

Methylxanthines are structural analogs of adenosine and function pharmacologically as adenosine antagonists. Adenosine is believed to modulate histamine release and cause bronchoconstriction, which may explain the primary therapeutic efficacy of adenosine antagonists in the treatment of bronchospasm. Additionally, adenosine antagonism results in release of norepinephrine, and to a lesser extent epinephrine, through blockade of presynaptic A2 receptors. The additional methyl group possessed by caffeine (1,3,7 trimethylxanthine) affords this agent greater central nervous system (CNS) penetration relative to theophylline and theobromine, which are dimethylxanthines. Caffeine is an effective analgesic adjuvant, possibly because of the stimulant properties of the drug.[129,131,161,162]

Methylxanthines also inhibit phosphodiesterase, the enzyme responsible for degradation of intracellular cyclic AMP (cAMP), which has many effects, including an increase in intracellular calcium concentrations. Phosphodiesterase inhibition was long considered to be the primary therapeutic mechanism of the methylxanthines, but clinically significant elevations in cAMP levels are not achieved until serum methylxanthine concentrations are well above the therapeutic range. This likely occurs as a result of the structural similarity of the adenosine moiety of cAMP and the methylxanthines. cAMP is involved in the postsynaptic second messenger system of β-adrenergic stimulation. Thus, elevated cAMP levels cause clinical effects similar to adrenergic stimulation, including smooth muscle relaxation, peripheral vasodilation, myocardial stimulation, skeletal muscle contractility, and CNS excitation.

■ SELECTIVE β₂ ADRENERGIC AGONISTS

Selective β₂AAs act quite specifically at β₂ adrenergic receptors, resulting in an increase in intracellular cAMP. The effects of β₂ agonism include relaxation of vascular, bronchial, and uterine smooth muscle; glycogenolysis in skeletal muscle; and hepatic glycogenolysis and gluconeogenesis. These receptors are located on other cells such as type II alveolar cells, mast cells, and lymphocytes, but their significance is unknown. Selective β₂AAs have been characterized as either directly activating the β₂ receptor, such as albuterol, being taken up into a membrane depot, such as formoterol, or interacting with a receptor-specific auxiliary binding site, such as salmeterol. These differences do not appear to be relevant in acute toxicity.[91] However, emerging evidence suggests that prolonged overuse of long-acting β₂AAs may have severe or fatal adverse effects.[159]

PHARMACOKINETICS AND TOXICOKINETICS

■ CAFFEINE PHARMACOKINETICS

Caffeine is bioavailable by PO, intravenous (IV), subcutaneous, intramuscular, and rectal routes of administration. PO administration, which is by far the most common route of exposure, results in nearly 100% bioavailability of the drug. The presence of food in the gut does little to affect peak concentration. However, food in the gut does delay time until the peak serum concentration is reached, which is typically 30 to 60 minutes in the absence of food. Caffeine rapidly diffuses into the total body water and all tissues and readily crosses the blood–brain barrier and into the placenta. The volume of distribution (Vd) is 0.6 L/kg, and 36% is protein bound. Caffeine is secreted in breast milk with concentrations of 2 to 4 μg/mL in breast milk after 100 mg PO dosing in a breastfeeding mother.[180] Consumption of very large caffeine doses or chronic caffeine use might result in breast milk concentrations capable of causing clinical effects in the breastfeeding child, but this is not typical.

When taken in amounts greater than the typical therapeutic dose in a caffeinated beverage, caffeine exhibits Michaelis-Menten kinetics and is metabolized via the microsomal cytochrome P450 system, primarily by the isoenzyme CYP1A2. The major pathway involves demethylation to 1,7 dimethylxanthine (paraxanthine) followed by hydroxylation or repeated demethylation followed by hydroxylation. To a lesser extent, caffeine is also metabolized to theobromine and theophylline. Neonates demethylate caffeine, producing theophylline, and possess the unique ability to convert theophylline to caffeine by methylation.[1,11,12,31,71] By approximately 4 to 7 months of age, infants metabolize and eliminate caffeine in a manner similar to adults.[10] All patients demethylate some quantity of caffeine to active metabolites, including theophylline and theobromine. The degree to which this occurs is dependent on the patient's age, cytochrome P450 enzyme induction status, and other factors.

Less than 5% of caffeine is excreted in the urine unchanged. The half-life of caffeine is highly variable and dependent on several factors. Generally speaking, younger patients, particularly infants as well as

patients with cytochrome P450 inhibition, such as pregnant patients and patients with cirrhosis, have longer caffeine half-lives than the 4.5 hour half-life in healthy, adult, nonsmoking patients.[33,50,54,179]

Caffeine Toxicokinetics Caffeine toxicity is a dose-dependent phenomenon. Unfortunately, the range of toxic concentrations reported in different references varies greatly, and no definite conclusions can be drawn regarding the relationship between serum concentrations and symptomatology in overdose. Therapeutic dosing in neonates is typical loading dose is 20 mg/kg, with daily maintenance dosing of 5 mg/kg. Based on case reports and series, lethal dosing in adults is estimated at 150 to 200 mg/kg, and death may be associated with serum concentrations above 80 µg/mL. Numerous fatalities are reported with serum concentrations under 200 µg/mL; survival of a patient with an acute caffeine overdose and a serum concentration over 400 µg/mL has been reported.[184] Infants survive toxicity with greater serum concentrations of caffeine than are tolerated by children and adults.

■ THEOPHYLLINE PHARMACOKINETICS

Theophylline is approximately 100% bioavailable by the PO and IV routes. Many of the available PO preparations are sustained release designed to provide stable serum concentrations over a prolonged period of time with less frequent dosing. Peak absorption for immediate-release preparations is 60 to 90 minutes and sustained-release preparations generally occurs 6 to 10 hours after ingestion.

Similar to caffeine, theophylline rapidly diffuses into the total body water and all tissues, readily crosses the blood–brain barrier, and crosses into the placenta and breast milk.[14,109,197,199] Theophylline's Vd is 0.5 L/kg, and 56% of it is protein bound at therapeutic concentrations.

Theophylline is metabolized via the microsomal cytochrome P450 system, primarily by the isozyme CYP1A2. The major pathway is demethylation to 3-methylxanthine in addition to being demethylated or oxidized to other metabolites. Less than 10% of theophylline is excreted in the urine unchanged.

Similar to caffeine, the half-life of theophylline is highly variable and is dependent on several factors. In healthy, adult, nonsmoking patients, the half-life is 4.5 hours. Infants and the elderly as well as patients with cytochrome P450 inhibition, pregnant patients, and patients with cirrhosis have longer theophylline half-lives than healthy children and adult nonsmoking patients.[92,123,178] Factors that induce cytochrome P450, such as cigarette smoking, or others that inhibit cytochrome P450, such as exposure to cimetidine, erythromycin, and PO contraceptives, can significantly alter theophylline clearance.[79,121,137,138,153,189] Cessation of smoking, such as when a COPD patient develops bronchitis, leads to a reversal of P450 induction and predisposes to the development of chronic toxicity.

Theophylline Toxicokinetics As in the case of caffeine, theophylline exhibits Michaelis-Menten kinetics, presumably when greater than a single therapeutic dose is taken.[152] At higher doses and in overdose, it undergoes zero-order elimination, and only a fixed amount of the drug can be eliminated in a given time because of saturation of metabolic enzymes.[150]

Therapeutic serum concentrations of theophylline are 5 to 15 µg/mL. Although morbidity and mortality are not always predictable based on serum levels, life-threatening toxicity are associated with serum concentrations of 80 to 100 µg/mL in acute overdoses and of 40 to 60 µg/mL in chronic toxicity.

■ THEOBROMINE TOXICOKINETICS AND PHARMACOKINETICS

As is the case with the other methylxanthines, theobromine is well absorbed from the gut and is 80% bioavailable when administered in solution. It is bioavailable PO and rectally. Theobromine has 21% protein binding, a Vd of 0.62 L/kg and a plasma half-life of 6 to 10 hours.[58,147] Theobromine undergoes hepatic metabolism by the CYP1A2 and CYP2E1.[30] Similar to the other methylxanthines, theobromine is excreted in breast milk. Toxic concentrations of theobromine in animals are known, but comparable human data are lacking.

■ SELECTIVE β₂ ADRENERGIC AGONIST PHARMACOKINETICS

The β₂AAs are bioavailable by both the inhalational and enteral route, and much of "inhaled" β₂AAs may actually be swallowed and absorbed from the gastrointestinal (GI) tract. Absorption, distribution, and elimination vary among these agents. The half-life of albuterol is approximately 4 hours, less than 5% crosses the blood–brain barrier, it is metabolized extensively in the liver, and it is excreted in urine and feces as albuterol and metabolites.[3]

Terbutaline is partially metabolized in the liver, mainly to inactive conjugates. With parenteral administration, 60% of a given dose is excreted in the urine unchanged.[2]

Clenbuterol has a terminal half-life of approximately 22 hours and a prolonged duration of action. Additionally, it is more potent than other β₂AA, with a typical therapeutic dose of 20 to 40 µg, as opposed to milligram doses for other β₂AAs.

Selective β₂AA Toxicokinetics Overdose of albuterol, which typically happens predominantly in young children treated with PO albuterol preparations, may cause significant symptomatology.[106] For PO albuterol poisoning, 1 mg/kg appears to be the dose threshold for developing clinically significant toxicity.[194]

Clenbuterol toxicity occurs from use by a variety of routes, generally as a result of the varied route of illicit drug use. Ingestion, intranasal use, and IV use of clenbuterol or clenbuterol-tainted street drug have been reported.

■ METHYLXANTHINE AND β₂AA TOXICITY

Caffeine, theobromine, and theophylline affect the same organ systems and cause qualitatively similar effects.

It should be noted, however, that there are distinct differences in the activity and effects of the various methylxanthines, particularly in therapeutic dose. Toxicity affects the GI, cardiovascular, central nervous, and musculoskeletal systems in addition to causing a constellation of metabolic derangements. A putative cause for toxicity involves the increase in metabolism that occurs with methylxanthine toxicity, particularly in the setting of a decreased ability to meet the increased demand by way of impaired perfusion.

Polypharmacy poisoning with other xenobiotics that result in adrenergic stimulation, such as pseudoephedrine, ephedrine, amphetamines, or cocaine, may be particularly severe.[55,192]

Gastrointestinal In overdose, methylxanthines cause nausea, and most significant acute overdoses result in severe and protracted emesis. Whereas emesis occurs in 75% of cases of acute theophylline poisoning, only 30% of cases of chronically poisoned patients have emesis.[171] When it occurs, the emesis is often quite severe and may be difficult to control despite the use of potent antiemetics. This is especially evident with sustained-release theophylline preparations.[4] Emesis is less common with β₂AA, and when it does occur, it is uncommonly as severe as is associated with methylxanthines.

Methylxanthines cause an increase in gastric acid secretion and smooth muscle relaxation. These factors contribute to the gastritis and esophagitis reported in chronic methylxanthine users.[45] Gastritis is noted in drinkers of decaffeinated coffee, so some adverse gastric

effects associated with coffee drinking may be caused by ingredients other than caffeine.

Cardiovascular Methylxanthines are cardiac stimulants and result in positive inotropy and chronotropy even with therapeutic dosing. Dysrhythmias, particularly tachydysrhythmias, are common in patients with methylxanthines overdose. Tachydysrhythmias, particularly ventricular extrasystoles, are more common after overdose of methylxanthines.[41,130,164] Cardiac dysrhythmias, although described with β₂AA poisoning, are most frequently supraventricular in origin and clinically inconsequential. Dysrhythmias other than sinus tachycardia associated with β₂AA toxicity are not routinely noted with toxicity from other β₂AAs, but clenbuterol may result in atrial fibrillation.[53] Palpitations, tachycardia, and chest pain are common presenting complaints for patients with clenbuterol toxicity.

In the setting of acute poisoning, generally benign sinus tachycardia is nearly universal in patients without antecedent cardiac disease. In any patient, particularly those with underlying cardiac disease, sinus tachycardia may degenerate to a more severe rhythm disturbance, and these represent the most common causes of fatality associated with methylxanthines poisoning. Both atrial and ventricular dysrhythmias, including supraventricular tachycardia (SVT), multifocal atrial tachycardia, atrial fibrillation, premature ventricular contractions, and ventricular tachycardia, may all result from methylxanthine toxicity.[21,168] Electrolyte disturbances, particularly hypokalemia, may be a contributing factor in the development of dysrhythmias. Dysrhythmias occur more commonly and at lower serum concentrations in cases of chronic poisoning with methyxanthines. Consequential dysrhythmias occur in 35% of patients with chronic theophylline poisoning but in only 10% of acute poisoning.[168] Ventricular dysrhythmias occur at serum concentrations of 40 to 80 µg/mL in patients with chronic theophylline overdoses and most commonly at serum levels greater than 80 µg/mL in patients with acute overdoses. Neonates born to mothers who consumed more than 500 mg/day of caffeine are more likely to have dysrhythmias compared with cohorts born to mothers consuming less than 250 mg/day of caffeine.[80] For reference, a cup of coffee or bottle of cola may contain 50 to 100 mg of caffeine.

Myocardial ischemia and myocardial infarction may result from acute caffeine or theophylline poisoning.[64,85,125] Myocardial infarction has been associated with both albuterol[61] and more recently clenbuterol.[105] Isoproterenol, once a common asthma therapy before widespread use of selective β₂AAs, has both β₁- and β₂-adrenergic agonist activity and is a well-reported cause of myocardial infarction. Given the frequency of use of selective β₂AAs as well as toxicity and adverse effects, it seems as though myocardial infarction is unlikely to occur. The same cannot be presumed about clenbuterol because the toxicity profile for this drug is still emerging.

Elevation of creatine phosphokinase muscle (CPK-MM) and cardiac (CPK-MB) fractions after large doses of β₂AA, particularly terbutaline infusions and continuous albuterol nebulization, have been well described.[47,48,183] In the absence of electrocardiographic (ECG) changes suggestive of ischemia, the clinical significance of increased CPK-MB and cardiac troponins in patients receiving terbutaline infusions, particularly children, is unclear and has not been demonstrated to correlate with clinically adverse effects.[43]

In therapeutic doses, methylxanthines cause cerebral vasoconstriction, which is a desirable effect when caffeine is used to treat a migraine headache. However, in overdose, this effect likely exacerbates CNS toxicity by diminishing cerebral perfusion.[125] Tolerance to the vasopressor effects of methylxanthines develops after several days of use and rapidly disappears after relatively brief periods of abstinence.

It has been noted that dietary caffeine use is associated with a slight but significant increase in blood pressure that may contribute to population levels of morbidity and mortality.[95] At elevated serum concentrations, patients with methylxanthine or β₂AA poisoning often develop a characteristic widened pulse pressure or divergence of the systolic and diastolic blood pressures. This is caused by enhanced inotropy (β₁), resulting in systolic hypertension combined with peripheral vasodilation (β₂), resulting in diastolic hypotension. In cases of acute theophylline overdose, serum concentrations greater than 100 µg/mL are usually associated with severe hypotension.

Methylxanthines cause renal vasodilation that, in addition to the increased cardiac output, results in a mild diuresis.[139]

Pulmonary Methylxanthines stimulate the CNS respiratory center, causing an increase in respiratory rate. For this reason, caffeine and theophylline are used to treat neonatal apnea syndromes. Caffeine and theophylline overdose may cause hyperventilation, respiratory alkalosis, respiratory failure, respiratory arrest, and acute lung injury.

Neuropsychiatric The stimulant and psychoactive properties of methylxanthines, particularly caffeine, elevate mood and improve performance of manual tasks.[25,35,94] These stimulant effects are typically considered desirable and are one reason caffeine is so widely used. CNS stimulation is an effect sought by users of coffee, tea, cocoa, and chocolate, but CNS stimulation resulting from therapeutic use of theophylline is generally considered to be an undesirable side effect. Although at low doses methylxanthines improve cognitive performance and elevate mood, with increasing doses they result in adverse effects. Headache, anxiety, agitation, insomnia, tremor, irritability, hallucinations, and seizures may result from caffeine or theophylline poisoning. In adults, caffeine doses of 50 to 200 mg result in increased alertness, decreased drowsiness, and lessened fatigue, and caffeine doses of 200 to 500 mg produce adverse effects such as tremor, anxiety, diaphoresis, and palpitations. Children tend to develop CNS symptoms at lower serum theophylline concentrations than adults, and such excitation is a significant clinical disadvantage of theophylline use.

Seizures are a major complication of methylxanthine poisoning. Caffeine's ability to both promote and prolong seizures is well recognized, and caffeine has been used to prolong therapeutically induced seizures in electroconvulsive therapy (ECT).[52,103] Seizures resulting from methylxanthine overdose tend to be severe and recurrent and may be refractory to conventional treatment. Antagonism of adenosine, the endogenous neurotransmitter responsible for halting seizures, contributes to the profound seizures associated with methylxanthine overdose.[59,65,169,198] When studied prospectively, whereas chronic theophylline toxicity results in seizures in 14% of patients, 5% of acutely poisoned patients experience seizures. In cases of chronic and acute-on-chronic toxicity, seizures are more likely to occur, and they occur at lower serum concentrations.[141] Patients at extremes of age—those younger than age 3 years and older than age 60 years—are more likely to experience seizures with overdose.

Musculoskeletal Methylxanthines increase striated muscle contractility, secondarily decreasing muscle fatigue. They also increase muscle oxygen consumption and increase the basal metabolic rate. These effects are sought by users of methylxanthines to enhance or improve athletic performance or weight loss.[9,19,44,60,74,75] Theobromine has the most potent activity to increase muscle contractility—more than 100 times that of caffeine—and theophylline has the least muscle-stimulating activity. All methylxanthines cause smooth muscle relaxation.

Tremor is the most common adverse effect of methylxanthines. Skeletal muscle excitation, which may include fasciculation, hypertonicity, myoclonus, or even rhabdomyolysis, may occur with methylxanthine overdose.[110,120,155,197] Mechanisms by which rhabdomyolysis may result include increased muscle activity, particularly from seizures, and direct cytotoxicity from excessive sequestered intracytoplasmic calcium. Interestingly, there have been multiple case reports of compartment syndrome with rhabdomyolysis resulting from theophylline overdose.[119,185]

Metabolic Numerous metabolic derangements result from acute methylxanthine toxicity and are similar to those in other hyperadrenergic situations.[79,82,159,170]

Severe hypokalemia may result from β_2 adrenergic stimulation.[186] This results from influx of extracellular potassium into the intracellular compartment despite normal total body potassium content. Both ECG and neuromuscular complications of hypokalemia may develop. Other metabolic effects of methylxanthine and β_2AA poisoning include hypomagnesemia and hypophosphatemia.[29,106,191]

Transient hypokalemia resulting from β-adrenergic agonism occurs in 85% of patients with acute theophylline overdose, and typically the serum potassium decreases to approximately 3 mEq/L.[5,173] Stimulation of Na⁺-k⁺ ATPase results in a shift of serum potassium to the intracellular compartment of skeletal muscle. Total body potassium stores are unchanged. The significance of hypokalemia in patients with methylxanthine overdose is unclear. Vomiting and renal losses do not contribute significantly to hypokalemia, but these may result in fluid loss. Hyperkalemia may result from rhabdomyolysis and overly aggressive repletion of potassium.

Metabolic acidosis with increased serum lactate levels is commonly noted as a complication of theophylline overdose.[24,114] Tachypnea and respiratory alkalosis secondary to stimulation of the respiratory center are also common. Clenbuterol is unique among β_2AAs in that its toxicity is associated with anion gap metabolic acidemia in some cases.

Hyperglycemia, with serum glucose of approximately 200 mg/dL in nondiabetics, is common and occurs in 75% of patients with acute theophylline overdose. Hyperthermia caused by increased metabolic activity and increased muscle activity may result from caffeine and theophylline overdose. Leukocytosis, probably secondary to the high levels of circulating catecholamines, results from acute methylxanthine overdose. This phenomenon apparently lacks clinical significance. In the absence of seizures or protracted emesis, chronic methylxanthine poisoning does not typically lead to metabolic derangements because such toxicity is an ongoing, compensated process.

CHRONIC METHYLXANTHINE TOXICITY

The major difference between acute and chronic toxicity is the duration of exposure to the xenobiotic. Patients with chronic toxicity may manifest subtle signs such as anorexia, nausea, palpitations, or emesis, although they may also present with seizures or dysrhythmias.

Patients chronically receiving theophylline or caffeine have higher total body stores and often underlying medical disorders, and they may develop toxicity with a smaller amount of additional theophylline or caffeine. Chronic methylxanthine poisoning typically occurs in the setting of therapeutic use of theophylline and may occur with iatrogenic administration of caffeine or from frequent, chronic consumption of caffeinated products. Patients often manifest subtle signs of illness, such as anorexia, nausea, palpitations, or emesis. However, the initial presentation in these patients, even with serum concentrations in the 40 to 60 μg/mL range, may be a seizure. In children chronically overdosed with theophylline, the peak serum theophylline concentration may fail to identify those who will progress to life-threatening toxicity. In the absence of protracted emesis or seizures, the initial electrolytes and blood gases are expected to be normal in patients with chronic methylxanthine toxicity.

CHRONIC METHYLXANTHINE USE

An inconclusive link to cancer, heart disease, osteoporosis, hyperlipidemia, and hypercholesterolemia is associated with caffeine use.[63,66,78,151,195] Excessive consumption of caffeine-containing beverages may cause hypokalemia.[154]

Debate centers on the psychiatric and cognitive effects of chronic theophylline use, particularly in children.[118] To date, evidence suggests that although theophylline may acutely result in excessive CNS stimulation and hyperactivity, chronic use of methylxanthines does not adversely affect children's cognitive development.[20]

CAFFEINE WITHDRAWAL

Caffeine induces tolerance, and a withdrawal syndrome, including headache, yawning, nausea, drowsiness, rhinorrhea, lethargy, irritability, nervousness, a disinclination to work, and depression may result upon abstinence.[182] Caffeine withdrawal symptoms are described in neonates born to mothers with consequential caffeine use.[127] The onset of caffeine withdrawal symptoms begins 12 to 24 hours after cessation and lasts up to 1 week.[77] In a double-blind trial, 52% of adults with low to moderate caffeine intake, defined as 2.5 cups of coffee daily, developed a withdrawal syndrome upon caffeine abstinence.[176]

REPRODUCTION

Massive doses of methylxanthines are teratogenic, but the doses of typical use are not associated with birth defects. Decreased fecundity and adverse fetal outcome are noted in animals with chronic exposure to methylxanthines.[67,72,126] Human studies of fertility, fetal loss, and fetal outcome produce divergent results, and the effects of methylxanthines use during gestation are unclear.[91,98,132,136]

DIAGNOSTIC TESTING

An ECG, serum electrolytes, and a serum caffeine or theophylline concentration as appropriate are indicated in cases of suspected methylxanthine toxicity. Because toxicity is dose related in acute overdose, serum concentrations of caffeine and theophylline may be loosely applied as a correlate with toxicity.

Hospitals in which caffeine is used therapeutically, usually for treatment of apnea of prematurity, typically have the capability to assay serum caffeine concentration within the institution. Overdose of caffeine may result in a spuriously elevated serum theophylline concentration.[62,99]

Theophylline concentrations, and to a lesser extent, caffeine concentrations, may be used prognostically to guide management of poisoning. Proper interpretation requires insight into the context of poisoning, that is, whether acute or chronic. In the setting of toxicity, serum methylxanthines concentrations should be obtained immediately and then serially every 1 to 2 hours until a downward trend is evident. In neonates there may be a role for assessment of serum theophylline concentration in the management of suspected caffeine overdose, but such a role is not clearly defined.

Likewise, serum electrolytes, particularly potassium, should be monitored serially as long as the poisoned patient remains symptomatic and such values are in a range that may warrant treatment. Cardiac monitoring should continue until the patient is free of dysrhythmias other than sinus tachycardia, the patient has a decreasing serum methylxanthine concentration, and the patient is clinically stable. In patients with systemic illness, hyperthermia, or increased muscle tone, assessing serum CPK and urinalysis to detect rhabdomyolysis is also indicated.

MANAGEMENT

GENERAL PRINCIPLES AND GASTROINTESTINAL DECONTAMINATION

After assuring adequacy of airway, breathing, and circulation, supportive care and maintenance of vital signs within acceptable limits are the mainstays of therapy for patients with methylxanthine and selective

β$_2$AA toxicity. Decisions regarding GI decontamination, including orogastric lavage, administration of activated charcoal (AC), or whole-bowel irrigation (WBI), depends on the dosage and type of preparation involved, the time since exposure, and the patient's physical condition. AC is the only GI decontamination that should be routinely considered for selective β$_2$AA ingestion.

Emesis Induced emesis is not indicated for selective β$_2$AA ingestion or methylxanthine ingestion. A simulated overdose controlled volunteer study with sustained-release theophylline was unable to demonstrate reduction of absorption of theophylline in patients treated with syrup of ipecac.[136] Seizures are possible with any significant methylxanthine poisoning, and emesis in a patient experiencing a seizure is contraindicated. Because the benefits of emetics are undemonstrated and emesis interferes with administration of AC, induced emesis is rarely considered for those with methylxanthine poisoning.[6,165]

Orogastric Lavage Orogastric lavage may be considered for patients with potentially toxic methylxanthine ingestions who reach medical care immediately after ingestion. Selective β$_2$AA liquid ingestion that occurs within 1 hour before treatment may warrant aspiration through a nasogastric tube.

Ingestion of sustained-release theophylline tablets is associated with the formation of bezoars that may be difficult to remove or dislodge. Treatment in such cases has included endoscopic removal.[39]

Activated Charcoal AC may play an important role in the treatment of methylxanthine poisoning. AC can adsorb methylxanthines and selective β$_2$AA present in the GI tract and limit their absorption. Multiple-dose AC (MDAC) is helpful to enhance the elimination of methylxanthine toxicity but is not indicated for selective β$_2$AA ingestion. MDAC may be useful for any sustained-release preparations of methylxanthine. Additionally, MDAC enhances elimination of theophylline by "gut dialysis" (see Antidote in Depth A2: Activated Charcoal). Such enhanced elimination by gut dialysis is not demonstrated experimentally or otherwise, for caffeine or theobromine toxicity. Because caffeine is to some extent metabolized to theophylline, in cases of caffeine poisoning, MDAC would at the very least enhance elimination of theophylline metabolites. The pharmacologic similarity of the methylxanthines and the relative safety of MDAC therapy warrant the use of such treatment for patients with any methylxanthine toxicity. MDAC is used for enhanced elimination.

Whole-Bowel Irrigation Treatment of patients with significant ingestions of sustained-release pills may include WBI with a balanced electrolyte solution to enhance GI elimination (see Antidotes in Depth A3: Whole-Bowel Irrigation and Other Intestinal Evacuants). Polyethylene glycol electrolyte solution used for WBI may displace theophylline already bound to charcoal.[88] This may be a particular problem in patients who have taken several doses of AC before WBI, in which desorption of methylxanthines from AC may result in a bolus of methylxanthines available for GI absorption. Also, WBI is experimentally demonstrated to provide no additional benefit to AC in treatment of sustained-released theophylline ingestion.[37] Despite these data, WBI with MDAC remains the preferred and recommended treatment of a patient with ingestion of sustained-release theophylline.

Selecting a Method of Decontamination The use of decontamination methods that involve more than minimal risk, specifically orogastric lavage, should only occur after careful consideration of the indications. Patients with potentially life-threatening acute ingestions occurring no more than 1 hour previously may be treated with orogastric lavage (see Chap. 7).

■ TREATMENT

Gastrointestinal Toxicity Phenothiazine antiemetics are contraindicated in those with methylxanthine poisoning because they are typically ineffective and may lower the seizure threshold. Metoclopramide

may be used, but a more potent 5HT$_3$ antagonist antiemetic, such as ondansetron or granisetron, may be required.[51,148,158] Histamine (H$_2$) blockers or proton pump inhibitors may be administered to any patient with hematemesis. Cimetidine is contraindicated because it inhibits CYP450, delaying clearance of methylxanthines.

Cardiovascular Toxicity Hypotension should initially be treated by administration of isotonic IV fluid, such as 0.9% sodium chloride or lactated Ringer solution, in bolus volumes of 20 mL/kg. If acceptable blood pressure cannot be maintained despite several fluid boluses or if there are contraindications to fluid bolus, vasopressor therapy should be considered.

Methylxanthines and selective β$_2$AA toxicity may cause hypotension via β-adrenergic agonism; therefore, administration of vasopressors with β-adrenergic agonist effects, such as epinephrine, dobutamine, or isoproterenol, are not optimal. An α-adrenergic agonist such as phenylephrine is the first-line pressor of choice in such a situation, although norepinephrine is also acceptable (Table 65–1).

In rare cases of refractory hypotension, the administration of a β-adrenergic antagonist may be warranted.[56] Administration of a β-adrenergic antagonist to a hypotensive patient may seem counterintuitive, but it may reverse β$_2$-adrenergic mediated vasodilation. In addition, β$_1$-adrenergic blockade treats tachycardia and any decreased cardiac output that may result from inefficient tachycardiac activity. In dogs with aminophylline-induced tachycardia and hypotension, administration of esmolol results in a return to normal heart rate and blood pressure, and it does not exacerbate hypotension.[68] Propranolol, esmolol, and metoprolol have been used successfully to treat methylxanthine-induced hypotension.[26,145] It is most appropriate to use a β-adrenergic blocker with a brief duration of action, such as esmolol, at least initially, in such circumstances. In the event of an adverse reaction or side effect such as hypotension or bronchospasm, the duration of such will be relatively brief. Any β-adrenergic blocker therapy should ideally be preceded and accompanied by assessment of cardiac output and central venous blood pressure, either directly or noninvasively.[104]

When drug toxicity is not in question, adenosine or electrical cardioversion are the preferred treatment for SVT, but this is not so for SVT resulting from methylxanthine toxicity. Because of the antagonist effects at the adenosine receptor, administration of adenosine should not be expected to convert a methylxanthine-induced SVT. However, even if adenosine is successfully used to convert an SVT, the effect is likely to be transient. Because methylxanthine toxicity has a global effect on the myocardium and methylxanthine concentrations do not change rapidly, cardioversion, which is effective in electrically "reorganizing" depolarization, is unlikely to sustain a normal rhythm.

The primary treatment for methylxanthine-induced SVT includes administration of benzodiazepines, which work to abate CNS stimulation and concomitant release of catecholamines. More focused pharmacologic therapy to treat SVT would be through cautious administration of a conduction-attenuating calcium channel blocker such as diltiazem or verapamil.

In animal models, treatment of acute theophylline toxicity with the calcium channel blockers diltiazem, verapamil, and nifedipine each results in decreased cardiac-related deaths and prevention of dysrhythmias, hypotension, myocardial necrosis, and seizures.[193] In addition to the cardiovascular benefit of calcium channel blockers, they may also afford neurologic protection and prevention of seizure. In non-asthmatic patients, methylxanthine-induced SVT and other tachydysrhythmias may be treated by administration of β-adrenergic antagonist.

Central Nervous System Toxicity Administration of a benzodiazepine, such as diazepam or lorazepam, is appropriate treatment for anxiety, agitation, or seizure. The seizures associated with methylxanthine

TABLE 65–1. Therapeutic Interventions for Methylxanthines and Selective β_2 Adrenergic Agonist Poisoning

System	Indication	Therapeutic Agent	Comments

Cardiovascular	Hypotension	Vasopressors
		    Phenylephrine

			Requires hemodynamic monitoring

toxicity are severe and often refractory to treatment. Seizures not controlled with one or two therapeutic doses of a benzodiazepine should be treated with a barbiturate such as phenobarbital or pentobarbital or another suitable sedative–hypnotic such as propofol. No delay should occur before administering such medications. Unsuccessful treatment of methylxanthine-induced seizures with any particular agent should quickly be abandoned in favor of treatment with an additional or more efficacious anticonvulsant. The administration of barbiturates may result in or exacerbate hypotension. Treatment of any aforementioned problem with benzodiazepines, barbiturates, or other sedative–hypnotic may require repeated dosing until clinical effect is achieved.

Administration of phenobarbital to prevent seizures in theophylline-poisoned rabbits and mice increases survival by decreasing the incidence of seizures.[49,73] Although historically, phenobarbital was the recommended drug for such prophylaxis, use of a benzodiazepine such as lorazepam seems preferable based on pharmacokinetic and practical considerations. Patients at risk for seizure include those identified earlier in this chapter—patients older than age 60 years or younger than age 3 years , those with chronic overdose and a serum concentration above 40μg/mL, and acutely overdosed patients with serum levels greater than 100 μg/mL.

Phenytoin and fosphenytoin are of no benefit in controlling methylxanthine-induced seizures and they have no role in such treatment.[87,124] Retrospective review of human cases demonstrated phenytoin to be ineffective in treating seizures in 21 of 22 cases.[93] Phenytoin results in the occurrence of seizures at an earlier time after overdose and results in higher mortality when administered to theophylline-poisoned mice.[27]

Metabolic Derangements Patients with symptomatic hypocalcemia should be treated with electrolyte repletion. Most cases of mild hypokalemia are well tolerated, but any patient with symptomatic hypokalemia, particularly those associated with ECG changes of T waves or QTc prolongation, should be treated. The frequency of ventricular dysrhythmias in methylxanthine poisoning is exacerbated by hypokalemia coupled with increased intrinsic catecholamine release. Correction of hypokalemia may be crucial in methylxanthine poisoning associated with ventricular dysrhythmias.

There is no specific level of hypokalemia that absolutely necessitates treatment. In the absence of associated dysrhythmia, the clinical significance of such hypokalemia is unclear. Although correction is generally performed with the administration of IV or PO potassium, hypokalemia has been experimentally demonstrated to respond to treatment with β-adrenergic antagonist.

Cautious administration of potassium to treat symptomatic hypokalemia may be indicated, but this is distinct from higher doses of potassium used in total body potassium repletion. In cases of hypokalemia secondary to β-adrenergic agonism, after the β-adrenergic agonism returns to baseline level, an efflux of potassium from the intracellular compartment occurs. A concomitant increase of the serum potassium concentration occurs at that time. Overly aggressive attempts to correct hypokalemia may result in hyperkalemia after the β-adrenergic agonist effects abate. Acute methylxanthine-induced hypokalemia may be treated with potassium supplementation, but because of the nature of the problem with excess β-adrenergic agonism, potassium supplementation is typically unnecessary.

Experimentally, administration of propranolol to theophylline-poisoned dogs prevented or partially reversed hypokalemia, hypophosphatemia, hyperglycemia, and metabolic acidosis as well as hypotension.[102] Prevention or correction of the metabolic derangements associated with theophylline toxicity by administration of a β-adrenergic antagonists is congruent with the fact that these derangements, particularly hypokalemia, are the consequence of β-adrenergic agonism. The efficacy of β-adrenergic antagonists as

therapy for hypokalemia resulting from acute methylxanthine poisoning in humans is unstudied.

The importance of treating hypomagnesemia, hypophosphatemia, and hypocalcemia is not evident, and these phenomena should be treated as they would for other patients. As with hypokalemia, QTc prolongation is an absolute indication to treat these derangements.

Hyperglycemia, likely resulting from increased circulating catecholamines, is common. This hyperglycemia does not necessitate treatment with any type of hypoglycemic agent, both because it is a transient effect and because in other situations of hyperglycemia resulting from adrenergic agonism, rebound hypoglycemia may occur.

Musculoskeletal Toxicity The use of benzodiazepines is appropriate treatment for fasciculations, hypertonicity, myoclonus, and rhabdomyolysis. Rhabdomyolysis necessitates aggressive IV fluid therapy, possibly with sodium bicarbonate (see Antidotes in Depth: Sodium Bicarbonate).

Enhanced Elimination Fortunately, methylxanthine toxicity lends itself well to several methods of enhanced elimination, including gastrointestinal dialysis with MDAC, charcoal hemoperfusion, and hemodialysis, as well as lesser-used methods such as continuous arteriovenous hemoperfusion (CAVHP), continuous venovenous hemoperfusion (CVVH), and plasmapheresis.[16,111,117]

Infants with methylxanthine poisoning may be too ill, unstable, or small to be treated with hemodialysis or hemoperfusion. Both MDAC and exchange blood transfusion are effective methods of enhanced elimination in infants and may be the preferred method of treatment in these patients if hemodialysis is unavailable.[142,144,172,174]

The therapeutic effects of AC in such cases are much greater than simply limiting absorption of ingested methylxanthines. AC, particularly MDAC, allows elimination of theophylline by way of GI dialysis.[13] MDAC is extremely effective at enhancing elimination of theophylline.[23,69,116,140] Experimentally in dogs, rabbits, and human volunteers, AC administered after IV aminophylline administration results in increased systemic clearance and decreased half-life of theophylline.[90,108,128,146] The pharmacologic similarity of the methylxanthines suggests that MDAC may be effective in GI dialyzing of caffeine or theobromine, and MDAC certainly will be effective in eliminating any theophylline generated from metabolism of caffeine or theobromine. The efficacy of MDAC combined with the safety and ease with which this therapy can be administered make MDAC the mainstay of enhanced elimination in methylxanthine toxicity. Severe emesis associated with methylxanthine poisoning may result in intolerance of MDAC[166] (see Antidotes in Depth: Activated Charcoal).

Charcoal hemoperfusion is the single most effective method of enhanced elimination of methylxanthines, decreasing theophylline's half-life to 2 hours and increasing its clearance possibly up to sixfold.[36,135,156,196] Variations of charcoal hemoperfusion, including albumin colloid hemoperfusion, resin hemoperfusion, and charcoal hemoperfusion in series with hemodialysis, have been reported.[40,89,112,149,181]

If hemoperfusion is available, it is preferable, but because charcoal hemoperfusion is typically unavailable,[167] hemodialysis is acceptable therapy.

Hemodialysis is less efficient than hemoperfusion in the extracorporeal removal of methylxanthines.[8,113,115,177] The ability of hemodialysis to correct fluid and electrolyte imbalances, the greater availability of hemodialysis, greater technical ease, and lower complication rates have resulted in a paradigm shift from considering charcoal hemoperfusion to be the definitive treatment for significant methylxanthine toxicity to one in which charcoal hemoperfusion and hemodialysis are considered equivalent treatment options.[175]

In the treatment of patients with methylxanthine poisoning, the specific indications for hemodialysis are not agreed upon. Several

> **TABLE 65–2.** Methylxanthine Poisoning: Indications for Charcoal Hemoperfusion or Hemodialysis
>
> 1. Acute serum theophylline or caffeine concentration >90 µg/mL and any symptom
> 2. Serum theophylline or caffeine concentration >40 µg/mL and
>   A. Seizures
>   B. Hypotension unresponsive to intravenous fluid or
>   C. Ventricular dysrhythmias

studies and clinical experience are the basis for the following suggested indications for extracorporeal elimination by charcoal hemoperfusion, hemodialysis, combined charcoal hemoperfusion and hemodialysis, or combined hemodialysis and MDAC.

Many recommendations regarding hemoperfusion and hemodialysis for theophylline toxicity use serum theophylline concentration as a guideline. Serum levels may not be available in instances of caffeine poisoning and do not exist for theobromine poisoning. Thus, the clinical aspects of theophylline management guidelines can be generalized to all methylxanthine toxicities.

When indicated, hemodialysis preferably should be initiated while the patient is still hemodynamically stable. Hemodialysis therapy should be used for patients with consequential chronic theophylline poisoning associated with a serum theophylline concentration above 40 to 60 µg/mL or with a deteriorating clinical status.

Hemodialysis should be strongly considered any time a methylxanthine exposure results in a serum theophylline or caffeine concentration of greater than 90 µg/mL and symptoms, regardless of clinical stability (Table 65–2). Any patient with a symptomatic methylxanthine poisoning that is associated with ventricular dysrhythmias, seizures, hypotension unresponsive to fluids, or emesis unresponsive to antiemetics should also be treated with charcoal hemoperfusion, hemodialysis, or both.

The fact that a patient experiences seizure or dysrhythmias or becomes extremely ill is not a contraindication for extracorporeal drug removal. To the contrary, these events make administration of such therapy more critical to ensure survival of the patient.

■ TREATMENT OF CHRONIC METHYLXANTHINE TOXICITY

Treatment of chronic methylxanthine toxicity is determined by the patient's clinical status and by the efficacy of MDAC. The precise serum theophylline or caffeine concentration at which patients with chronic theophylline or caffeine toxicity should receive hemodialysis is controversial. For a hemodynamically stable patient without signs of life-threatening methylxanthine toxicity such as ventricular dysrhythmias or seizure, therapy with MDAC may be sufficient. If the serum theophylline or caffeine concentration does not decline after the administration of AC or if the patient's clinical status deteriorates, hemodialysis is indicated.

■ TREATMENT OF ACUTE-ON-CHRONIC METHYLXANTHINE TOXICITY

Patients chronically receiving theophylline or caffeine who acutely overdose should be initially managed in the same manner as patients with acute overdose, although action concentrations for dialysis are the same for chronic toxicity. Total body stores of the methylxanthines are higher in patients who are chronically exposed, and the threshold for toxicity may be reached at lower serum concentrations.

SUMMARY

Selective β_2AAs were widely used for the treatment of bronchospasm. Selective β_2AA toxicity typically results from excessive therapeutic use of these agents, but illicit use of clenbuterol or admixture of clenbuterol with drugs of abuse has become prominent. Methylxanthine toxicity results from both the use of medicinal and therapeutic agents as well as from consumption of methylxanthine-containing foods and beverages. There are significant differences in the clinical presentation and management of patients with acute and chronic methylxanthine poisoning. Supportive care and treatment of GI, cardiovascular, CNS, metabolic, and musculoskeletal toxicities are the mainstay of therapy. The unique properties of methylxanthines necessitate specific therapies for the GI, cardiovascular, and CNS toxicities of methylxanthines. With some unique exceptions, selective β_2AA toxicity is usually well tolerated and only requires supportive care. Clenbuterol is such an exception, and toxicity from this substance is typically more severe than that from other β_2AA. For this reason, clenbuterol toxicity should be managed with greater caution and cognizance for the potential for severe morbidity and possible mortality from this substance.

Methods of enhanced elimination, particularly extracorporeal elimination by charcoal hemoperfusion, hemodialysis, or charcoal hemoperfusion and hemodialysis in series, as well as gut dialysis with MDAC, are effective treatments for patients with methylxanthine toxicity. Supportive care is typically the management strategy for β_2AAs.

ANESTHETICS AND RELATED MEDICATIONS

CHAPTER 66

LOCAL ANESTHETICS

David R. Schwartz and Brian Kaufman

Local anesthetics are xenobiotics that block excitation of, and transmission along, a nerve axon in a predictable and reversible manner. The anesthesia produced is selective to the chosen body part in contrast to the nonselective effects of a general anesthetic. Local anesthetics do not require the circulation as an intermediate carrier, and they usually are not transported to distant organs. Therefore, the actions of local anesthetics are largely confined to the structures with which they come into direct contact. Local anesthetics may provide analgesia in various parts of the body by topical application, injection in the vicinity of peripheral nerve endings and major nerve trunks, or via instillation within the epidural or subarachnoid spaces. The various local anesthetics differ with regard to their potency, duration of action, and degree of effects on sensory and motor fibers. Toxicity may be local or systemic. With systemic toxicity, the central nervous system (CNS) and cardiovascular systems typically are affected.

HISTORY

Until the 1880s, the only xenobiotics available for pain relief were centrally acting depressants such as alcohol and opioids, which blunted the perception of pain rather than attacking the root cause. The coca shrub (*Erythroxylon coca*) was brought back to Europe from Peru by Karl Von Scherzer, an Austrian explorer, in the mid-1800s. Some of the coca leaves were analyzed by the chemist Albert Niemann, who in 1860 successfully extracted and named the active principle, the alkaloid *cocaine* (see Chap. 76). Sigmund Freud studied the use of cocaine to cure morphine addiction. Koller at the Ophthalmological Clinic at the University of Vienna dissolved coca powder in distilled water; instilled the solution in the conjunctival sacs of a frog, a rabbit, a dog, and himself; and noted that their corneas as well as his own could be touched without any evidence of a reflex blink. In 1884, Koller performed an operation for glaucoma with topical cocaine anesthesia, and the news spread rapidly, leading to diversification of use.[42]

Although the clinical benefits of cocaine anesthesia were significant, so were its toxic and addictive potential. At least 13 deaths were reported in the first 7 years after the introduction of cocaine in Europe, and within 10 years after the introduction of cocaine as a regional anesthetic, reviews of "cocaine poisoning" appeared in the literature.[66,84] The toxicity of cocaine, coupled with the tremendous advantages it provided for surgery, led to a search for less toxic substitutes.

After the elucidation of the chemical structure of cocaine (the benzoic acid methyl ester of the alkaloid ecgonine) in 1895, other amino esters

were examined. Synthetic compounds with local anesthetic activity were introduced, but they were either highly toxic or irritating or had an impractically brief clinical effectiveness. In 1904, Einhorn synthesized procaine, but its short duration of action limited its clinical utility. Research then focused on synthesis of xenobiotics with more prolonged durations of action.

The potent, long-acting local anesthetics dibucaine and tetracaine were synthesized in 1925 and 1928, respectively, and were introduced into clinical practice. However, these anesthetics were not safe for regional anesthetic techniques because of systemic toxicity secondary to the large volumes of drug that were required to ensure distribution throughout the entire neuronal sheath. On the other hand, these drugs were very useful for spinal anesthesia, which required much smaller volumes.

Lofgren synthesized the prototypical local anesthetic lidocaine from a series of aniline derivatives in 1943. This amino amide combined high tissue penetration and a moderate duration of action with acceptably low systemic toxicity. Additionally, the metabolites of lidocaine did not include *para*-aminobenzoic acid (PABA), which was the reported cause of allergic reactions to the amino ester anesthetics. Subsequent to the release of lidocaine in 1944, several other amino amide compounds were synthesized and introduced into clinical practice. These include mepivacaine in 1956, prilocaine in 1959, bupivacaine in 1963, etidocaine in 1971, and ropivacaine in 1996.

EPIDEMIOLOGY

Considering how frequently local anesthetics are administered, both within and outside healthcare facilities, clinically significant toxic reactions are few, and most are iatrogenic. In reports of fatalities resulting from toxic exposures reported to U.S. poison centers, local anesthetics are rare, representing less than 0.5% of cases (see Chap. 135). Most poisonings result from inadvertent injection of a therapeutic dose into a blood vessel, repeated use of a therapeutic dose, or unintentional administration of a toxic dose. The amide local anesthetics have largely replaced the esters in clinical use because of their increased stability and relative absence of hypersensitivity reactions (see Pharmacology below). Poisoning from topical benzocaine is relatively common because of the large number of nonprescription products available for treatment of teething and hemorrhoids and because of the widespread use of benzocaine, mostly as a spray, for topical mucosal anesthesia before intubation, upper endoscopy, and transesophageal echocardiography. With nonprescription use, toxic effects after exposure are typically mild, and death rarely occurs. Toxicity usually occurs as a therapeutic misadventure, but child abuse or neglect should be considered if the patient is younger than 2 years, and suicide should be considered in older children and adults.

Benzocaine spray may be the most important cause of severe acquired methemoglobinemia in the hospital setting[3] (see Chap. 127). Between November 1997 and March 2002, the U.S. Food and Drug

Administration (FDA) received 198 reported adverse events secondary to benzocaine products. A total of 132 cases (66.7%) involved definite or probable methemoglobinemia; most were serious adverse events, and two deaths occurred.[75] In these cases, a single spray of unspecified duration of 20% benzocaine was the dose most commonly reported. Because of the difficulty in limiting the dose to the manufacturer's recommendation given the current formulations available, these authors recommend a metered-dosing preparation and prominent package warnings.

PHARMACOLOGY

■ CHEMICAL STRUCTURE

Local anesthetics fall into one of two chemically distinct groups: amino esters and amino amides (Fig. 66–1). The basic structure of all local
anesthetics consists of three major components. A lipophilic, aromatic ring is connected by an ester or amide linkage to a short alkyl, intermediate chain that is bound to a hydrophilic tertiary (or, less commonly, secondary) amine. The amine is a base (proton acceptor) that is partially charged in the physiologic pH range.

■ MODE OF ACTION

All local anesthetics function by reversibly binding to specific receptor proteins within the membrane-bound sodium channels of conducting tissues. These receptors can be reached only via the cytoplasmic side of the cell membrane, that is, by intracellular drug. Blockade of ion conductance through the sodium channel eventually leads to failure to form and propagate action potentials (Fig. 66–2). The analgesic effect results from inhibiting axonal transmission of the nerve impulse in small-diameter myelinated and unmyelinated nerve fibers carrying pain and temperature sensation. Conduction block of these fibers occurs at lower concentrations than in the larger fibers responsible for touch, motor function, and proprioception.[22] This likely occurs in myelinated nerves because smaller fibers have closer spacing of the nodes of Ranvier. Given that a fixed number of nodes must be blocked for conduction failure to occur, the shorter critical length of nerve is reached sooner by the locally placed anesthetic in small fibers.[36] For unmyelinated fibers, the smaller diameter limits the distance that such fibers can passively propagate the electrical impulse. In addition, differential nerve block may relate to voltage and time dependence of the affinity of local anesthetics to the sodium channels.

The sodium channel may exist in three states (see Chap. 23). At resting membrane potential or in the hyperpolarized membrane, the channel is closed to sodium conductance. With an appropriate activating stimulus, the channel opens, allowing rapid sodium influx and membrane depolarization. Milliseconds later, the channel is inactivated, terminating the fast sodium current. Blockade is much stronger for channels that are activated (open) or inactivated than for channels that are resting. Pain fibers have a higher firing rate and longer action potential (ie, more time with the sodium channel open or inactivated) than other fiber types and therefore are more susceptible to local anesthetic action.[48]

These effects also occur in other conductive tissues in the heart and brain that rely on sodium current. Although sodium channel

FIGURE 66–1. Representative local anesthetics in common clinical use.
FIGURE 66–2. The multi-unit sodium channel is embedded in the nerve cell membrane. Local anesthetics (LA) enter the nerve cell at the exposed membranes of the Nodes of Ranvier and bind to the cytoplasmic side of the sodium channel (also located at the Node of Ranvier) and alter sodium conductance.

blockade initially was believed to be the sole cause of systemic toxicity, the mechanisms are more complex, especially in the heart, and may occur at systemic concentrations lower than previously thought.[68] Local anesthetics may interact with other cellular systems at clinically relevant concentrations. For example, lidocaine inhibited muscarinic signaling in *Xenopus* oocytes at less than 50% of the concentration required for sodium channel blockade.[47] Growing evidence indicates that local anesthetics can directly affect many other organ systems and functions such as the coagulation, immune, and respiratory systems at concentrations much lower than those required to achieve sodium channel blockade.[16,46,47] Study of these less well-described effects may help elucidate both therapeutic and toxic phenomenon that are incompletely explained.

■ PHYSICOCHEMICAL PROPERTIES

The primary determinant of the onset of action of a local anesthetic is its pK_a, which affects the lipophilicity of a drug (Table 66–1). All of the local anesthetics are weak bases, with a pK_a between 7.8 and 9.3. At physiologic pH (7.4), xenobiotics with a lower pK_a have more uncharged molecules that are free to cross the nerve cell membrane, producing a faster onset of action than xenobiotics with a higher pK_a. The onset of action also is influenced by the total dose of local anesthetic administered, which affects the concentration available for diffusion.

Local anesthetic potency is highly correlated with the lipid solubility of the xenobiotic. Therefore, the aromatic side of the anesthetic is the primary determinant of potency. The hydrophilic amine is important in occupying the sodium channel, which involves an ionic interaction with the charged form of the tertiary amine. The length of the intermediate chain is another determinant of local anesthetic activity, with three to seven carbon-equivalents providing maximal activity.[22] Shorter or longer intermediate chain lengths are associated with rapid loss of local anesthetic action, suggesting that a critical length of separation of the aromatic group from the tertiary amine is required for sodium channel blockade to occur.

The degree of protein binding influences the duration of action of a local anesthetic. Anesthetics with greater protein binding remain associated with the neural membrane for a longer time interval and therefore have longer durations of action.[22] When high serum concentrations are achieved, a higher degree of protein binding increases the risk for cardiac toxicity.

PHARMACOKINETICS

A distinction must be made between local disposition (distribution and elimination) and systemic disposition. Local distribution is influenced by several factors, including spread of local anesthetic by bulk flow, diffusion, transport via local blood vessels, and binding to local tissues. Local elimination occurs through systemic absorption, transfer into the general circulation, and local hydrolysis of amino ester anesthetics. Systemic absorption decreases the amount of local anesthetic that is available for anesthetic effect, thereby limiting the duration of the block. Systemic absorption is dependent on the avidity of binding of local anesthetics to tissues near the site of injection and on local perfusion. Both of these factors vary with the site of injection. In general, areas with greater blood flow will have more rapid and complete systemic uptake of local anesthetic therfore, intravenous (IV) > tracheal > intercostal > paracervical > epidural > brachial plexus > sciatic > subcutaneous.

Because of their lipophilicity, local anesthetics readily cross cell membranes, the blood–brain barrier, and the placenta. Once absorbed, systemic tissue distribution is highly dependent on tissue perfusion. After local anesthetics enter into the venous circulation, they pass through the lungs, where significant uptake may occur, thereby lowering peak arterial concentrations. Thus, the lungs may serve as a buffer against systemic toxicity.[59] This mechanism, however, has saturable kinetics. Part of the reason why most local anesthetic–induced seizures result from unintentional intravascular injection rather than absorptive uptake is that lung uptake of these drugs appears to exceed 90%.

TABLE 66–1. Pharmacologic Properties of Local Anesthetics[48,100]

	pK_a	Protein Binding (%)	Relative Potency	Duration of Action	Approximate Maximum Allowable Subcutaneous Dose (mg/kg)
Esters					
Chloroprocaine	9.3	Unknown	Intermediate	Short	10
Cocaine	8.7	92	Low	Medium	3
Procaine	9.1	5	Low	Short	10
Tetracaine	8.4	76	High	Long	3
Amides					
Bupivacaine	8.1	95	High	Long	2
Etidocaine	7.9	95	High	Long	4
Lidocaine	7.8	70	Low	Medium	4.5
Mepivacaine	7.9	75	Intermediate	Medium	4.5
Prilocaine	8.0	40	Intermediate	Medium	8
Ropivacaine	8.2	95	Intermediate	Long	3.

The very high peak venous concentrations produced by rapid injection usually are necessary to produce toxic arterial concentrations.

All local anesthetics, except cocaine, cause peripheral vasodilation by direct relaxation of vascular smooth muscle. Vasodilation enhances vascular absorption of the local anesthetic. Addition of epinephrine (5 μg/mL or 1:200,000) to the local anesthetic solution decreases the rate of vascular absorption, thereby improving the depth and prolonging the duration of local action. An epinephrine local anesthetic mixture also decreases bleeding into the surgical field and serves as a marker for inadvertent intravascular injection (by producing tachycardia) when a test dose of the mixture is injected through a needle or catheter.[72]

Significant drawbacks to epinephrine use include uncomfortable side effects such as palpitations and tremors, local tissue ischemia, and life-threatening systemic adverse reactions in susceptible patients, such as myocardial ischemia and hypertensive crisis. Inadvertent intravascular injection of local anesthetics mixed with epinephrine can be fatal, although generally, the epinephrine in these mixtures is very dilute.[63]

The two classes of local anesthetics undergo metabolism by different routes (see Chap. 76). The amino esters are rapidly metabolized by plasma cholinesterase to the major metabolite, PABA. The amino amides are metabolized more slowly in the liver to a variety of metabolites that do not include PABA.[21] Patients with atypical or low concentrations of plasma cholinesterase are at increased risk for systemic toxicity from ester local anesthetics. Factors that decrease hepatic blood flow or impair hepatic function increase the risk for toxic reactions to the amino amides and make management of serious reactions more difficult. The patient's age, as it relates to liver enzyme activity and plasma protein binding, influences the rate of metabolism of local anesthetics. Whereas the lidocaine terminal half-life after IV administration averaged 80 minutes in volunteers ages 22 to 26 years, the half-life was 138 minutes in those ages 61 to 71 years[80] (see Chap. 63). Newborn infants with immature hepatic enzyme systems have prolonged elimination of amino amides, which is associated with seizures when high continuous infusion rates are used.[1,69] Lidocaine elimination is reduced by congestive heart failure or coadministration of xenobiotics that reduce hepatic blood flow, thus explaining the increased risk of toxicity with cimetidine and propranolol.[90] Propranolol and cimetidine also potentially decrease lidocaine clearance by inhibiting hepatic mixed-function oxidase enzymes.

Local anesthetics are often mixed to take advantage of desirable pharmacokinetics. Ideally, rapid-acting, relatively short-duration local anesthetics such as chloroprocaine or lidocaine can be combined with the longer latency, long-acting tetracaine or bupivacaine. In practice, the advantages of the mixtures are small, and toxicities are additive.[5] Administration of one local anesthetic increases the free plasma fraction of another by displacement from protein-binding sites.[51]

Local anesthetics usually cannot penetrate intact skin in sufficient quantities to produce reliable anesthesia.[11] Efficient skin penetration requires the combination of a high water content and a high concentration of the water-insoluble base form of the local anesthetic. This combination of properties has been achieved by mixing lidocaine and prilocaine in their base forms in a 1:1 ratio (eutectic mixture of local anesthetics [EMLA]).[14] Application for at least 45 minutes is required to achieve adequate dermal analgesia. Local anesthetic uptake continues for several hours during application. A liposomal formulation of 4% lidocaine (ELA-Max) facilitates skin absorption. It is as effective as EMLA for topical anesthesia.[31] In addition, a 4% tetracaine gel preparation has been used in children for topical skin anesthesia with an onset of action and efficacy at least as good as EMLA and without any systemic side effects.

CLINICAL MANIFESTATIONS OF TOXICITY

■ TOXIC REACTIONS

Regional Side Effects and Tissue Toxicity At some concentration, all local anesthetics are directly cytotoxic to nerve cells. However, in clinically relevant doses, they rarely produce localized nerve damage.[55,79] Significant direct neurotoxicity may result from intrathecal injection or infusion of local anesthetics for spinal anesthesia. In this setting, studies suggest lidocaine has an increased risk for both persistent lumbosacral neuropathy and a syndrome of painful but self-limited postanesthesia buttock and leg pain or dysesthesia referred to as *transient neurologic symptoms.*[50] Nerve damage often is attributed to use of excessively concentrated solutions or inappropriate formulations. Several reports of cauda equina syndrome have been associated with use of hyperbaric 5% lidocaine solutions for spinal anesthesia. Hyperbaric solutions are more dense than cerebrospinal fluid. This neurotoxicity appears to be a phenomena that occurs when the anesthetic is injected through narrow-bore needles or through continuous spinal catheters. This process may result in very high local concentrations of the anesthetic that might pool around the sacral roots because of inadequate mixing.[91] The mechanism of this neurotoxic effect is unknown but is believed to be independent of sodium channel blockade.[50] Because an equally effective block can be achieved with injection of larger volumes of lower concentration, 5% lidocaine should be avoided and bupivacaine used instead.

Similar severe neurotoxic reactions have occurred after massive subarachnoid injection of chloroprocaine during attempted epidural anesthesia.[88] The neurotoxicity initially appeared to be associated with use of the antioxidant sodium bisulfite and the low pH of the commercial solution rather than use of the anesthetic itself.[108] Although chloroprocaine has been reformulated without bisulfite, new animal data suggest that it is the anesthetic that may be responsible for the neurotoxicity.[104] Skeletal muscle changes are observed after intramuscular injection of local anesthetics, especially the more potent, longer-acting xenobiotics. The effect is reversible, and muscle regeneration is complete within 2 weeks after injection of local anesthetics.[8]

■ SYSTEMIC SIDE EFFECTS AND TOXICITY

Allergic Reactions Allergic reactions to local anesthetics are extremely rare. Fewer than 1% of all adverse drug reactions caused by local anesthetics are immunoglobulin (Ig)E-mediated.[39] In one study designed to determine the prevalence of true local anesthetic allergy in patients referred to an allergy clinic for suspected hypersensitivity, skin prick and intradermal testing results were negative for all 236 subjects tested.[9] As noted, the amino esters are responsible for the majority of true allergic reactions. When hydrolyzed, the amino ester local anesthetics produce PABA, a known allergen (see Chap. 55). Cross-sensitivity to other amino ester anesthetics is common. Some multidose commercial preparations of amino amides may contain the preservative methylparabens, which is chemically related to PABA and is the most likely cause of the much rarer allergic reaction to amino amides or seeming allergic responses to both the amides and esters. Preservative-free amino amides, including lidocaine, can be used safely in patients who have reactions to drug preparations containing methylparabens unless the patient is specifically sensitive to lidocaine. Again, if the patient with a history of allergic reaction to a particular drug requires a local anesthetic, a paraben preservative-free drug from the opposite class can be chosen because there is no cross-reactivity between the amides and esters.

Methemoglobinemia Methemoglobinemia is reported frequently as an adverse effect of topical and oropharyngeal benzocaine use and occasionally with lidocaine, tetracaine, or prilocaine use. The diagnosis can be established by direct measurement of methemoglobin percent with a

cooximeter. Most reports of methemoglobinemia associated with local anesthetics are the result of an excessive dose, a break in the normal mucosal barrier for topical anesthetics, or a deficiency of a congenital reducing enzyme such as methemoglobin reductase (see Chap. 127).

Benzocaine is metabolized to aniline and then further metabolized to phenylhydroxylamine and nitrobenzene, which are both potent oxidizing agents (see Chap. 127). Although reports describe methemoglobinemia resulting from standard doses of benzocaine topical oropharyngeal spray given for laryngoscopy or gastrointestinal upper endoscopy,[29,75] affected patients commonly have abnormal mucosal integrity, as occurs with thrush or mucositis. Prilocaine is an amino ester local anesthetic primarily used in obstetric anesthesia because of its rapid onset of action and low systemic toxicity in both the mother and fetus. Use of large doses of prilocaine may lead to the development of methemoglobinemia.[45,61] Prilocaine is an aniline derivative that, when metabolized in the liver, produces *ortho*-toluidine, another oxidizing agent.[45] A direct relationship exists between the amount of epidural prilocaine administered and the incidence of methemoglobinemia. A dose greater than approximately 8 mg/kg is generally necessary to produce symptoms, which may not become apparent until several hours after epidural administration of the drug. Standard doses of EMLA cream used for circumcision in term neonates are associated with minimal production of methemoglobin, but risks may be increased in neonates with metabolic disorders.[102] EMLA-associated methemoglobinemia has been reported in children and rarely in adults.[41] When clinically indicated, affected patients with symptomatic methemoglobinemia should be treated with IV methylene blue (see Chap. 127 and Antidotes in Depth A41: Methylene Blue).

Other Reactions The most common adverse reactions to local anesthetics are vasovagal reactions.[106]

Systemic Toxicity Systemic toxicity for all local anesthetics correlates with serum concentrations. Factors that determine the concentration include (1) dose; (2) rate of administration; (3) site of injection (absorption occurs more rapidly and completely from vascular areas, such with neck blocks and intercostal blocks); (4) the presence or absence of a vasoconstrictor; and (5) the degree of tissue–protein binding, fat solubility, and pK_a of the local anesthetic.[73] The brain and heart are the primary target organs for systemic toxicity because of their rich perfusion, moderate tissue–blood partition coefficients, lack of diffusion limitations, and presence of cells that rely on voltage-gated sodium channels to produce an action potential.

Recommendations for maximal local anesthetic doses designed to minimize the risk for systemic toxic reactions have been published.[100] These maximal recommended doses aim to prevent infiltration of excessive drug. However, because most episodes of systemic toxicity from local anesthetics, with the exception of methemoglobinemia from topical drug, occur secondary to unintentional intravascular injection rather than from overdosage, limiting the maximal dose will not prevent most toxic systemic reactions.[97]

Toxicity is also related to the metabolism for a given local anesthetic. The rapidity of elimination from the plasma influences the total dose delivered to the CNS or heart. The amino esters are rapidly hydrolyzed in the plasma and eliminated, explaining their relatively low potential for systemic toxicity. The amino amides have a much greater potential for producing systemic toxicity because termination of the therapeutic effect of these drugs is achieved through redistribution and slower metabolic inactivation.[35] Another factor that creates difficulty in specifying the minimal toxic plasma concentration of lidocaine results from the fact that its *N*-dealkylated metabolites are pharmacologically active. Although these factors make it difficult to establish safe doses of local anesthetics, Table 66–2 summarizes the estimates of minimal toxic intravenous doses of various local anesthetics.

TABLE 66–2. Toxic Doses of Local Anesthetics	
Local Anesthetic	Minimum IV Toxic Dose of Local Anesthetic in Humans (mg/kg)
Procaine	19.2
Chloroprocaine	22.8
Tetracaine	2.5
Lidocaine	6.4
Mepivacaine	9.8
Bupivacaine	1.6
Etidocaine	3.4

IV, intravenous.

Central Nervous System Toxicity Systemic toxicity in humans usually presents as CNS abnormalities. IV infusion studies in volunteers have demonstrated an inverse relationship between the anesthetic potency of various local anesthetics and the dosage required to induce signs of CNS toxicity.[98] A similar relationship exists between the convulsive concentration of various local anesthetics and their relative anesthetic potency. In humans, seizures are reported at serum concentrations of approximately 2 to 4 μg/mL for bupivacaine and etidocaine. Concentrations in excess of 10 μg/mL are usually required for production of seizures when less-potent drugs such as lidocaine are administered. Despite the strong relationship between local anesthetic potency and CNS toxicity, several other factors influence the CNS effects, including the rate of injection, drug interactions, and acid–base status.[24]

The rapidity with which a particular serum concentration is achieved influences the toxicity of the anesthetic. Volunteers could tolerate an average dose of 236 mg of etidocaine and a serum concentration of 3 μg/mL before onset of CNS symptoms when the anesthetic was infused at a rate of 10 mg/min. However, when the infusion rate was increased to 20 mg/min, the same individuals could tolerate only an average of 161 mg of the drug, which produced a serum concentration of approximately 2 μg/mL.[96]

Centrally acting local anesthetics can modify the clinical presentation of a systemic toxic reaction. In general, whereas CNS-depressant drugs minimize the signs and symptoms of CNS excitation, they increase the threshold for local anesthetic–induced seizures. Flumazenil increases the sensitivity of the CNS to the amino amide anesthetics.[13]

Both metabolic and respiratory acidoses increase local anesthetic–induced CNS toxicity. Acidemia decreases plasma protein binding, increasing the amount of free drug available for CNS diffusion despite promoting the charged form of the amine. The convulsive threshold of various local anesthetics is inversely related to arterial PCO_2.[26,32,33] Hypercarbia may lower the seizure threshold by several mechanisms: (1) increased cerebral blood flow, which increases drug delivery to the CNS; (2) increased conversion of the drug base to the active cation in the presence of decreased intracellular pH; and (3) decreased plasma protein binding, which increases the amount of free drug available for diffusion into the brain.[15,26,32,33]

A gradually increasing serum lidocaine concentration produces a common pattern of symptoms and signs (Fig. 66–3). In an awake patient, the initial symptoms are subjective and include tinnitus, lightheadedness, circumoral numbness, disorientation, confusion, auditory and visual disturbances, and lethargy. Subjective side effects occur at serum concentrations between 3 and 6 μg/mL. Significant
FIGURE 66–3. Relationship of signs and symptoms of toxicity to serum lidocaine concentrations.

psychological effects of local anesthetics have also been reported. Near-death experiences and delusions of actual death are described as specific symptoms of local anesthetic toxicity.[64] Thus, the appearance of psychologic symptoms during administration of local anesthetics should not be disregarded as unrelated nervous reactions or effects of sedatives given as premedication but rather as a possible early sign of CNS toxicity.

Objective signs, usually excitatory, then develop and include shivering, tremors, and ultimately generalized tonic–clonic seizures. Objective CNS toxicity usually is evident at concentrations between 5 and 9 μg/mL. Seizures may occur at concentrations above 10 μg/mL, with higher concentrations producing coma, apnea, and cardiovascular collapse. The excitatory phase has a wide range of intensity and duration, depending on the chemical properties of the local anesthetic. With the highly lipophilic, highly protein-bound drugs, the excitement phase is brief and mild. Toxicity from a large IV bolus of bupivacaine may present without any CNS excitement and with bradycardia, cyanosis, and coma as the first signs.[93] Rapid intravascular injection of lidocaine may produce a brief excitatory phase followed by generalized CNS depression with respiratory arrest. Seizures may follow even a small dose injected into the vertebral or carotid artery (as may occur during stellate ganglion block).[54] A relative overdose produces a slower onset of symptoms (usually within 5–15 minutes of drug injection), with irritability progressing into seizures.

The mechanism of the initial CNS excitation involves a selective block of cerebral cortical inhibitory pathways in the amygdala.[103,107] The resulting increase in unopposed excitatory activity leads to seizures. As the concentration increases further, both inhibitory and excitatory neurons are blocked, and generalized CNS depression ensues.

■ TREATMENT OF LOCAL ANESTHETIC CENTRAL NERVOUS SYSTEM TOXICITY

At the first sign of possible CNS toxicity, administration of the drug must be discontinued. One hundred percent oxygen should be supplied immediately, and ventilation should be supported if necessary. Patients with minor symptoms usually do not require treatment, provided adequate respiratory and cardiovascular functions are maintained. The patient must be followed closely so that progression to more severe effects can be detected.

Although most seizures caused by local anesthetics are self-limited, they should be treated quickly because the hypoxia and acidosis produced by prolonged seizures may increase both CNS

and cardiovascular toxicity.[76,78] Intubation is not mandatory, and the decision to intubate must be individualized. Maintaining adequate ventilation is of proven value, but modest hyperventilation in theory might decrease CNS toxicity. By decreasing CNS extraction of drug, lowering extracellular potassium, and hyperpolarizing the neuronal cell membrane, normalizing (lowering) PCO_2 may decrease the affinity or accelerate separation of the local anesthetic from the sodium channel. Barbiturates and benzodiazepines have been used for treatment of local anesthetic–induced seizures. An induction dose of thiopental, which is readily available to the anesthesiologist or an IV benzodiazepine such as lorazepam, can rapidly terminate a seizure, but either of these medication groups can also exacerbate circulatory and respiratory depression.[24,71] Propofol 1 mg/kg IV was as effective as thiopental 2 mg/kg IV in stopping bupivacaine-induced seizures in rats and has been used successfully in a patient with uncontrolled muscle twitching secondary to local anesthetic toxicity.[10,43] However, propofol may cause significant bradydysrhythmias and even asystole, especially when used with other xenobiotics that cause bradycardia. Whether propofol interacts with local anesthetics to enhance their bradydysrhythmic effects is not known, and it is not possible to generally recommend propofol over barbiturates and benzodiazepines for treatment of local anesthetic CNS toxicity. Neuromuscular blocking agents have been proposed as adjunctive treatment for local anesthetic–induced seizures. They block muscular activity, decreasing oxygen demand and lactic acid production. However, neuromuscular blocking agents should never be used to treat seizures per se because they have no anticonvulsant effect and can make clinical diagnosis of ongoing seizures problematic by abolishing muscle contractions. To avoid this potentially lethal complication, chemical paralysis should be used only to facilitate endotracheal intubation if needed. Use of short-acting neuromuscular blockers is desirable to allow for subsequent repeated neurologic assessments. Succinylcholine may not be ideal because of its significant side effects, including hyperkalemia and dysrhythmias. Newer short-acting nondepolarizing neuromuscular blockers with less potential for cardiac side effects, such as rocuronium, should be considered (see Chap. 68).

When severe systemic toxicity occurs, the cardiovascular system must be monitored closely because cardiovascular depression may go unnoticed while the seizures are being treated. Because local anesthetic–induced myocardial depression may occur even with preserved blood pressure, it is important to be aware of early signs of cardiac toxicity, including electrocardiographic (ECG) changes.

If toxicity results from an oral ingestion, activated charcoal is generally indicated, but its benefits are unproven. If the patient has presented for care immediately after ingestion, orogastric lavage with a nasogastric tube may be considered. Induction of emesis is contraindicated even after oral administration because of the risk of seizures and aspiration. Contaminated mucous membranes should be washed off. Hemodialysis is not of proven utility and may be impractical, as is hemoperfusion.

Cardiovascular Toxicity Cardiovascular side effects are the most feared manifestations of local anesthetic toxicity. Shock and cardiovascular collapse may be related to effects on vascular tone, inotropy, and dysrhythmias related to indirect CNS and direct cardiac and vascular effects of the local anesthetic. Animal studies and clinical observations clearly demonstrate that for most local anesthetics, CNS toxicity develops at lower serum concentrations (exception: bupivacaine) than those needed to produce cardiac toxicity, that is, they have a high CV:CNS toxicity ratio.[54,77,78,93] When cardiac toxicity occurs, management may be exceedingly difficult. Some of the discrepancy between the incidence of CNS and cardiac toxicity may result from a detection bias. Not only can the treating physicians fail to recognize cardiac effects because of

preoccupation with CNS manifestations of toxicity, but significant early cardiac toxicity may be quite subtle. An experimental study attempting to identify early warning signs of bupivacaine-induced cardiac toxicity in pigs evaluated bupivacaine-induced changes in cardiac output, heart rate, blood pressure, and ECG.[83] A 40% reduction in cardiac output was not associated without significant change in heart rate or blood pressure, the latter secondary to a direct vasoconstrictive effect of bupivacaine at the concentrations produced. [17]

Changes in systemic vascular tone induced by local anesthetics may be mediated by direct effect on vascular smooth muscle or indirectly via effects on spinal cord sympathetic outflow. Predictably, sympathetic blockade after spinal anesthesia or epidural anesthesia above the T5 dermatome results in peripheral venodilation and arterial dilation. Shock may result when high doses of anesthetic are used in hypovolemic patients. Local anesthetics have a biphasic effect on peripheral vascular smooth muscle. Whereas lower doses produce direct vasoconstriction, higher doses are associated with severe cardiovascular toxicity and cause vasodilation, contributing to cardiovascular collapse.

All local anesthetics directly produce a dose-dependent decrease in cardiac contractility, with the effects roughly proportional to their peripheral anesthetic effect. Although the classic anesthetic action of sodium channel blockade in heart muscle accounts in large part for the negative inotropy by affecting excitation–contraction coupling, it does not explain the entire difference in myocardial depression produced by different anesthetics.[28] Poorly understood effects on calcium handling or effects of the intracellular drug directly on contractile proteins or mitochondrial function may be operable.[28]

Blockade of the fast sodium channels of cardiac myocytes decreases maximum upstroke velocity (V_{max}) of the action potential (see Chap. 22 and 23 and Fig. 63–1). This effect slows impulse conduction in the sinoatrial and atrioventricular (AV) nodes, the His-Purkinje system, and atrial and ventricular muscle.[20] These changes are reflected on ECG by increases in PR interval and QRS duration. At progressively higher anesthetic concentrations, hypotension, sinus arrest with junctional rhythm, and eventually cardiac arrest occur.[4] Asystole has been described in patients who received unintentional IV bolus injections of 800 to 1000 mg of lidocaine.[4,34] Cardiovascular toxicity of local anesthetics usually occurs after a sudden increase in serum concentration, as in unintentional intravascular injection. Cardiovascular toxicity is rare in other circumstances because large doses are necessary to produce this effect and because CNS toxicity precedes cardiovascular events, thus providing a warning. Cardiac toxicity usually is not observed with lidocaine use in humans until the serum lidocaine concentration greatly exceeds 10 μg/mL unless the patient is also receiving xenobiotics that depress sinus and AV nodal conduction such as calcium channel blockers, β-adrenergic antagonists, or cardioactive steroids.

Bupivacaine is significantly more cardiotoxic than most other local anesthetics commonly used. Inadvertent intravascular injection produces near-simultaneous signs of CNS and cardiovascular toxicity.

Animal studies have compared the dosage or serum concentrations of local anesthetics required to produce irreversible circulatory collapse with those necessary to produce seizures.[25,77,78] This cardiovascular collapse/CNS toxicity (CC/CNS) ratio for lidocaine is approximately 7; therefore, CNS toxicity should become evident well before potentially cardiotoxic concentrations are reached. In contrast, the CC/CNS ratio for bupivacaine is 3.7. Bupivacaine produces myocardial depression out of proportion to its anesthetic potency and, more importantly, may cause refractory ventricular dysrhythmias.[95] Enhanced cardiovascular toxicity may relate to enhanced CNS effects at cardiovascular centers,[105] direct effects on myocyte metabolism, and important differences related to sodium channel blockade. Although lidocaine and bupivacaine both block sodium channels in the open or inactivated states lidocaine quickly dissociates from the channel at diastolic potentials, allowing

rapid recovery from block during diastole (fast on–fast off). Therefore, sodium channel blockade with lidocaine is much more pronounced at rapid heart rates (accounting for the antidysrhythmic effects for ventricular tachycardia).[63] On the other hand, at high concentrations, bupivacaine rapidly binds to and slowly dissociates from sodium channels (fast on–slow off), with significant block accumulating at all physiologic heart rates.[20] Accordingly, at heart rates of 60 to 150 beats/min, approximately 70 times more lidocaine is needed than bupivacaine to produce an equal effect on V_{max}. Enhanced conduction block in Purkinje fibers and ventricular muscle cells can set up a reentrant circuit responsible for the ventricular tachydysrhythmias induced by bupivacaine.[70]

Bupivacaine, a potent and long-acting amide anesthetic, has the highest potential for cardiovascular toxicity, which can be refractory to conventional therapy. Inadvertent intravascular injection produces near-simultaneous signs of CNS and cardiovascular toxicity. Bupivacaine has an asymmetrically substituted carbon, and the kinetics of sodium channel binding are stereospecific.[56] The S (levo)-enantiomer levobupivacaine is significantly less cardiotoxic than the R (dextro)-enantiomer despite having similar anesthetic properties.[6,68] Consequently, bupivacaine, the racemic mixture of both enantiomers, is more cardiotoxic than levobupivacaine, which contains only the levo-enantiomer.[40] The stereospecific effect on sodium channels seems to differ between the heart and the peripheral nerves because the local anesthetic potency of levobupivacaine is the same as, or perhaps even greater than, that of bupivacaine.[30,81] Ropivacaine is a pure enantiomer and is less cardiotoxic than bupivacaine, but it is also slightly less potent as an analgesic.[85,86]

Effects other than sodium channel blockade may contribute to cardiotoxicity. Lipophilic local anesthetics such as bupivacaine may directly impair mitochondrial energy transduction via two mechanisms: (1) uncoupling of oxygen consumption and adenosine triphosphate (ATP) synthesis and (2) inhibition of complex I in the respiratory chain.[101] This effect is related to the lipophilic properties of the drug rather than to stereospecific effects on ion channels. Lidocaine has no effect on mitochondrial respiration, and ropivacaine has less effect than bupivacaine.[114] There is no difference between the two bupivacaine enantiomers. These effects occur with higher concentrations of the local anesthetic, as occur after unintentional intravascular injection.

Low-dose bupivacaine-induced cardiotoxic effects have been described in humans under certain circumstances and at concentrations that are not associated with seizure activity in pigs.[52,113] Severe cardiac toxicity is described after injection of a small subcutaneous dose of bupivacaine in a patient with secondary carnitine deficiency.[113] Myocytes are highly dependent on oxidation of fatty acids for energy turnover. Interference with this mechanism via bupivacaine-induced inhibition of carnitine-acylcarnitine translocase has been proposed to contribute to the cardiotoxicity of lipophilic local anesthetics[113] (see Chap. 47 and Fig. 47–2 and Antidote in Depth A21: Intravenous Fat Emulsion). Bupivacaine may produce dysrhythmias by blocking GABAergic neurons that tonically inhibit the autonomic nervous system.[44] In addition to its other effects on the heart, bupivacaine may induce a marked decrease in cardiac contractility by altering Ca^{2+} release from sarcoplasmic reticulum.[62]

In a large series of patients receiving bupivacaine, systemic toxicity occurred in only 15 of 11,080 nerve blocks.[74] Of these patients, 80% convulsed; the other 20% had milder symptoms. A series of cases was described in which bupivacaine use, particularly at 0.75% concentration, was associated with severe cardiovascular depression, ventricular dysrhythmias, and even death. Pregnant women were disproportionately affected. Some of these patients required prolonged and difficult resuscitation.[89] In 1983, 49 incidents of cardiac arrest or ventricular tachycardia that occurred over a 10-year period were presented to the U.S. FDA Anesthetic and Life Support Advisory Committee. Among these cases, 0.75% bupivacaine was used in 27 obstetric patients with 10 deaths, and 0.5% bupivacaine was used in eight obstetric patients

TABLE 66–3. Types of Local Anesthetic Reactions

Cause	Major Clinical Features
Local anesthetic toxicity (intravascular injection)	Immediate seizure or cardiac toxicity
Reaction to catecholamine	Tachycardia, hypertension, headache
Vasovagal reaction	Bradycardia, rapid onset and recovery, hypotension, pallor
Allergic reaction	Anaphylaxis
High spinal or epidural block	Bradycardia, hypotension, respiratory distress, respiratory arrest

with six deaths. Among the 14 nonobstetric patients, five died. The overall mortality was 21 of 49 (43%). Partly as a result of these reports, in 1984, the U.S. FDA withdrew approval of bupivacaine 0.75% for use as obstetric anesthesia.[89]

Acid–base and electrolyte status influence the cardiac toxicity of a given drug because all depressant properties are potentiated by acidosis, hypoxia, or hypercarbia.[12] Table 66–3 outlines the spectrum of acute local anesthetic reactions.

LABORATORY STUDIES

In cases of possible local anesthetic toxicity, an ECG should be obtained to detect dysrhythmias and conduction disturbances. Serum electrolytes, blood urea nitrogen (BUN), creatinine, and arterial blood gas analysis should be obtained to help assess the cause of cardiac dysrhythmias. A methemoglobin percent should be obtained in patients in whom methemoglobinemia is suspected clinically. Rapid, sensitive assays are available for measuring concentrations of lidocaine and its monoethylglycylxylidide (MEGX) metabolite. When properly interpreted, the results of these assays may be used to prevent lidocaine toxicity and to identify lidocaine toxicity in the nontherapeutic setting. Assays for determining serum concentrations of other local anesthetics are not routinely available. Treatment should never be delayed while waiting for results of xenobiotic concentration determinations.

TREATMENT

■ TREATMENT OF LOCAL ANESTHETIC CARDIAC TOXICITY

Treatment of cardiovascular complications of local anesthetics is complicated by the complex effects of local anesthetics on the heart. Initial therapy should focus on correcting the physiologic derangements that may potentiate the cardiac toxicity of local anesthetics, including hypoxemia, acidosis, and hyperkalemia.[12,92] Prompt support of ventilation and circulation limits hypoxia and acidosis. Early recognition of potential cardiac toxicity is critical to achieving a good outcome because patients with cardiac toxicity that goes unrecognized for any interval are more difficult to resuscitate.[7] If a potentially massive intravascular local anesthetic injection is suspected, maximizing oxygenation of the patient before cardiovascular collapse occurs is critical.

■ INTRAVENOUS FAT EMULSIONS

While investigating the relationship between lipid metabolism and bupivacaine toxicity (described above), a rat study of bupivacaine-induced asystolic arrest showed that pretreatment with IV fat emulsion

(IFE) increased the toxic dose of bupivacaine by 50%. In addition, a dose of bupivacaine that was uniformly fatal in control rats showed universal survival in animals that also received fat emulsion.[117] Subsequent studies with experimental models of local anesthetic toxicity have demonstrated accelerated return of cardiac function after IFE both in intact animals and the isolated heart.[115,116]

In clinical reports, epinephrine has limited efficacy in the treatment of cardiac arrest that occurs from bupivacaine toxicity. This could possibly be secondary to inhibition of intracellular cyclic adenosine monophosphate production by bupivacaine. The efficacy of IFE was compared with epinephrine for resuscitation of bupivacaine-induced cardiovascular collapse in a rodent model.[112] IFE led to improved recovery.

A 20% IFE was successfully used to resuscitate a patient from a prolonged cardiac arrest caused by bupivacaine toxicity. The patient rapidly stabilized with IFE after failing to improve with 20 minutes of advanced cardiopulmonary resuscitation (CPR).[94] Subsequently, several case reports have been published describing successful use of IFE (in various formulations) to treat patients in cardiac arrest after regional anesthesia with various local anesthetic agents, including bupivacaine, ropivacaine, and levobupivacaine.[49,58,109]

The mechanism by which IFE reverses local anesthetic toxicity is uncertain. One of the hypotheses is that the exogenous fat emulsion provides a competing source for binding of lipid-soluble local anesthetics, a circulating lipid sink. This view is supported by a study that demonstrated decreased cardiac bupivacaine concentrations after IFE.[116] Another possibility is that the fat emulsion load might overwhelm the inhibition of the carnitine acylcarnitine translocase by mass action and thereby increase the myocardial energy supply, making the heart more likely to respond to resuscitation. In addition, IFE has positive inotropic effects in isolated heart preparations and reversed bupivacaine-induced cardiac depression at lipid levels less than those needed to reduce aqueous bupivacaine concentration.[99]

The limited clinical data suggest that an IV bolus of fat emulsion may be lifesaving in patients with refractory cardiovascular collapse secondary to local anesthetic overdose. Optimal dosing is uncertain.[110] Suggested dosing for a patient in cardiac arrest is 1.5 mL/kg bolus of 20% IFE over 1 minute while continuing chest compressions followed by 15 mL/kg/min for 30 to 60 minutes. If there is evidence of recovery, dosing should be changed to a continuous infusion of 20% IFE at a rate of 0.25 mL/kg/min [15 mL/kg/h] given until hemodynamic recovery, which can be increased as indicated.[111] IFE should be given after signs of local anesthetic toxicity become manifest[110] (see Antidote in Depth A21: Intravenous Fat Emulsion).

In addition to lipid therapy, standard advanced cardiac life support (ACLS) protocols should be generally followed when dealing with most episodes of local anesthetic cardiac toxicity. Hypotension in sinus rhythm results from both peripheral vasodilation and myocardial depression and should be treated with α- and β-adrenergic agonists. Vasopressin may be administered during CPR in addition to epinephrine. Atropine supplemented with electrical pacing should be used to treat bradycardia. The effectiveness of epinephrine in reversing local anesthetic–induced cardiac depression is inconsistent in various animal models. The dysrhythmic effects of epinephrine are of particular concern. Amrinone, a phosphodiesterase III inhibitor, was evaluated for treatment of bupivacaine-induced cardiac toxicity.[38,57] Anesthetized pigs with cardiovascular collapse induced by bupivacaine infusion survived when they were treated with amrinone; all of the control animals died of irreversible cardiac arrest.[57] A phosphodiesterase III inhibitor would be a good choice for reversing bupivacaine-induced cardiac depression.[96]

Bupivacaine-induced dysrhythmias often are refractory to cardioversion, defibrillation, and pharmacologic treatment. Lidocaine, phenytoin, magnesium, bretylium, amiodarone, calcium channel blockers, and combined therapy with clonidine and dobutamine have all been

used in animal models with variable results.[27,65,67] Therapy for bupivacaine toxicity should be directed toward dissociating bupivacaine from the myocardial sodium channel, thereby reversing the drug's effects on cardiac conduction. Lidocaine competes with bupivacaine for cardiac sodium channels and at high doses may displace it. Anecdotal reports suggest that lidocaine has occasionally helped in this application.[23] However, concern persists about additive CNS effects when lidocaine is used to treat bupivacaine cardiac toxicity, and we do not recommend its routine use.

With toxicity from the longer-acting, highly lipid-soluble, protein-bound amide local anesthetics (bupivacaine and etidocaine), if the patient does not respond promptly to therapy, CPR can be expected to be difficult and prolonged (1–2 hours) before depression of the cardiac conduction system spontaneously reverses as a result of redistribution and metabolism of the drugs.[2,87] Vital organ perfusion is seriously compromised during CPR despite optimal chest compression. The significance of this problem increases with the duration of resuscitation; therefore, rapid initiation of cardiopulmonary bypass should be considered, if practical. Its use has resulted in a successful outcome in some cases of lidocaine and bupivacaine overdose.[37,60] Cardiopulmonary bypass provides circulatory support that is far superior to that provided by closed-chest cardiac massage. The improved perfusion prevents tissue hypoxia and the development of metabolic acidosis, which in turn decreases the binding of local anesthetics to myocardial sodium channel receptors. Hepatic blood flow is better maintained, enhancing local anesthetic metabolism, and increased myocardial blood flow helps redistribute local anesthetics out of the myocardium.[60]

Cardiac pacing was used successfully for treatment of cardiac arrest after unintentional administration of a 2 g bolus of lidocaine into a cardiopulmonary bypass circuit as the patient was being removed from bypass.[82] Pharmacologic therapy was unsuccessful, and resumption of bypass was necessary. Forty-five minutes after the injection, AV pacing restored perfusion and permitted discontinuation of bypass.

Use of sodium bicarbonate early in resuscitation to prevent acidosis-mediated potentiation of cardiac toxicity may have been beneficial in some cases,[23] but paradoxical effects on intracellular pH during CPR suggest against its use in the absence of strong experimental or clinical data. In another canine model, an infusion of 2 mL/kg 50% dextrose plus 1 Unit/kg insulin was superior to saline or dextrose alone in reversing bupivacaine-induced cardiac depression.[19] (see A18: Insulin Euglycemia) Effects on potassium current, calcium handling, and myocardial energy utilization all may have contributed to the salutary effects of the insulin infusion.

■ PREVENTION OF SYSTEMIC TOXICITY OF LOCAL ANESTHETICS

Despite the development of new, relatively less toxic amide local anesthetics such as levobupivacaine and ropivacaine, severe CNS and cardiovascular effects are not eliminated. Several cases of ropivacaine-induced cardiac arrest have been reported.[18,49,53] In these cases, patients with both asystolic arrest and ventricular fibrillation–associated arrest were successfully resuscitated. Nonetheless, it is clear that prevention is more prudent and effective than treatment of toxicity. The keys to prevention are to use the lowest possible anesthetic concentration and volume consistent with effective anesthesia and to avoid a significant intravascular injection. The latter is accomplished by careful, slow aspiration of a needle or catheter before injection; injection of a small test dose of anesthetic mixed with epinephrine to assess a cardiovascular response if injection is intravascular; and use of slow, fractional dosing of large-volume injections with vigilance for early signs of CNS and cardiac toxicity.

SUMMARY

Local anesthetics are frequently used xenobiotics that provide surgical analgesia and acute and chronic pain relief. The analgesic effect of local anesthetics is primarily caused by inhibition of neural conductance secondary to sodium channel blockade. Systemic toxicity, which primarily affects the heart and brain, is also largely related to sodium channel blockade. Severe systemic toxicity usually occurs secondary to inadvertent intravascular injection. In most cases of systemic toxicity, CNS manifestations precede cardiovascular events. If cardiovascular collapse and cardiac arrest occur, resuscitation may be difficult and prolonged. A novel therapy of IV fat emulsion is shown to reverse, by uncertain mechanisms, local anesthetic toxicity. Cardiopulmonary bypass may be useful because it provides cardiovascular support, limits exacerbating factors such as tissue hypoxia and acidosis, and improves hepatic blood flow, thereby increasing local anesthetic metabolism. Avoidance of intravascular injection and vigilance for early signs of CNS and cardiac toxicity are keys to preventing serious adverse events.

INTRAVENOUS FAT EMULSIONS

Theodore C. Bania

Intravenous fat emulsion (IFE) has been used as a source of parenteral nutrition for over 40 years. More recently, IFE has also been used as a diluent for intravenous drug delivery of highly lipophilic xenobiotics such as propofol and liposomal amphotericin. The use of IFE as an antidote is most extensively studied for the treatment of local anesthetic toxicity, specifically from bupivacaine, but new applications that are being investigated and reported on include the treatment of overdose from lipophilic drugs such as calcium channel blockers, cyclic antidepressants, clomipramine, and beta adrenergic antagonists, to name a few.

PHARMACOLOGY

Intravenous fat emulsion is composed of two types of lipids, triglycerides and phospholipids. Triglycerides are hydrophobic molecules that are formed when three fatty acids are linked to one glycerol. The fatty acid chain length varies, producing different triglycerides. The main triglycerides in IFE are linoleic, linolenic, oleic, palmitic, and stearic acids, and concentrations of these vary slightly in the different commercially available fat emulsions. These long-chain triglycerides (12 or more carbons) are extracted from safflower oil and/or soybean oil depending on the brand of the emulsion.[42] Newer fat emulsions contain long-chain triglycerides in addition to medium-chain triglycerides (6–12 carbons) derived from coconut, olive, and fish oils but are currently not available in the United States.[46]

Phospholipids contain two fatty acids bound to glycerol along with a phosphoric acid moiety at the third hydroxyl (Fig A21–1). Phospholipids are amphipathic, that is, the nonpolar fatty acids are hydrophobic while the polar phosphate head is hydrophilic. This imparts important pharmacological properties to this carrier molecule, allowing it to solubilize nonpolar xenobiotics into the aqueous serum. The phospholipids in IFE are extracted from egg yolks.

The lipids in IFE are dispersed in the serum by forming an emulsion of small lipid droplets. To create the emulsion droplets, the phospholipids form a layer around a triglyceride core. The hydrophobic fatty acid component of the phospholipid molecule is directed toward the triglycerides while the hydrophilic glycerol component is directed outward away from the triglyceride core. The presence of small amounts of glycerol, which is hydrophilic, allows the lipid droplets to be suspended as an emulsion in water and serum.

Intravenous fat emulsion is a white, milky liquid. It is sterile and nonpyrogenic with a pH of about 8 (range 6 to 9). IFEs are isotonic solutions (260–310 mOsm/L) and are available in 5%, 10%, 20%, and 30% solutions. The 30% solution should be diluted before administration. IFE can be delivered through a peripheral or central vein.[42]

Intravenous fat emulsions have different globule sizes depending on their uses.[7] Microemulsions (mean droplet size less than 0.1 μm) are used for drug delivery. Mini-emulsions (mean droplet size greater than 0.1 μm but less than 1.0 μm) are used for parenteral nutrition. Droplet sizes in commercially available nutritional IFEs range from 0.4 to 0.5 μm. After intravenous administration, IFEs are found in the serum as chylomicron-like lipid droplets that turn the serum turbid or milky. Macro-emulsions (mean droplet size greater than 1.0 μm) are used for chemoembolization. These macro-emulsions contain antineoplastics that are delivered intraarterially directly into the tumor blood supply. The lipid droplets occlude the artery and slowly release the antineoplastic.

Lipid droplets that are less than 1 μm are primarily removed from circulation as they pass through the capillaries of adipose tissue and the liver. The capillary endothelium in these tissues contains lipoprotein lipase, which hydrolyzes triglycerides releasing fatty acids and glycerol that then diffuses into the cells. Fatty acids also enter the cardiac myocyte either by passive diffusion or protein-mediated transport.[39]

Once inside the cells, fatty acids are used as energy or resynthesized into triglycerides and stored. For use as energy, triglycerides are transported into the mitochondria by carnitine palmitoyl transferase, where they undergo β oxidation sequentially releasing acetylcoenzyme A (acetyl-CoA) as the fatty acid chain is reduced in length. These acetyl-CoA molecules enter the Krebs cycle, where they ultimately generate adenosine triphosphate (ATP) (see Fig. 12-3 and 12-8). Although glucose, lactate, and fatty acid metabolism may ultimately lead to the production of acetyl-CoA, fatty acid metabolism produces the largest amount of energy. For example, 1 mol of glucose produces 38 ATP while 1 mol of stearic acid produces 146 ATPs[55] and the metabolism of longer fatty acid chains may produce more ATP.

The half-life of IFE is 30 to 60 minutes, and can vary substantially depending on the patient's clinical state, dose of IFE, and droplet size.[8] Larger droplet sizes have slower clearances, and are removed by reticuloendothelial phagocytosis. These larger droplets are more likely to induce an inflammatory response, obstruct the microvasculature, and produce capillary fat emboli.

MECHANISM OF ACTION

The mechanisms of action of IFE in toxicology are not clearly understood. There are currently three proposed mechanisms of action of IFE in toxicology: modulation of intracellular metabolism, a lipid sink or sponge mechanism, and activation of ion channels.

In experimental models of poisoning from xenobiotics that alter intracellular energy metabolism, toxicity was successfully treated with IFE, suggesting that repairing or circumventing this dysfunction may be involved. Bupivacaine blocks carnitine-dependent mitochondrial lipid transport and inhibits adenosine triphosphatase (ATPase) synthetase in the electron transport chain.[6,51] Verapamil also inhibits intracellular processing of fatty acids,[20,21] but it inhibits insulin release and produces insulin resistance as well.[21] The cyclic antidepressant amitriptyline depresses human myocardial contraction independent of an effect on conduction[16] and inhibits medium- and short-chain fatty acid metabolism.[48] Propranolol changes intracellular energy from primarily fatty acid to carbohydrate-dependent metabolism.[28]
FIGURE A21–1. Biologic membranes are comprised of phospolipids that have a hyrophilic phosphoglycerol "head" and hydrophobic fatty acid "tails.".

Theoretically, adding excess fatty acids may overcome blocked or inhibited enzymes by mass action, providing energy to an energy "starved" heart, reversing toxicity. There is limited experimental evidence to support a modulation of intracellular energy metabolism as the mechanism of action of the IFE for poisoning. The only evidence to support this mechanism comes from IFE effect in reversing myocardial depression resulting from myocardial ischemia.[43] In a canine model of 10 minutes of regional myocardial ischemia, treatment with IFE after ischemia resulted in improved systolic wall thickening. In the same canine model, pretreatment with oxfenicine, which blocks carnitine palmitoyl transferase one blocked the beneficial effect of IFE.[20] This implies that the effects of IFE on myocardial contraction following ischemia are mediated by mitochondrial metabolism. To determine if this is the mechanism of action in verapamil toxicity, rodents were pretreated with oxfenicine or control solution and had verapamil toxicity induced. Both groups were then resuscitated with IFE.[1] There was no significant difference in survival time and mean arterial pressure between the oxfenicine-treated and control groups. This implies that in verapamil toxicity IFE works by a mechanism other than supplying energy to the mitochondria.

In the lipid sink/sponge mechanism, IFE soaks up lipid-soluble xenobiotic and removes it from the site of toxicity. In a slight variation of this mechanism, IFE may pull the xenobiotic out of the aqueous plasma, which bathes the tissue, and into a nonaqueous part of the plasma that is not in contact with the site of toxicity. IFE may also change the distribution of lipid-soluble xenobiotics and deposit them away from the site of toxicity into an area with high lipid content. There is some experimental support for this lipid/sponge mechanism. In an isolated heart model, hearts were perfused with bupivacaine until asystole and then treated with control or IFE. The IFE-treated hearts had a faster recovery from asystole, lower concentration of bupivacaine in the tissue, and higher concentrations of bupivacaine in the venous effluent.[52] In a successful resuscitation from bupropion overdose, bupropion concentrations increased dramatically after administration of IFE.[36] These findings in the experimental model and case report can be explained by the lipid sink/sponge model, where IFE pulls a xenobiotic out of tissue stores. However, the increased concentrations in both could also be explained by an increased perfusion of tissues with the return of circulation and release of the drug. Stronger evidence for the lipid sink/sponge mechanism comes from a pharmacokinetic study of clomipramine concentrations following infusion of IFE. In a rabbit model of clomipramine-induced hypotension, IFE resulted in a more rapid increase in blood pressure compared with saline.[15] These hemodynamic effects were associated with an increased concentration and decreased volume of distribution of clomipramine.

Additionally, IFE may activate ion, particularly Ca^{2+}, channels. Fatty acids directly activate myocardial calcium channels and induce a dose-dependent increase in the Ca^{2+} current. Oleic, linoleic, and linolenic acids act directly on the Ca^{2+} channel to increase Ca^{2+} current.[18] Unfortunately, there is no direct support for this mechanism of action of IFE.

Despite the lack of studies on mechanisms of action, the lipid sink/sponge model is the most likely hypothesis since beneficial effects from IFE are most frequently noted for lipid-soluble xenobiotics. Other mechanisms may be consequential and the mechanism of action may vary for different xenobiotics.

EFFICACY IN POISONING

■ EXPERIMENTAL MODELS

IFE was first studied as an antidote to bupivacaine toxicity and then evaluated for calcium channel blockers, cyclic antidepressants, and β-adrenergic antagonist toxicity. In a rodent model, pretreatment with IFE (10%–30%) followed by a continuous infusion of bupivacaine (10 mg/kg/min) increased the dose of bupivacaine needed to induce asystole.[53] In the second part of this study, bupivacaine was infused into rodents until the development of cardiac arrest. Rodents were resuscitated with IFE (30% IFE, 7.5 mL/kg bolus then 3 mL/kg/min for 2 minutes) or an equivalent volume of saline. Animals were more successfully resuscitated with IFE from a larger dose of bupivacaine then

when saline treated. The LD_{50} for saline resuscitation was 12.5 mg/kg, whereas the LD_{50} for IFE resuscitation was 18.5 mg/kg. In a larger animal model, bupivacaine was administered until cardiac arrest and then the animal was resuscitated with IFE (20% IFE, 4 mL/kg bolus, then 0.5 mL/kg/min for 10 minutes) or saline. Intravenous fat emulsion resulted in a dramatic improvement in survival as six of six survived following IFE versus none in the control (zero of six).[49,50]

In a controlled study of rodents given a continuous infusion of verapamil, treatment with 12.4-mL/kg bolus of 20% IFE resulted in an increase in heart rate and survival compared with control.[41] In a larger animal model of verapamil toxicity where animals were also treated with calcium and atropine, 7 mL/kg of 20% IFE over 30 minutes resulted in improved blood pressure and survival.[2]

In an experimental model of clomipramine toxicity,[14] rabbits were given clomipramine until mean arterial pressure decreased to 50% of baseline. They were then treated with sodium bicarbonate (3 mL/kg of 8.4%), IFE (12 mL/kg of 20%), or sodium chloride (12 mL/kg of 0.9%). Intravenous fat emulsion resulted in an increase in mean arterial pressure over sodium chloride and $NaHCO_3$. In a second part of this study, clomipramine was administered until cardiovascular collapse followed by resuscitation with $NaHCO_3$ (2 mL/kg of 8.4%) or IFE (8 mL/kg of 20%) delivered over 2 minutes. Intravenous fat emulsion resulted in improved survival (four of four) whereas $NaHCO_3$ resulted in no resuscitations (zero of four).

In a rodent model with a constant infusion of propranolol, IFE decreased QRS prolongation, but the study was underpowered to detect an effect on heart rate or survival.[5] In another rodent and rabbit model of propranolol toxicity, IFE resulted in an increase in blood pressure.[4,13]

CLINICAL CASE REPORTS

Based upon the experimental evidence in bupivacaine toxicity, IFE was subsequently successfully used in several reported human cases of cardiovascular collapse from local anesthetic overdose. Previously, cardiopulmonary bypass was the only effective treatment for these patients, as most cases were refractory to standard cardiac resuscitative measures (see Chap. 66). The first reported case occurred in a patient who developed cardiac arrest after the inadvertent intravenous administration of bupivacaine and mepivacaine during an interscalene block.[32] The patient was treated with cardiopulmonary resuscitation (CPR) and advanced cardiac life support (ACLS) for 20 minutes, but only had return of spontaneous circulation after administration of the first dose of IFE (100 mL of 20% IFE followed by 0.5 mL/kg/min for 2 hours). The second successfully treated case occurred when a patient developed asystole after inadvertent intravenous administration of ropivacaine during an axillary plexus block.[25] The patient received CPR and ACLS and had return of spontaneous circulation 10 minutes after administration of IFE (100 mL of 20% or 2 mL/kg followed by an infusion at 10 mL/min for an additional dose of 100 mL of IFE). Additionally, a 60-year-old man with diabetes, coronary artery disease, and end-stage renal failure became unresponsive and developed ventricular fibrillation and torsades de pointes after administration of mepivacaine and bupivacaine for a supraclavicular brachial plexus block. The patient was treated with CPR and ACLS for 10 minutes and then was treated with IFE (250 mL of 20% over 30 minutes). He had return of pulse and blood pressure 11 minutes later.[47]

In addition to its use during resuscitation, IFE has been used to treat milder symptoms of local anesthetic toxicity such as central nervous system symptoms and dysrhythmias without loss of pulse. A patient developed agitation, dizziness, unresponsiveness, and atrial premature contractions and bigeminy after administration of mepivacaine and prilocaine for a brachial plexus block. The patient was only treated with IFE (1 mL/kg of 20%, repeated at 3 minutes for a total of 100 mL, followed by a continuous infusion of 0.25 mL/kg/min or 14 mL/min) and had rapid resolution of his dysrhythmia and regained consciousness.[26] A 75-year-old patient developed seizure, wide complex dysrhythmia, and hypotension following administration of levobupivacaine for a lumbar plexus block. The patient was treated with propofol and metaraminol and IFE (20%, 100 mL over 5 minutes). During the IFE infusion, the QRS narrowed and blood pressure and electrocardiogram (ECG) normalized within 10 minutes.[10] A 13-year-old patient developed ventricular tachycardia at 150 beats/min after being administered lidocaine with epinephrine and ropivacaine for a lumbar plexus block. The patient was only treated with IFE (150 mL or 3 mL/kg of 20% IFE over 3 minutes) and reverted to a normal QRS complex within 2 minutes.[27]

Intravenous fat emulsion has also been successfully used to resuscitate a 17-year-old patient with prolonged cardiovascular collapse after overdose of bupropion and lamotrigine. In this remarkable case the patient, who had seizures and hypotension, received ACLS and CPR for 70 minutes and had return of spontaneous circulation after administration of IFE (a bolus of 100 mL of 20%).[36]

Although the optimal dosing regimen for human poisonings remains undefined, several animal models of high-dose IFE have been performed. In a rodent and canine model of verapamil toxicity, 12.4- and 7-mL/kg boluses of 20% IFE were given,[3,41] and in a rabbit model of clomipramine, 12 mL/kg of 20% IFE was used.[42] These animal models used large doses of xenobiotic and were designed to produce a rapid onset of toxicity, so it is difficult to extrapolate from these models to typical human cases. However, the onset of action of IFE in these models was relatively rapid with effects occurring within 5 minutes for clomipramine, and 25 to 30 minutes for verapamil. Higher doses of IFE also are more effective than lower doses. In a model of verpamil toxicity, higher doses of IFE were more effective in improving blood pressure, acidemia, and survival than lower doses of IFE up to a maximum of 18.6 mL/kg of 20% IFE. Higher doses improved hemodynamic parameters transiently but may have also resulted in overall decreased survival times.[31]

DOSING

The dose of IFE administered depends on the implicated xenobiotic and the patient's clinical condition. Dosing is best defined for local anesthetic toxicity, specifically bupivacaine, with generalization of this dosing regimen to poisoning by other local anesthetics and other xenobiotics. The recommended dose of 20% IFE is 1.5-mL/kg bolus followed by 0.25 mL/kg/min or 15 mL/kg/h to run for 30 to 60 minutes.[11,49] The bolus can be repeated several times for persistent asystole, and the infusion rate can be increased if blood pressure decreases. For local anesthetic poisoning, earlier recommendations limited use of IFE only if standard resuscitative measures failed. As a result of the experimental evidence and many successful case reports, some authors are recommending adding IFE at the first signs of local anesthetic toxicity or, in the setting of cardiovascular collapse, to use IFE concomitantly with CPR and ACLS.[54] Generalization of this practice to other xenobiotics is not currently studied or recommended. Some authors are also recommending that IFE be stored for easy and rapid access in operating rooms or in areas where local anesthetics are frequently used.[33] Most case reports documenting successful treatment of local anesthetic toxicity with lipids have been with Intralipid®; however, other parenteral lipid formulations such as Medialipid® (a mixture of 50%

long-chain triglycerides and 50% medium-chain triglycerides; Braun, Germany)[27] and Liposyn III® (Hospira Inc., Lake Forest, IL)[47] have also been successful, suggesting that all currently available parenteral lipid products will be as effective.

Propofol is formulated as a 10% lipid emulsion, but it is not recommended for use a lipid rescue agent[50] because of the adverse effect of the propofol from the dose needed as a lipid rescue agent. For bupivacaine toxicity, 1.5-mL/kg bolus of 20% IFE is recommended which equates to 3 mL/kg of the 10% lipid emulsion in the propofol solution. As normal dose of propofol (1%) for general anesthesia is 2.5 mg/kg or 0.25 mL/kg.[34] Using propofol as a lipid rescue agent would deliver a bolus of 12 times the recommended dose of propofol. This would exacerbate any drug-induced hypotension and bradycardia.

Experimental evidence indicates that IFE may be potentially beneficial in verapamil,[2,31,41] clomipramine,[14,15] and propranolol[4,13] toxicity and this may be extrapolated to other lipid-soluble calcium channel blockers, cyclic antidepressants, or β-adrenergic antagonists. These xenobiotics will usually demonstrate continued absorption, longer duration of toxicity, severe hypotension, and either dysrhythmias or bradycardia over several hours or days. The precise indications and dose of IFE for these situations has not been studied.

It may occasionally be necessary to administer a continuous infusion of IFE following initial resuscitation. The dose of IFE used for nutrition is generally considered a safe dose, except for the potential complications described above. Currently, the nutritional dose of IFE is 1 to 2 g/kg/d or 5 to 10 mL/kg/d of 20% IFE, which is administered over 6 to 24 hours.[8,33] The dose can be increased daily up to 3 g/kg/d. This dose and rate is less than the dose recommended for bupivacaine toxicity (1.5 mL/kg bolus of 20% IFE followed by 15 mL/kg/h for 30 to 60 minutes)[11] and less than the doses used in experimental models for other xenobiotic toxicity. Based on the current data available from animal models, if IFE is used for severe xenobiotic-induced toxicity other than for that of local anesthetics, the safest dosing would be to start with the low dose suggested for bupivacaine toxicity and titrate up, every hour, if hemodynamic parameters continue to worsen.

ADVERSE EFFECTS AND CONTRAINDICATIONS

There have been no reported adverse effects attributed to IFE in the case reports of IFE use in local anesthetic or bupropion toxicity. With the doses used in these cases and the short durations of administration, most patients recovered fully without any significant adverse effects.[10,25-27,33,36,47] Based on these case reports, a dose of 1.5-mL/kg bolus of 20% IFE followed by 0.25 mL/kg/min or 15 mL/kg/h to run for 30 to 60 minutes appears to be safe in bupivacaine-induced cardiac arrest and severe toxicity.

Because of the limited number of case reports, toxicity from IFE remains a concern. Pulmonary toxicity has been reported when IFE is used as a source of parenteral nutrition. In patients with acute respiratory distress syndrome (ARDS), 500 mL of 20% IFE administered over 8 hours resulted in an increase in pulmonary artery pressures, pulmonary shunting, pulmonary vascular resistance, and a decrease in partial pressure of oxygen in the alveoli/fraction of inspired oxygen (PaO_2/FIO_2).[45] Similar results were found in patients with ARDS administered 500 mL of 10% IFE over 4 hours resulting in an increase in pulmonary shunting and a decrease in the fraction of PaO_2/FIO_2.[19] The pulmonary effect of IFE in ARDS may be related to the rate of infusion. In patients with ARDS, 500 mL of 20% IFE infused over 5 hours resulted in an increase in pulmonary pressures, and slower infusion over 10 hours

had no effect on pulmonary pressures.[29] There are conflicting results of the effects of IFE in patients without ARDS. In septic and nonseptic patients without ARDS, 500 mL of 20% IFE administered over 10 hours resulted in an increase in pulmonary artery pressures and pulmonary shunting.[44] In patients with chronic obstructive pulmonary disease (COPD) and pneumonia, 500 mL of 10% IFE administered over 4 hours did not have any pulmonary effects, and in a group of healthy postoperative patients this dose actually decreased pulmonary shunting and increased PaO_2/FIO_2 ratio.[19]

In these studies, when pulmonary effects occurred they were mild and resolved after the IFE infusion was stopped or within 3 to 4 hours. Larger doses may result in clinically significant toxicity and more prolonged effect. However, studies using fat emulsions with medium-chain triglycerides have shown less pulmonary toxicity.[9,37]

There are two mechanisms by which IFE may cause pulmonary toxicity. IFE may occlude the pulmonary vasculature with micro–fat emboli. This is supported by the finding of macrophages containing lipid droplets in the bronchial alveolar lavage fluid of ARDS patients treated with IFE.[24] Experimental evidence also supports the possibility that the high concentrations of linoleic acid in IFE are converted to arachidonic acid and then into vasoactive prostaglandins. Indomethacin, an inhibitor of prostaglandin synthesis, prevented any pulmonary vascular effect caused by IFE in a sheep model.[30]

In addition to pulmonary toxicity, large dose and/or more rapid infusion of IFE have the potential to induce a fat overload syndrome. The fat overload syndrome is characterized by hyperlipemia, fever, fat infiltration, hepatomegaly, jaundice, splenomegaly, anemia, leukopenia, thrombocytopenia, coagulation disturbances, seizures, and coma. Multiple end-organ dysfunction is attributed to inadequate clearance of lipids and sludging in the lungs, brain, kidney, retina, and liver.[7,8,12,17,22,24,34,35,40] Because of the rapid redistribution of most local anesthetics, prolonged IFE infusion should not be required (see Chap. 66). However, many other lipid-soluble xenobiotics have a long duration of toxicity and prolonged IFE infusions may be recommended, resulting in a fat overload syndrome.

Intravenous fat emulsion has the potential to increase gastrointestinal absorption of lipid-soluble xenobiotics. Although this is only currently a theoretical concern, the excessive xenobiotic would likely be partitioned into the IFE and thus be unlikely to result in additional toxicity. Intravenous fat emulsion also has the potential to interact with other antidotes being used. If an antidote is lipid soluble, it may be incorporated by the IFE and result in decreased effectiveness. This is a theoretical concern, and there are no clinical data supporting this concern. IFE has been used with several medications during resuscitation from bupivacaine toxicity including epinephrine, atropine, amiodarone, vasopressin, sodium bicarbonate, magnesium sulfate, calcium chloride, naloxone, and metaraminol.[10,25,32,36,47]

The combined use of IFE and high-dose insulin-euglycemia was evaluated in a model of severe verapamil toxicity and there was no improvement in hemodynamics, metabolic parameters, or survival.[3] Therefore, while other resuscitative drugs should be used as indicated, there is no evidence yet to support or refute the simultaneous use of IFE and high-dose insulin-euglycemia therapy.

IFE is contraindicated in patients with egg allergy, soybean allergy, disorders of fat metabolism, and liver disease. It is contraindicated in patients with myocardial ischemia and infarction because in animal models it increased dysrhythmias and impaired cardiac pump performance when administered during ischemia,[23,38] but was of benefit when administered after ischemia. In an ischemic myocardial cell, fatty acid metabolism is thought to result in lipid peroxidation and free radical production, which increases dysrhythmias and impairs myocardial performance.[43]

SUMMARY

IFE should be used for local-anesthetic-induced cardiac arrest and severe toxicity such as persistent ventricular dysrhythmias. IFE can be used with standard resuscitation and should be stored where local anesthetics are used. A bolus dose of 1.5 mL/kg of 20% IFE should be followed by an infusion for 30 to 60 minutes of 0.25 mL/kg/min or 15 mL/kg/h. Repeat boluses of IFE can be used for persistent asystole.

The use of IFE for other xenobiotics is unclear at this time, though animal data support its use for several lipid-soluble xenobiotics such as verapamil, clomipramine, and β-adrenergic antagonists.

CHAPTER 67
INHALATIONAL ANESTHETICS

Brian Kaufman and Martin Griffel

General anesthesia occurs as a result of reversible changes in neurologic function caused by xenobiotics that modulate synaptic neurotransmission. The commonly accepted elements of general anesthesia include hypnosis, amnesia, analgesia, inhibition of noxious reflexes, and skeletal muscle relaxation.[8] However, precise definitions for some of these terms are lacking. In addition, different effects occur at varying concentrations of inhaled anesthetics. Side effects may be redefined as toxicity, depending on the clinical situation.

HISTORY

The earliest description of the use of an inhalational anesthetic was made by Paracelsus, a Swiss physician and alchemist who prepared a mixture of diethyl ether, alcohol, and water called sweet oil of vitriol. He described the administration of this preparation to hens that fell into a deep sleep from which they recovered unharmed. In 1735, Wilhelm Froben gave this substance its modern name of "ether." Ether was used topically, particularly via the intranasal route, as a treatment of headache, nervous diseases, and fits.

Modern anesthetic practice often is stated to have begun in 1846 at the Massachusetts General Hospital, when the dentist William Morton gave the first public demonstration of the ability of inhaled ether vapor to alleviate the pain of surgery. Oliver Wendell Holmes chose the Greek-related noun *anesthesia* (without feeling) to characterize the process.

Observations on circulatory and respiratory physiology eventually led to an understanding of the effects of inhalation gases and vapors. In the last decade of the 18th century, centers for the pneumatic treatment of disease were established in Birmingham and Bristol, England. Experiments with ether that was inhaled via a funnel and with nitrous oxide were conducted at these institutions. After Humphry Davy described his own pleasurable and exhilarating experience when he inhaled the "laughing" gas, many of his colleagues and friends inhaled nitrous oxide to experience its inebriating effects. Davy also described how inhalation of nitrous oxide relieved headache and the pain of an erupting molar tooth. Although Davy recognized the analgesic properties of nitrous oxide and its possible application for surgery, he failed to pursue the idea.

The public soon took up the use of nitrous oxide in the form of nitrous oxide frolics. Audiences to itinerant medicine shows volunteered to experience the exhilarating effects of nitrous oxide inhalation. At one such show in 1844 in Hartford, Connecticut, a man under the influence of nitrous oxide injured his leg but did not feel any pain. Dr. Horace Wells, a dentist in the audience that day, inhaled nitrous oxide the following day and had his partner painlessly remove a troublesome tooth. A subsequent public demonstration of the use of nitrous oxide for dental extraction caused concern, impeding its general acceptance as a surgical anesthetic.

In Great Britain in 1847, James Simpson, an obstetrician, first used ether to relieve the pain of labor. He subsequently adopted chloroform

for this purpose because of its more pleasant odor and more rapid induction and emergence. The clergy and other physicians opposed the concept of relieving pain during childbirth, but the method ultimately was accepted after Queen Victoria gave birth to Prince Leopold with chloroform given by John Snow.

Over the next century, several volatile anesthetics were introduced, including ethyl chloride in 1848, divinyl ether in 1933, trichloroethylene in 1934, and ethyl vinyl ether in 1947. All had significant safety problems associated with their use, including combustibility and direct organ toxicity.

Advances in fluorine chemistry led to the cost-effective incorporation of fluorine into molecules used in the development of modern anesthetics. Fluroxene was the first of the new fluorinated anesthetics to be widely used clinically. However, this anesthetic was flammable and hepatotoxic. It was largely replaced by the nonflammable halothane, which was synthesized in 1951 and introduced into clinical practice in 1956. Methoxyflurane was evaluated in humans in 1960 but is no longer used because of nephrotoxicity and hepatotoxicity. Other halogenated hydrocarbons with improved clinical properties have been introduced, including enflurane, isoflurane, desflurane, and sevoflurane (Fig. 67–1). The inert gas xenon has been shown to be a useful anesthetic and is being studied. It is both cardio- and neuroprotective in experimental studies.[38] The clinical use of xenon is limited both by its cost and difficulty to manufacture. Although xenon is environmentally friendly compared with presently used anesthetics, its toxicity is relatively unknown but is believed to be minimal.

PHARMACOLOGY

Because a wide range of chemically distinct xenobiotics can produce anesthesia, a unique receptor for the inhaled anesthetics is improbable. More likely, the volatile anesthetics cause general anesthesia by modulating synaptic function from within cell membranes. Anesthetics are known to interact with many proteins. The most likely, but not yet proven, targets for the inhalational anesthetics are the ion channels that control ion flow across the cytoplasmic membrane. An in-depth discussion is beyond the scope of this chapter, but several concepts are important to consider. First, more than 20 different ion channels have been identified, each controlling various anion and cation flows. The results of these ion channel effects include release of inhibitory neurotransmitters and inhibition of excitatory neurotransmitters. In fact, each anesthetic type has variable actions. The receptor for γ-aminobutyric acid type A ($GABA_A$) is the best studied and plays an important role because $GABA_A$ is an inhibitory neurotransmitter. The interaction of all of these receptor effects produces the condition we refer to as *general anesthesia.* Many of the side effects of the inhalational anesthetics result directly from ion channel effects in nonneural tissue, primarily cardiac cell membranes.

Reversible changes in neurologic function cause loss of perception and reaction to pain, unawareness of immediate events, and loss of memory of those events. The common pharmacologic mechanisms for general anesthesia include the physical–chemical behavior of volatile hydrocarbons within the hydrophobic regions of biologic membrane lipids and proteins.

The potency of the various inhaled anesthetics correlates with their physicochemical properties. The dominant theories of the molecular mechanisms by which volatile anesthetics affect membrane function are based on the lipid solubility of the drugs and experimental demonstration of pressure reversal of anesthesia. Anesthetic potency correlates directly with the relative lipid solubility of each drug, suggesting that the primary molecular actions of anesthetics occur in the lipid portion of cell membranes. This mechanism is known as the
FIGURE 67–1. The inhalational anesthetics.

Meyer-Overton lipid solubility theory. Potential membrane regions for anesthetic action include the hydrophobic areas of proteins and protein–lipid interface regions, as well as the phospholipid matrix. High pressures (100–200 atm) can reverse the anesthetic effects of several drugs, suggesting that the drugs cause anesthesia by increasing membrane volume at normal atmospheric pressure, an effect known as the *volume expansion theory*.

PHARMACOKINETICS

Because the inhaled anesthetics enter the body through the lungs, the factors that influence their absorption by blood and distribution to other tissues, particularly the brain, include the solubility of the drug in blood, blood flow through the lungs, blood flow distribution to the various organs, solubility of the anesthetic in tissue, and the mass of the tissue. The goal of inhalation anesthesia is to develop and maintain a satisfactory partial pressure of anesthetic in the brain, the primary site of action.

The pharmacokinetics of anesthetics can be linked to their pharmacodynamics by considering anesthetic potency. The linkage exists because anesthesia strives to achieve and maintain a desired alveolar concentration. For the inhaled anesthetics, potency is commonly referred to as the *minimum alveolar concentration* (MAC) of the anesthetic. MAC is the alveolar concentration at 1 atm that prevents movement in 50% of subjects in response to a painful stimulus. MAC is used when comparing the effects of equipotent doses of anesthetics on various organ functions.

NITROUS OXIDE

Nitrous oxide is the most commonly used inhalational anesthetic in the world. Recently, clinicians have questioned its continued use. In a recent exhaustive review,[39] the toxicity of nitrous oxide was reviewed both from its chemical perspective and its clinical activity. The authors concluded that a ban on its use is not required. Its advantages include a mild odor, absence of airway irritation, rapid induction and emergence, potent analgesia, and minimal respiratory and circulatory effects.

When administered in a modern operating room using current standards of monitoring to prevent unintentional hypoxia, nitrous oxide is a remarkably safe xenobiotic. Unfortunately, nitrous oxide also has a potential for abuse, particularly among hospital and dental personnel.[26] Death and permanent brain damage have been reported but do not generally result from direct toxic effects; instead, they are secondary to hypoxia as a result of simple asphyxiation[13] (see Chap. 124).

Death may occur when patients receive commercially prepared nitrous oxide from tanks contaminated with impurities such as nitric oxide or nitrogen dioxide. Pulmonary toxicity resulting from similar contaminants has been reported after illicit preparation of nitrous oxide from the combustion of ammonium nitrate fertilizer.[32]

Injury may result from the physical properties of this anesthetic. Nitrous oxide is 35 times more soluble in blood than is nitrogen. When nitrous oxide is inhaled, any compliant air-containing space, such as bowel, increases in size; noncompliant spaces, such as the eustachian tubes, exhibit an increase in pressure. These effects occur because nitrous oxide diffuses along the concentration gradient from the blood into a closed space much more rapidly than nitrogen can be transferred in the opposite direction. Clinical consequences include rapid progression of a pneumothorax to a tension pneumothorax, tympanic membrane rupture with hearing loss, bowel distension, and tracheal or laryngeal trauma caused by increased endotracheal cuff pressure resulting from replacement of air by a larger volume of nitrous oxide. Nitrous oxide may be particularly dangerous in patients who have suffered air emboli, and its use should be immediately discontinued upon recognition of these events. When intracranial or neuraxial air is injected during placement of an epidural catheter, it also can theoretically expand upon subsequent exposure to nitrous oxide.

■ HEMATOLOGIC EFFECTS

Bone marrow depression was first recognized as a complication of long-term nitrous oxide exposure in the 1950s, when the gas was used to sedate intubated patients who had severe tetanus.[25] Leukopenia with hypoplastic bone marrow and megaloblastic erythropoiesis typically developed 3 to 5 days after initial exposure and was followed by thrombocytopenia. Recovery usually occurred within 4 days after the anesthetic was discontinued. Healthy patients undergoing routine surgical procedures demonstrate mild megaloblastic bone marrow changes within 12 hours of exposure to 50% nitrous oxide and marked changes within 24 hours.[36] Critically ill patients may be more sensitive to the effects of nitrous oxide on the bone marrow, with megaloblastic changes described after only 1 hour of exposure.[3]

The hematologic effects of exposure to nitrous oxide strongly resemble the biochemical characteristics of pernicious anemia.[2,34,35] Vitamin B_{12}, or cyanocobalamin, is a bound coenzyme of cytoplasmic methionine synthase. The cobalt moiety in the enzyme functions as a methyl carrier in its transfer from 5-methyltetrahydrofolate to homocysteine to form methionine (Fig. 67–2). Nitrous oxide oxidizes the cobalt, converting vitamin B_{12} from the active monovalent form (Co^+) to the inactive divalent form (Co^{2+}), which irreversibly inhibits methionine synthase.[34] The metabolic consequences of this inhibition are significant because methionine and tetrahydrofolate are required for both DNA synthesis and myelin production. This interference is responsible for the development of bone marrow depression and polyneuropathy resembling the characteristic findings that occur in pernicious anemia.[34]

■ NEUROLOGIC EFFECTS

Disabling polyneuropathy in healthcare workers who habitually abused nitrous oxide was first described in 1978.[26] The neurologic disorder improved slowly when the patients abstained from further nitrous oxide
FIGURE 67–2. Hematologic effects of exposure to nitrous oxide (NO) resemble those characteristic of pernicious anemia and are related to oxidation and inactivation of vitamin B_{12}. The irreversible blockade of methionine synthase is consequential with regard to DNA synthesis and myelin production.

abuse. As discussed, this neuropathy is clinically indistinguishable from subacute combined degeneration of the spinal cord associated with pernicious anemia. The syndrome of nitrous oxide neuropathy is characterized by sensorimotor polyneuropathy, often combined with signs of posterior and lateral spinal cord involvement. Signs and symptoms include numbness and paresthesias in the extremities, weakness, and truncal ataxia. Neurologic changes develop only after several months of frequent exposure to nitrous oxide. Those at risk include individuals who chronically abuse the gas and those who are occupationally exposed for prolonged periods to environments contaminated with high concentrations of nitrous oxide.[4] Animal studies demonstrate that methionine synthase may be inactivated by exposure to greater than 1000 parts per million (ppm) of nitrous oxide, a concentration often exceeded in dental procedure rooms. This scenario is highly unlikely in the modern operating room, where inhalational anesthetics are scavenged, but it may occur in poorly ventilated dental offices, where personnel are exposed to concentrations greater than 1000 ppm nitrous oxide. This problem probably is markedly underdiagnosed because the neurologic changes that occur in mild cases mimic other more common neurologic conditions.[7]

■ CHRONIC EXPOSURE TO TRACE LEVELS OF NITROUS OXIDE

Dentists and dental assistants are often exposed to greater concentrations of waste anesthetic gases than are individuals working in well-vented operating rooms. An epidemiologic survey compared 15,000 dentists who used with 15,000 dentists who did not use nitrous oxide in their practices.[7] A 1.2- to 1.8-fold increase in liver, kidney, and neurologic disease was found in the dentists and their chairside assistants who were chronically exposed to trace concentrations of nitrous oxide. For those with heavy office use of nitrous oxide, a fourfold increase in the incidence of neurologic complaints compared with the nonexposed group was observed. Female dental assistants who were exposed to nitrous oxide had a two- to threefold increase in spontaneous abortion rates, reduced fertility, and a higher rate of congenital abnormalities in their offspring.[7]

■ TREATMENT

General Removal of the acutely affected person from the toxic environment should be the initial intervention. Individuals who have developed toxicity from abuse of the gas should be educated about the relationship between their recreational activities and their clinical findings.

Specific Vitamin B_{12} may help patients with a vitamin B_{12} deficiency who develop megaloblastic anemia and neurologic dysfunction after brief exposure to nitrous oxide, but it is not beneficial in patients who have toxicity resulting from more chronic exposure.[40] The reason for the ineffectiveness of vitamin B_{12} in this situation is uncertain.

The bone marrow abnormalities associated with nitrous oxide toxicity may be reversed by administration of a single 30-mg intravenous (IV) dose of folinic acid (the active form of folate)[31] (see Antidotes in Depth A13: Leucovorin and Folic Acid). In primates, a methionine-supplemented diet greatly reduced demyelination and neurologic damage from chronic exposure to 15% nitrous oxide.[41]

HALOGENATED HYDROCARBONS

The inhaled anesthetics were initially considered biochemically inert. Initial reports of toxicity after their administration were poorly explained and were attributed to direct effects on susceptible organs. It now is clear that the inhalational anesthetics are metabolized in vivo and that their metabolites are responsible for acute and chronic toxicity. Much of the toxicity relates to predictable responses that are dose related.

■ HALOTHANE HEPATITIS

Two distinct types of hepatotoxicity are associated with halothane use. The first is a mild dysfunction that develops in approximately 20% of exposed patients. Patients often are asymptomatic but exhibit modestly elevated serum aminotransferase concentrations within a few days of anesthetic exposure. Recovery is complete.[32] In contrast, a life-threatening hepatitis occurs in approximately one in 10,000 exposed patients and

produces fatal massive hepatic necrosis in one in 35,000 patients.[44] Because the histologic findings of massive hepatocellular necrosis are indistinguishable from many of the causes of viral hepatitis,[48] differentiating halothane hepatitis from other causes of hepatitis in the postoperative period is difficult without positive serologic studies. Jaundice, which is common after anesthesia and surgery, usually results from factors such as preexisting liver disease, blood transfusion, sepsis, or other causes of hepatitis. Thus halothane hepatitis is a diagnosis of exclusion or inclusion based on the chemical history.

Several studies report an association between multiple exposures to halothane and subsequent development of hepatitis.[33,47,52] In one study, 95% of cases of halothane hepatitis occurred after repeat exposures, 55% of which involved reexposure within 4 weeks.[52] Under these circumstances, liver dysfunction usually is more severe, and the latency before clinical presentation usually is shorter than when the syndrome develops after initial exposure to halothane.[47]

Obesity is a risk factor commonly implicated in halothane hepatotoxicity.[1,49] Increased fat stores may act as a "reservoir" for halothane, with slow and prolonged release into the circulation and subsequent increase in production of potentially hepatotoxic metabolites.

Most cases of halothane hepatitis occur in middle-aged patients, with women having twice the risk.[22] Genetic factors may play a role in some patients, as indicated by a report of this syndrome in three pairs of related Mexican women.[21]

Mechanism of Toxicity Halothane is the most extensively metabolized inhalational anesthetic (Fig. 67–3). Approximately 20% of the absorbed anesthetic undergoes oxidative metabolism, principally by cytochrome P450 2E1 in the liver, to trifluoroacetic acid. Reduction to trifluorochloroethane and difluorochloroethylene is a minor route of halothane metabolism that requires the absence of oxygen and the presence of an electron donor. These volatile metabolites are free radicals, which may directly produce acute hepatic toxicity by irreversibly binding to and destroying hepatocellular structures. Alternatively, by acting as haptens, they may trigger an immune-mediated hypersensitivity response.[37,50] The high percentage of patients with halothane hepatitis who had recent exposure to the xenobiotic is most consistent with the latter mechanism in which the first exposure primes the development of antibodies to a haptenized protein.[22]

Enflurane, which was used extensively in North America since 1966, is rarely used now. It is too weakly associated with hepatotoxicity.

Some authorities believe the evidence does not support the existence of enflurane-induced hepatic necrosis.[14,16,43] Isoflurane, desflurane, and sevoflurane all appear to have low hepatotoxic potential. The immune form of hepatitis has been reported with all anesthetics except sevoflurane. Cross-sensitivity may be applicable, such that prior exposure to one anesthetic triggers hepatotoxicity upon subsequent exposure to a different anesthetic.

■ NEPHROTOXICITY

The kidneys are the only other organ at risk for toxicity from modern inhalational anesthetics. Methoxyflurane is an anesthetic that was introduced in 1962. By 1966, it was linked to the development of vasopressin-resistant polyuric renal insufficiency (nephrogenic diabetes insipidus) in 16 of 94 patients receiving prolonged methoxyflurane anesthesia for abdominal surgery[11] (see Chap. 16). Polyuria was associated with a negative fluid balance, elevations of serum sodium and urea nitrogen concentrations; osmolality, and a fixed urinary osmolality close to that of serum. Renal abnormalities lasted from 10 to 20 days in most patients but persisted for more than 1 year in three patients. Subsequent studies demonstrated that renal toxicity was caused by inorganic fluoride (F^-) released during biotransformation of methoxyflurane.[46] The risk of toxicity was highly correlated with both the total dose of methoxyflurane (concentration times duration) and the peak serum F^- concentration.[10,31] The nephrotoxic serum fluoride concentration is 50 to 60 μmol/L.[10] The factors that enhance biotransformation such as obesity and enzyme induction also increase the risk of toxicity. Although the precise mechanism by which fluoride produces its toxic effect on the kidneys is not clear, one hypothesis is that fluoride inhibits adenylate cyclase, thereby interfering with the normal action of antidiuretic hormone on the distal convoluted tubules.

Although methoxyflurane is no longer used, lessons learned regarding its toxicity are applied when evaluating the nephrotoxic potential of other fluorinated anesthetics. Of the currently used anesthetics: halothane, isoflurane, enflurane, desflurane, sevoflurane; only enflurane and sevoflurane undergo biotransformation by defluorination.

Approximately 5% of sevoflurane is metabolized. This process occasionally results in sufficient serum fluoride concentrations to produce transient decreases in urine-concentrating ability.[24] However, clinically evident renal impairment almost never occurs with use of
FIGURE 67–3. Reductive metabolism of halothane results in formation of a reactive metabolite that may directly bind macromolecules and create neoantigens, or undergo further metabolism to trifluorochloroethane and difluorochloroethylene. CYP = cytochrome P450

either enflurane or sevoflurane.[18] In addition, volunteer studies failed to show any urine-concentrating defect after exposure to sevoflurane that resulted in high serum fluoride concentrations. In patients with preexisting renal insufficiency, the risk of postoperative renal dysfunction is believed to be worse with exposure to inhalational anesthetics. However, studies demonstrate that deterioration of renal function does not occur after exposure to desflurane and isoflurane,[28] possibly because intrarenal fluoride concentrations are more important than serum fluoride concentrations in the development of nephrotoxicity.

■ PHARMACOKINETICS

Chronic use of isoniazid induces CYP2E1, the enzyme responsible for enflurane metabolism. This induction results in elevated serum fluoride concentrations in approximately 50% of isoniazid-treated patients who receive an enflurane anesthetic.[31] The fluoride concentrations, however, are neither high enough nor sustained enough to produce clinically significant renal dysfunction. Nonetheless, a prudent course is to avoid prolonged use of enflurane in patients taking isoniazid or other xenobiotics, such as ethanol, phenobarbital, or phenytoin, which elevate the activity of cytochrome P450 2E1 (see Chap. 12).

Unusually high serum fluoride concentrations are reported in morbidly obese patients anesthetized with enflurane.[9] This finding may be related to a large storage capacity for fat-soluble anesthetics. Although prolonged postoperative release and metabolism of enflurane may occur, renal dysfunction has not been reported with enflurane use even in obese patients.

Sevoflurane reacts with the alkali within carbon dioxide absorbers to produce several degradation products, including a vinyl ether called compound A ($CF_2C(CF_3)OCH_2F$), which is nephrotoxic and hepatotoxic in rats.[23,51] The site of compound A–induced nephrotoxicity in rats is the renal tubule, especially at the corticomedullary junction.[23] The extent of nephrotoxicity is determined by both the concentration of compound A and the duration of exposure. Compound A is also conjugated, and its breakdown products are nephrotoxic.

Technical Issues Extensive clinical experience with several million patients who were exposed to sevoflurane and 4000 closely studied volunteers failed to demonstrate nephrotoxicity.[30] Higher concentrations of compound A are generated during low-flow anesthesia, use of high concentrations of sevoflurane, fresh calcium hydroxide and barium hydroxide use, and increased temperature conditions. A high fresh-gas flow rate dilutes the concentration of compound A. Concern that higher compound A concentrations are generated when a low fresh-gas flow rate (eg, <2 L/min) is used in a closed circuit led to the current sevoflurane package labeling, which warns the anesthesia provider against fresh-gas flow rates below 2 L/min in a circle absorber system.[29]

Some controversy exists regarding the safety of low-flow sevoflurane anesthesia. Although there have been no clinical reports of sevoflurane-induced nephrotoxicity as measured by changes in blood urea nitrogen (BUN), serum creatinine, or creatinine clearance, clinical data demonstrate transient nephrotoxicity when more subtle measurements of glomerular and tubular function are used.[15,20] For example, when young, healthy patients without underlying renal disease were anesthetized with low-flow sevoflurane for a mean of 6.7 hours, transient but statistically significant increases in urinary glucose and protein excretion were documented without any changes in BUN, creatinine, or creatinine clearance.[20] The clinical significance of such transient abnormalities in renal function is uncertain. Regardless, it seems prudent to not use low-flow sevoflurane in patients with preexisting renal disease until clinical data document the safety of this practice. Newer carbon dioxide absorbents that are free of strong alkali have been identified and studied in an attempt to find products that generate less compound A.

INHALATIONAL ANESTHETIC–RELATED CARBON MONOXIDE POISONING

■ PHARMACOLOGY

Desflurane, enflurane, and isoflurane contain a difluoromethoxy moiety that can be degraded to carbon monoxide (CO). This process occasionally results in patient exposure to toxic CO concentrations and, in rare instances, severe CO poisoning.[6] The true incidence of CO exposure during clinical anesthesia is unknown. Routine detection of intraoperative CO exposure is not currently used, but newer pulse oximeters will permit continuous carboxyhemoglobin evaluations.

CO production is inversely proportional to the water content of CO_2 absorbents. Calcium hydroxide and barium hydroxide (Baralyme) and soda lime, the two most frequently used CO_2 absorbents, are sold wet (13%–15% water by weight), but wet absorbents may dry with high gas-inflow rates. Higher concentrations of CO are most apt to be present during the first case after a weekend because of drying of CO_2 absorbent from a continuous inflow of dry oxygen over the weekend.[17]

Other factors influence the concentration of CO that may result from anesthetic degradation, including temperature (higher temperature increases CO formation), type of absorbent, choice of anesthetic, and concentration of anesthetic. Strong alkalis, such as potassium and sodium hydroxide, initiate the reaction that forms CO. Baralyme, which contains potassium hydroxide, forms more CO than does soda lime, which contains a combination of both.

In one experiment, Baralyme was exposed to 48 hours of dry gas flowing at 10 L/min. Nine swine were then anesthetized with desflurane. Three of the animals died of cardiac arrest within 20 minutes; the other six were successfully resuscitated with IV epinephrine and discontinuation of desflurane.[19] Extremely high concentrations of CO (mean peak concentration, 37,000 ppm) were detected in the circuit within 15 minutes of initiating desflurane anesthesia. All the animals had carboxyhemoglobin concentrations above 80%, with a concentration above 90% in seven of the swine. Lower CO concentrations were detected when the CO_2 absorbent was exposed to only 24 hours of dry gas and when soda lime was substituted for Baralyme.

Clinical monitors routinely used in the operating room cannot detect CO. Mass spectrometry (available in some operating rooms) cannot directly detect CO because its molecular weight is equivalent to that of nitrogen, a gas usually present in much greater amounts. In addition, detection of CO by fragmentation products is not possible by mass spectrometry because CO_2 is present in greater amounts and has similar fragmentation products. However, the presence of CO should be suspected if the mass spectrometer shows the presence of enflurane when it is not being administered.

Trifluoromethane is produced by degradation of isoflurane and desflurane and is responsible for the false readings for enflurane.[56] Simultaneous production of trifluoromethane and CO during chemical decomposition of isoflurane and desflurane allows the false reading of the former as enflurane by mass spectrometry to serve as a gross CO monitor and allows for interventions to prevent further CO production and enhance CO elimination. The overall incidence of CO exposure from anesthetic degradation was six of 1372 (0.44%) first cases of the day in which either isoflurane or desflurane was administered.[56] Mass spectrometry is a useful monitor for indirect detection of CO poisoning in the clinical setting.[55]

Although no case reports document patient morbidity or mortality from intraoperative CO exposures, carboxyhemoglobin reportedly as high as 36% may cause morbidity and mortality in patients with concurrent disease.[6] Unfortunately, the diagnosis of CO poisoning during

anesthesia is difficult because the main clinical features of toxicity are masked by anesthesia, and no routinely available means can identify CO within the breathing circuit or detect when the CO_2 absorbent has been desiccated. Delayed neurologic sequelae from intraoperative CO poisoning are likely missed on the anesthesiologist's postoperative patient evaluation.[54]

The product labels of desflurane and isoflurane have been altered to include a precaution that the CO_2 absorbent should be replaced if a practitioner suspects the absorbent is desiccated. However, the problem associated with this warning is the lack of a reliable method for determining when the absorbent is fully or partially desiccated.

If an anesthetic machine is found with the fresh-gas flow "on" at the beginning of the day, a reasonable practice is to replace the absorbent. Changing from Baralyme to soda lime use also should be considered as a protective measure. Newer CO_2 absorbents that are less likely to degrade anesthetics are being evaluated but are not yet available in the United States.

Extreme heat and fires within the anesthesia circuits have been reported in a warning distributed by the manufacturer of sevoflurane. The cases involved desiccated carbon dioxide absorbents, high sevoflurane concentrations, and primarily but not exclusively Baralyme adsorbent. The exact mechanisms have not been entirely elucidated but again point to the need to change absorbent when it is dry or routinely every Monday morning before the first case.

ABUSE OF HALOGENATED VOLATILE ANESTHETICS

Fatal or life-threatening complications occur when halogenated inhalational anesthetics are used for nonanesthetic purposes such as suicide attempts, mood elevation, and topical treatment of herpes simplex labialis. When ingested, halothane usually produces gastroenteritis with vomiting followed by depressed consciousness, hypotension, shallow breathing, bradycardia with extrasystoles, and acute lung injury (ALI). Coma usually resolves within 72 hours.[12,53] The diagnosis should be suspected when these features occur in a patient with the sweet or fruity odor of halothane on the breath. Supportive care, including endotracheal intubation and nasogastric lavage, should be provided with protection for potentially exposed staff. Full recovery can occur without permanent organ injury.

IV injections of halothane may occur as a suicide attempt or unintentionally during anesthesia induction. A young patient who was found unconscious and hypotensive with ALI after self-administered IV injection of halothane was not successfully resuscitated.[5] A 16-year-old girl received an unintentional IV injection of 2.5 mL of halothane during anesthesia induction.[45] She became unconscious and apneic within 30 seconds but began to awaken within 2 to 3 minutes. Four hours later, she developed respiratory distress from ALI but subsequently made a full recovery.

Transient coma and apnea probably are secondary to a halothane bolus reaching the brain on its first pass through the bloodstream. Redistribution then occurs, explaining the rapid awakening. The ALI that develops after injection of halothane may result from a direct toxic effect of high concentrations of this hydrocarbon drug on the pulmonary vascular bed. After injection, the anesthetic likely travels as a bolus during the first passage through the pulmonary circulation because of its poor solubility in blood.

Hospital personnel are involved in most reported cases of halothane abuse by inhalation.[42] Inhalation of halothane produces a pleasurable sensation similar to that described with glue sniffing. Death may result from upper airway obstruction after loss of consciousness or from

dysrhythmias. Death occurred in a student nurse anesthetist suggested to have applied a full 250-mL bottle of enflurane over 3 hours to "cold sores" on her lower lip.[27]

SUMMARY

Inhalational anesthetics remain popular choices for maintenance of general anesthesia. Their advantage over IV drugs is that their drug concentration within the body can be rapidly increased or decreased at will. Toxicity with use of these drugs may result from a variety of mechanisms, including excessive physiologic drug effect, direct drug effects on metabolic pathways, and toxic effects of drug metabolites. Although life-threatening adverse reactions occur infrequently, physicians who use these drugs should be knowledgeable about their pharmacology and potential toxicity.

CHAPTER 68
NEUROMUSCULAR BLOCKERS

Kenneth M. Sutin

These remarkably powerful xenobiotics have evolved throughout history from essential weapons for hunting to critical adjuncts to modern anesthesia. Understanding the pharmacokinetics of the depolarizing and nondepolarizing neuromuscular blockers (NDNMBs) improves care in the emergency department, intensive care unit (ICU), and operating room. Understanding and early recognition of the complications of each NMB limit associated morbidity and mortality.

HISTORY

Curare is the generic term for the resinous arrowhead poisons used to paralyze hunted animals.[100] The curare alkaloids are derived from the bark of the *Strychnos* vine, and the most potent alkaloids, the toxiferines, are derived from *Strychnos toxifera*. Fortunately for the hunters who used curare, ingestion of their prey did not cause paralysis. Sir Walter Raleigh discovered the use of curare in Guyana in 1595, and he was the first person to bring curare to Europe. The use of curare (d-tubocurarine) in anesthesia spanned almost 60 years and has been replaced by superior agents (with less histamine release and hypotension). Curare played a pivotal role in the discovery of the mechanism of neuromuscular transmission. In 1844, Claude Bernard placed a small piece of dry curare under the skin of a live frog and observed that the frog became limp and died.[7] He performed an immediate autopsy and discovered that the heart was beating. Because direct muscle stimulation produced contraction but nerve stimulation did not, Bernard concluded that curare paralyzed the motor nerves. He later observed, however, that bathing the isolated nerve did not affect neuromuscular transmission, leading him to conclude: "Curare must act on the terminal plates of motor nerves."[12] Curare was also used by Nobel Laureate physiologists Charles Sherrington, John Eccles, and Bernard Katz to further elucidate neuromuscular physiology. Its first clinical use was described in 1878 when Hunter used curare to treat patients with tetanus and seizures.[100] In 1932, Raynard West used curare to reduce the muscular rigidity of hemiplegia.[100]

More recent nonmedical uses of succinylcholine have been less benign.[2] The anesthesiologist Dr. Carl Coppolino was accused of murdering his wife in 1965 by succinylcholine injection.[65] In 1983, shortly after Dr. Michael Swango began his internship at Ohio State University Hospital, patients began dying inexplicably, and he was relieved of his duties.[92] After multiple residencies and jobs over 14 years, extending as far as Mnene Hospital in Zimbabwe, the prosecution secured Swango's guilty plea for the murder of three victims. The toxicologic analysis of the 7-year-old remains of Thomas Sammarco revealed succinylcholine in the liver and gallbladder and its metabolite succinylmonocholine in multiple organs which assisted in the conviction.

With the advent of new modalities of drug delivery, toxicologists must be attuned to possible malicious intent. Emergency personnel responding to a 911 call observed the widow removing an insulin pump reservoir from her dead husband's body with the stated intent to donate the costly equipment.[4] A natural cause of death was presumed, yet surprisingly, forensic analysis revealed etomidate and laudanosine (a metabolite of atracurium) in the victim's liver.

MECHANISM OF NEUROMUSCULAR TRANSMISSION AND BLOCK

The purpose of a NMB is to selectively and reversibly inhibit transmission at the skeletal neuromuscular junction (NMJ). All NMBs possess at least one positively charged quaternary ammonium moiety that binds to the postsynaptic nicotinic acetylcholine (nACh) receptor at the NMJ, inhibiting its normal activation by acetylcholine (ACh). The nACh receptor is a ligand-gated ion channel that consists of four different protein subunits in a pentameric structure surrounding a central channel. The nACh receptor found in human skeletal muscle is present in two primary forms: a mature type found at the NMJ ($\alpha\alpha\beta\epsilon\delta$) or as a fetal (immature) type found on muscle at extrajunctional regions of the muscle fiber ($\alpha\alpha\beta\gamma\delta$). Before discussing the mechanism of neuromuscular block, it is first helpful to understand normal neuromuscular transmission and excitation–contraction coupling (Fig. 68–1).

Therapeutic and toxicologic skeletal muscle paralysis may occur by several mechanisms. For example, tetrodotoxin blocks voltage-sensitive sodium channels, preventing action potential conduction by the motor neuron. On the other hand, botulinum toxin blocks ACh release from the presynaptic neuron by inhibiting the binding of ACh-containing vesicles to the neuronal membrane in the region of the synaptic cleft. Modulation of postsynaptic ACh receptor activity at the NMJ may produce paralysis by one of two mechanisms: depolarizing (phase I block) and nondepolarizing (phase II block). Succinylcholine is the only depolarizing neuromuscular blocker (DNMB) in current clinical use. Nicotine at high doses may also cause a depolarizing block. All other drugs discussed are NDNMBs.

The process of DNMB requires several steps. First, two molecules of succinylcholine must bind to each α site of the nACh receptor. This action causes a prolonged open state of the nACh receptor ion channel. The initial depolarization generates a muscle action potential and usually causes brief contractions (fasciculations). In contrast to ACh, succinylcholine is not hydrolyzed efficiently by junctional (true) acetylcholinesterase (AChE); thus, the effect of succinylcholine lasts much longer than ACh. Persistence of succinylcholine at the ACh receptor causes a sustained local muscle endplate depolarization that, in turn, causes the voltage-gated sodium channel in the perijunctional region to remain in a prolonged inactive state, inducing a desensitization block. The muscle is temporarily refractory to presynaptic release of ACh (phase I block).

The NDNMBs cause skeletal muscle paralysis by competitively inhibiting the effects of ACh and thus preventing muscle depolarization. One molecule of an NDNMB bound to a single nACh receptor (on the α site) is sufficient to competitively inhibit normal channel activation. Because the NDNMBs do not block voltage-gated sodium channels on the skeletal muscle membrane, direct electrical stimulation with a current sufficient to cause membrane depolarization will still elicit a muscular contraction. The NDNMBs are classified by duration of action as ultrashort, short, intermediate, and long. They are also classified by chemical structure as either a synthetic benzylisoquinolinium or an aminosteroid (Table 68–1).

NDNMBs also block nACh receptors on the prejunctional nerve terminal and inhibit ACh-stimulated ACh production and release[83] by blocking local autoregulation of available ACh. This effect reduces the available pool of ACh and augments the extent of neuromuscular block.[9]
FIGURE 68–1. Excitation–contraction coupling in skeletal muscle. At the neuromuscular junction, acetylcholine (⬤) released from the presynaptic nerve terminal crosses the 50-nm synaptic cleft to reach the nicotinic acetylcholine (nACh) receptor (⬤). When agonist simultaneously occupies both receptor sites this ion channel opens, becoming nonselectively permeable to monovalent cations, resulting in an influx of Na^+ and an efflux of K^+. This produces local membrane depolarization (end plate potential), which, in turn, opens voltage-activated Na^+ channels (⬤). A depolarization of sufficient amplitude generates a propagated muscle action potential (MAP), which is conducted along the muscle membrane and down the transverse (T) tubules. In the T tubule, the MAP triggers a voltage-activated calcium channel (the dihydropyridine receptor (⬤) which then activates the skeletal muscle ryanodine receptor/ channel (⬤). To allow the fastest activation of mammalian skeletal muscle, calcium diffusion is not necessary for activation of RYR-1; instead, there is a direct electrical (protein) linkage between the dihydropyridine receptor and the ryanodine receptor.[26] Active ATPase driven calcium reuptake terminates muscle contraction. Many factors influence the activity of the RYR-1 channel, including Ca^{2+}, Mg^{2+}, and anesthetic drugs such as inhalation agents that accelerate Ca^{2+} release in persons susceptible to malignant hyperthermia. Antagonists such as conotoxin are red and agonists such as nicotine are green.

PHARMACOKINETICS

The NMBs are highly water soluble and relatively insoluble in lipids. Thus, they are rapidly distributed in the extracellular space and very slowly permeate lipid membranes such as the gut, placenta, and the normal blood–brain barrier. For this reason, they are devoid of central nervous system (CNS) effects. Because these drugs distribute in the extracellular space, their dosage is based on ideal body mass. In obese patients, estimation of drug requirement according to total body mass results in the administration of an excessive dose.

The speed of onset of an NMB is inversely related to its molar potency (ie, ED_{95} expressed as moles NMB drug per kilogram body weight).[48,49] Stated differently, the greater the affinity of the NDNMB for the ACh receptor, the fewer molecules per kilogram of tissue are required to produce a given degree of ACh receptor occupancy. Atracurium is the only drug that does not follow this generalization because it is a mixture of 10 isomers each having a different receptor affinity (cisatracurium consists of only one isomer).

In general, small, fast-contracting muscles such as the extraocular muscles are more susceptible to neuromuscular block than are larger, slower muscles such as the diaphragm. This is the so-called *respiratory sparing effect.* After an intravenous (IV) bolus of NDNMB, paralysis of the diaphragm is coincident with paralysis of laryngeal muscles because high tissue perfusion results in rapid drug distribution and diffusion into the NMJ of all tissues.[18] However, recovery from NMB is fastest for the diaphragm and intercostal muscles; intermediate for the large muscles of the trunk and extremities; and slowest for the adductor pollicis, larynx, pharynx, and extraocular muscles.[18]

COMPLICATIONS OF NEUROMUSCULAR BLOCKERS

Complications associated with the use of NMBs include (1) problems associated with the care of a paralyzed patient (eg, undetected hypoventilation resulting from ventilator or airway problems, impaired ability to monitor neurologic function, unintentional patient awareness, peripheral nerve injury, deep vein thrombosis, and skin breakdown), (2) immediate side effects, and (3) effects occurring after prolonged drug exposure.[72,73]

■ CONSCIOUSNESS

Even though NMB drugs do not affect consciousness, misconceptions about these drugs persist.[62] The pupillary light reflex, an important indicator of midbrain function, is preserved in healthy subjects who receive NDNMBs[35] because pupillary function is mediated by muscarinic cholinergic receptors, for which the NMBs have no affinity.

■ HISTAMINE RELEASE

Muscle relaxants may elicit dose- and injection rate-related nonimmunologic (non IgE-mediated) histamine release from tissue mast cells by an uncertain mechanism (see Table 68–1). The drugs most commonly associated with histamine release are atracurium and succinylcholine.[68]

■ ANAPHYLAXIS

Of the anaphylactic reactions occurring during general anesthesia, approximately 60% are the result of NMBs, but only 17% are the result of latex.[68] Rocuronium is responsible for 43% and succinylcholine for 23% of all NMB-associated anaphylaxis. In up to half of these patients,

TABLE 68–1. Pharmacology of Selected Neuromuscular Blockers

Generic Name	Class	Duration	Initial Dose (mg/kg)[A,B]	Onset (min)[C]	Clinical Duration (min)[D]
Succinylcholine	Depolarizer	Ultrashort	0.6–1	1–1.5	3–7
Atracurium	Nondepolarizer, benzylisoquinolinium	Intermediate	0.4	2–4	20–40
Cisatracurium		Intermediate	0.1	2–4	20–40
Mivacurium		Short	0.25	2–3	12–20
Pancuronium	Nondepolarizer, aminosteroid	Long	0.1	3–6	60–90
Rocuronium		Intermediate	0.6	1–3	30–40
Vecuronium		Intermediate	0.1	2–4	20–40

	Renal Excretion (%)[E]	Biliary Excretion (%)[F]	Metabolite	Histamine Release	Effect on Heart Rate
Succinylcholine	<10	Minimal	Succinic acid	Minimal	Bradycardia (rare)
Atracurium	5–10	Minimal	Laudanosine	Minimal	No
Cisatracurium	10–20	Minimal	Laudanosine	No	No
Mivacurium	<10	Minimal	Several	Minimal	No
Pancuronium	40–60	10–20	3-Desacetyl-pancuronium[G]	No	Tachycardia
Rocuronium	10–20	50–70	No	No	Tachycardia at high dose
Vecuronium	15–25	40–70	3-Desacetyl-vecuronium[G]	No	No

[A] Cisatracurium is labeled as milligram of base per milliliter. Other drugs are labeled and packaged as milligram of salt per milliliter.

[B] Typical initial dose is approximately $2 \times ED_{95}$ (mg/kg).

[C] Onset = time from bolus to 100% block.

[D] Clinical duration = time from drug injection until 25% recovery of single twitch height.

[E] Percent renal excretion in the first 24 hours of unchanged drug; if high, associated with prolongation of clinical effect.

[F] Percent Biliary excretion in first 24 hours of unchanged drug; if high, associated with prolongation of clinical effect.

[G] Active metabolite.

Data adapted from Donati F. Neuromuscular blocking drugs for the new millennium: current practice, future trends–Comparative pharmacology of neuromuscular blocking drugs. *Anesth Analg*. 2000;90(suppl):S2-S6; McManus MC. Neuromuscular blockers in surgery and intensive care, part 1. *Am J Health Syst Pharm.* 2001;58:2287-2299; and Murray MJ, Cowen J, DeBlock H, et al. Clinical practice guidelines for sustained neuromuscular blockade in the adult critically ill patient. *Crit Care Med.* 2002:30:142-156.

there is no prior exposure to an NMB, and cross-sensitization by another allergen is the likely explanation.[55] Pancuronium is the drug that is least associated with serious allergic reactions.[99]

■ CONTROL OF RESPIRATION

At subparalyzing doses, NDNMBs blunt the hypoxic ventilatory response (HVR) but not the ventilatory response to hypercapnia.[23,24] HVR returns to normal when chemical paralysis is completely reversed. Hypoventilation resulting from blunting of the HVR, especially when combined with the residual effects of other drugs used during anesthesia (eg, opioids or inhalational anesthetics), may cause delayed respiratory failure (eg, after general anesthesia).

■ AUTONOMIC SIDE EFFECTS

Nicotinic ACh receptors found in autonomic ganglia, similar to those at the NMJ, are pentamers composed of α and β subunits. In general, they are less susceptible to block by NMBs.[63] There is one notable exception. At the same dose that produces neuromuscular block, tubocurarine also blocks nACh receptors at the parasympathetic

ganglia, causing tachycardia, and at the sympathetic ganglia, blunting the sympathetic response.[87] In combination with tubocurarine-related histamine release, the sympathetic block may cause significant hypotension, especially in patients with heart failure or hypovolemia.[9] This is an important reason why tubocurarine is no longer available in the United States.

The muscarinic receptors (M_1–M_5) are members of the seven-transmembrane G-protein–coupled receptor family. As such, they are structurally unique and mostly unaffected by NMBs. At clinical doses, pancuronium elicits dose- and injection rate–related increases in heart rate, blood pressure, cardiac output, and sympathetic tone.[19,88,93] This is attributed to a selective block of parasympathetic transmission at the cardiac muscarinic receptors (atropine-like effect),[88] block of presynaptic (feedback) muscarinic receptors at sympathetic nerve terminals, and perhaps an indirect norepinephrine-releasing effect at postganglionic fibers.[19]

Dysrhythmias, including bradycardia, junctional rhythms, ventricular dysrhythmias, and cardiac arrest, occur rarely after use of succinylcholine. Dysrhythmias most likely result from stimulation of the cardiac muscarinic receptors and can be prevented by pretreatment

with 15 to 20 µg/kg IV of atropine. Bradycardia is uncommon, but it may be especially severe in children during anesthetic induction when large or repeated doses of succinylcholine are given.

■ INTERACTIONS OF NEUROMUSCULAR BLOCKERS WITH OTHER XENOBIOTICS AND PATHOLOGIC CONDITIONS

NMBs have significant interactions with many xenobiotics and coexisting medical conditions. These interactions may affect the neuromuscular system at any level from the CNS to the muscle itself [79,98] (Table 68–2). In most neuromuscular diseases, such as muscular dystrophy, Guillain-Barré syndrome, myasthenia gravis, and postpolio syndrome, the sensitivity to NDNMB is increased, so a small dose of NMB produces a profound degree of block.[1,10,37] However, persons with myasthenia gravis typically demonstrate resistance to the effects of succinylcholine.[1,10] In individuals with myopathy in whom the specific cause is not yet known, it is prudent to avoid succinylcholine because of the possible sensitivity to malignant hyperthermia (MH), hyperkalemia, or rhabdomyolysis; in place of succinylcholine, a short-acting NDNMB can be used (to lessen the chance of prolonged weakness).

Many pathologic conditions potentiate the duration or intensity of NDNMB, such as respiratory acidosis, hypokalemia, hypocalcemia, hypermagnesemia, hypophosphatemia, hypothermia, shock, and liver or kidney failure.[82] Alternatively, acute sepsis and inflammatory states are associated with mild resistance to the effect of NDNMB.[74]

PHARMACOLOGY OF SUCCINYLCHOLINE

Succinylcholine is a bis-quaternary ammonium ion composed of two molecules of ACh joined end to end at the acetate groups.[21] After a conventional IV induction dose (1 mg/kg), typical serum concentrations are approximately 62 µg/mL.[76]

Succinylcholine is hydrolyzed primarily by plasma cholinesterase (ChE) and to a slight extent by alkaline hydrolysis. Hydrolysis is a two-step reaction; first succinylmonocholine and choline are formed, and then succinic acid and choline are formed (the latter two are normal products of intermediary metabolism). The first reaction is approximately six times faster than the second reaction. Less than 3% of the administered dose is excreted unchanged in the urine.[33] After an IV bolus, the serum succinylcholine concentration increases abruptly, and there is a rapid onset of NMJ block. Later, the serum succinylcholine concentration undergoes a rapid decline as a result of drug redistribution to extravascular tissues and hydrolysis in the serum. Finally, succinylcholine leaves the NMJ to reenter the serum as a result of reversal of the concentration gradient.[32,44]

Succinylcholine 1 mg/kg IV usually increases cerebral blood flow, cortical electrical activity, intracranial pressure,[50] and intraocular pressure, especially in lightly anesthetized patients. These effects, when they occur, are usually modest and of no clinical significance.

TOXICITY OF SUCCINYLCHOLINE

The important adverse drug reactions associated with succinylcholine include anaphylaxis, prolonged drug effect, hyperkalemia, acute rhabdomyolysis in patients with muscular dystrophy, MH in susceptible patients, muscle spasms or trismus in patients with myotonia congenita, and cardiac dysrhythmias.

■ PROLONGED EFFECT

The effects of succinylcholine may last for several hours if metabolism is slowed because of decreased plasma ChE concentration, abnormal plasma ChE activity (genetic variant or drug inhibition), or a phase II block.[14] Acquired plasma ChE deficiency may be caused by hepatic disease, malnutrition, plasmapheresis, or pregnancy.[14] Inactivation of plasma ChE may be caused by fluoride poisoning, organic phosphorus compounds, and carbamates. However, even with only 20% to 30% of normal plasma ChE activity, the clinical duration of succinylcholine is less than doubled.[28]

Many genetic variants of plasma ChE are known. The most common atypical plasma ChE (atypical type, homozygous; incidence, one in 3000) can be assayed by its resistance to inhibition by the local anesthetic dibucaine.[80] A history of uneventful exposure to succinylcholine *excludes* the possibility of atypical plasma ChE except in the case of hepatic transplantation. Dibucaine inhibits the ability of normal plasma ChE to hydrolyze benzoylcholine by more than 70% (ie, dibucaine number >70), heterozygous atypical enzyme by 40% to 60%, and homozygous atypical enzyme by 30% or less. Fresh-frozen plasma or plasma ChE concentrates may be infused to hasten recovery in the case of a genetic enzyme defect or an acquired ChE deficiency. However, to avoid the risks of transfusion, it is best to simply keep the patient sedated, intubated, and ventilated until the drug is metabolized. In this setting, spontaneous reversal usually occurs within 3 to 4 hours, although in rare cases, full recovery requires up to 12 hours.[14] When the duration of succinylcholine is very prolonged, blood samples should be drawn for measurement of plasma ChE concentration and activity.

Prolonged nondepolarizing block may occur when unusually large IV doses of succinylcholine (3–5 mg/kg) are given over minutes.[57] This is called *phase II block*, and it can be partially reversed by neostigmine.

■ HYPERKALEMIA

Succinylcholine 1 mg/kg IV typically causes serum K$^+$ to increase within minutes by approximately 0.5 mEq/L both in normal individuals and in persons with renal failure. The acute hyperkalemic response to succinylcholine is exaggerated with coexisting myopathy or proliferation of extrajunctional muscle ACh receptors. However, the mortality is highest (30%) when rhabdomyolysis is present.[36] Severe, precipitous, potentially life-threatening hyperkalemia also occurs after succinylcholine administration in several conditions associated with proliferation of ACh receptors. These conditions include denervation (head or spinal cord injury, stroke, neuropathy, prolonged use of NDNMBs), muscle pathology (direct trauma, crush or compartment syndrome, muscular dystrophy), critical illness (hemorrhagic shock, neuropathy, myopathy, prolonged immobility), thermal burn or cold injury, and sepsis lasting several days (eg, intraabdominal infections). After a neurologic injury, susceptibility to hyperkalemia begins within 4 to 7 days and may persist indefinitely. In patients who have been in the ICU for more than 1 week, a prudent course is to avoid succinylcholine altogether because of the risk of hyperkalemic cardiac arrest, which is associated with a mortality rate of at least 19%.[6,8,36] Severe hyperkalemia is modified, but not prevented, by a dose of an NDNMB sufficient to prevent succinylcholine-induced muscle fasciculations.

Severe or even fatal hyperkalemia has been reported in a few patients who received succinylcholine immediately after exsanguinating hemorrhage or massive trauma. The mechanism for this condition is not the same as that after neurologic injury because of inadequate time for proliferation of extrajunctional ACh receptors. Succinic acid, a tricarboxylic acid cycle intermediate (which is also a metabolite of succinylcholine), facilitates activation of voltage-gated sodium channels in a dose-dependent fashion, increasing skeletal muscle excitability.[38] In hemorrhagic shock, accumulation of succinic acid as a result of cell breakdown and anaerobic metabolism possibly augments the potassium-releasing effect of succinylcholine.

TABLE 68–2. Effect of Prior Administration of Xenobiotics on Subsequent Response to Succinylcholine or Nondepolarizing Neuromuscular Blockers

Xenobiotic	Response to Succinylcholine	Response to Nondepolarizer	Comments
Aminoglycosides (eg, amikacin, gentamicin)	Potentiates	Potentiates	Dose-related decrease in presynaptic ACh release. May decrease postjunctional response to ACh. Partially reversible with calcium supplementation. Effect of neostigmine unpredictable.
Anticholinesterase, peripheral acting: neostigmine, edrophonium	Prolongs succinylcholine (except edrophonium)	No effect	Neostigmine, pyridostigmine, and physostigmine inhibit plasma AChE and prolong succinylcholine block. Edrophonium does not inhibit plasma cholinesterase.
Anticholinesterase, centrally acting: donepezil	Potentiates	Potentiates mivacurium	Inhibits AChE (junctional >> plasma); long half-life (70 h).
β-Adrenergic antagonist: propranolol	Potentiates in cats, effects in humans uncertain	Potentiates	When given alone, may unmask myasthenic syndrome. Blocks ACh binding at postsynaptic membrane. Reversal of block with neostigmine may cause severe bradycardia.
β-Adrenergic antagonist: esmolol	? Mild prolongation	Slows onset of rocuronium	Competes for plasma AChE.
Botulinum toxin	?	Early potentiation, delayed resistance	Single case report: acutely, subclinical systemic denervation leads to vecuronium hypersensitivity. Subsequent NMJ remodeling and ACh receptor upregulation lead to vecuronium resistance.
CAs			Pancuronium and CA may cause cardiac dysrhythmias because of sympathetic effects.
Calcium channel blockers: nifedipine, verapamil	Potentiates	Potentiates	Causes calcium channel block pre- and postjunctionally. Verapamil has local cholinesterase inhibitor effect on nerve. May inhibit block reversal by cholinesterase inhibitor.
Carbamazepine	?	Inhibits, shortened duration	Chronic therapy causes resistance to NDNMB, except for atracurium.
Cardioactive steroids	More prone to cardiac dysrhythmias	Pancuronium increases catecholamines and may cause dysrhythmias	
Dantrolene	?	Potentiates	Blocks excitation–contraction coupling by blocking ryanodine calcium channel in sarcoplasmic reticulum of skeletal muscle.
Furosemide <10 μg/kg 1–4 mg/kg	Potentiates/Inhibits	Potentiates/Inhibits	Biphasic dose response in cats; protein kinase inhibition at low doses and phosphodiesterase inhibition at high doses. Diuretic-related hypokalemia potentiates pancuronium in cats.
Glucocorticoids	?	Inhibits	Chronic steroid use induces resistance to pancuronium and decrease plasma cholinesterase activity by 50%. Steroids ± NDNMB associated with myopathies.
Inhalational anesthetics: isoflurane	Potentiates	Potentiates	Decrease CNS activity and potentiates NMB in anesthetic doses: dependent fashion (postsynaptic and muscle effects). Halothane causes less muscle relaxation than isoflurane.
Lidocaine	Potentiates	Low-dose potentiates block. High-dose inhibits nerve terminals and blocks ACh binding site at postsynaptic membrane.	The fast Na^+ channel blockers decrease action potential propagation, ACh release, postsynaptic membrane sensitivity, and muscle excitability. Weak inhibitor of plasma cholinesterase.
Lithium carbonate	Prolongs onset and duration	Prolongs effect of pancuronium	Inhibits synthesis and release of ACh. Lithium alone may cause myasthenic reaction.
Magnesium	Potentiates; may block fasciculations	Potentiates; may also prolong block	Decreases prejunctional ACh release, postjunctional membrane sensitivity, and muscle excitability.

(*Continued*)

TABLE 68–2. Effect of Prior Administration of Xenobiotics on Subsequent Response to Succinylcholine or Nondepolarizing Neuromuscular Blockers (*Continued*)

Xenobiotic	Response to Succinylcholine	Response to Nondepolarizer	Comments
NDNMB : pancuronium vecuronium rocuronium	"Precurarization" with NDNMB shortens the onset and decreases side effects of succinylcholine. Pancuronium increases block duration.	Chronic NDNMB induces resistance to their effect. Mixing different NDNMBs may cause greater than additive effects, especially combining pancuronium with tubocurarine or metocurine	Prior NDNMB inhibits plasma AChE and prolongs mivacurium and succinylcholine block. Rank order: pancuronium > vecuronium > atracurium. Heterozygote for atypical plasma AChE may develop phase II block when given succinylcholine and pancuronium.
Organic phosphorus compounds	Potentiates	?	Irreversible plasma AChE inhibitor. May totally block enzyme activity.
Phenelzine (MAOI)	Prolongs	?	Decreases plasma AChE activity.
Phenytoin	?	Resistant, shortened duration	Acutely, potentiates NDNMB paralysis. With chronic use (except for atracurium), phenytoin induces resistance to NDNMB and increases drug metabolism. This increases the initial dose and decreases the repeat dosing interval.
Polypeptide antibiotics: polymyxin	Potentiates	Potentiates	May cause severe weakness. May induce postsynaptic neuromuscular block. Neostigmine increases block.
Succinylcholine	Self-taming dose of succinylcholine may be used to limit muscular fasciculations	Pancuronium and vecuronium slightly prolonged by prior succinylcholine	
Theophylline		Inhibits	Pancuronium and theophylline may increase cardiac dysrhythmias.

ACh, acetylcholine; AChE, acetylcholinesterase; MAOI, monoamine oxidase inhibitor; NMJ, neuromuscular junction; NDNMB, nondepolarizing neuromuscular blocker; CA, cyclic antidepressant.

■ RHABDOMYOLYSIS

Severe hyperkalemia rarely occurs in the absence of a clinical history that readily discloses an obvious risk factor, with one important exception. Acute or delayed onset of rhabdomyolysis, hyperkalemia, ventricular dysrhythmias, cardiac arrest, and death have been reported in apparently healthy children who subsequently were found to have a myopathy.[53] Since March 1995, a black box warning on the package insert has stated that succinylcholine should be avoided in elective surgery in children, particularly in children younger than 8 years of age, because of the small risk of a previously undiagnosed skeletal myopathy, especially Duchenne muscular dystrophy. Sudden cardiac arrest occurring immediately after succinylcholine administration should always be assumed to be caused by hyperkalemia. If fever, muscle rigidity, hyperlactatemia, or metabolic and respiratory acidosis also is present, the presumptive diagnosis of MH should prompt immediate therapy with dantrolene.

■ MALIGNANT HYPERTHERMIA

MH is a syndrome characterized by extreme skeletal muscle hypermetabolism; it is initiated after exposure to an anesthetic that triggers abnormal calcium release from the skeletal muscle sarcoplasmic reticulum, and it can have a variable presentation.[85] Although MH is associated with certain myopathies (including Duchenne muscular dystrophy, central core disease, King-Denborough syndrome, hypokalemic periodic paralysis, and certain sodium channel forms of myotonia), the disorder typically affects individuals who are otherwise healthy. It is inherited as an autosomal dominant trait with variable penetrance.[64] Triggering xenobiotics that can precipitate an attack of MH include succinylcholine and volatile inhalational anesthetics (the prototypical agent is halothane). In individuals considered MH susceptible, xenobiotics that can be administered safely include NDNMBs, nitrous oxide, propofol, ketamine, etomidate, benzodiazepines, barbiturates, opioids, and local anesthetics.

In human MH, there is a causal association with several unique defects involving a skeletal muscle receptor/regulatory protein, especially defects involving the calcium-activated calcium release channel found in skeletal muscle; the type 1 ryanodine receptor (or RYR-1, chromosome 19q13.1). Mutations of the RYR-1 receptor are detected in more than 50% of patients with MH, and more than 40 different mutations have been described[94] (see Fig. 68–1). The structurally distinct type 2 ryanodine receptor (RYR-2) is the primary type expressed in cardiac muscle, and this could explain why the myocardium is relatively spared in the early phase of MH (with the exception that the heart is hyperdynamic).[84] Of practical importance, the existence of multiple mutations across multiple alleles means that genetic testing

is not likely to prove useful in detecting all individuals who are MH susceptible.

Although the prevalence of a genetic disorder associated with MH is one in 3000 to one in 8500, the observed incidence of MH reactions in patients exposed to general anesthesia (with triggering anesthetic agents) is one in 5000 to one in 60,000.[78,85] Each year in the United States, there are an estimated 700 cases of MH.[52] In patients who are MH susceptible, clinical manifestations develop less than half the time after exposure to triggering agents. For this reason, a previous uneventful anesthetic exposure does not preclude development of MH on a subsequent exposure.[3] In the operating room, MH most often presents abruptly soon after initial exposure to a triggering anesthetic agent, but the onset of MH may be delayed several hours into general anesthesia[71] or it may occur as long as 12 hours after surgery. In addition, MH can recur 24 to 36 hours after an initial episode.

The immediate systemic manifestations of MH result from extreme skeletal muscle hypermetabolism. The uncontrolled release of calcium from the terminal cisternae of the sarcoplasmic reticulum causes skeletal muscle contraction. Although muscular rigidity is a specific sign of MH, it is not consistently observed. Futile calcium cycling by sarcoplasmic Ca^{2+}-ATPase rapidly depletes intracellular ATP and leads to anaerobic metabolism. Clinically, MH presents as skeletal muscle hypermetabolism, increased CO_2 production (respiratory acidosis), increased O_2 consumption (mixed venous O_2 saturation far below normal of 75%, arterial hypoxemia, anaerobic metabolism, metabolic acidosis with elevated lactate concentration, cyanosis and skin mottling), and excess heat production (hyperthermia).[39] Other clinical findings include tachycardia, cardiac dysrhythmias, hyperkalemia, rhabdomyolysis, and disseminated intravascular coagulopathy.

The earliest signs of MH include an early and rapid increase in CO_2 production, causing an increase in arterial, venous, and end-tidal CO_2; tachycardia; tachypnea; hypertension or labile blood pressure; and skeletal and jaw muscle rigidity. Despite the name of the syndrome, hyperthermia is not a universal finding in MH, and moreover, it is often a late sign.[97] Acute potassium release from skeletal muscle cells may produce life-threatening hyperkalemia. Subsequent rhabdomyolysis may exacerbate the elevation of potassium by causing renal failure. In late-stage MH, cardiac decompensation results from hyperkalemia, heart failure, vascular collapse, or myocardial ischemia (especially with coexisting coronary artery disease). A standardized clinical grading scale has been published ranking the qualitative likelihood (ranging from "almost never" to "almost certain") that an adverse event represents a true episode of MH.[51]

The differential diagnosis of MH includes neuroleptic malignant syndrome, propofol infusion syndrome, serotonin syndrome, thyroid storm, pheochromocytoma, baclofen withdrawal, malignant syndrome in Parkinson's disease, tetanus, meningitis, poisoning by salicylates, amphetamines, cocaine, or antimuscarinics, unintentional intraoperative hyperthermia, heat stroke, and transfusion reactions. Of note, early septic shock is also associated with hypermetabolism, increased cardiac output, and fever, however, in contrast to MH, early septic shock is associated with an elevated mixed venous O_2 saturation (typically >75%).

Rarely, MH is triggered by severe exercise in a hot climate, IV potassium (which depolarizes the muscle membrane), antipsychotic drugs, or infection.[17,43] Some patients with hypermetabolism or rhabdomyolysis have responded favorably to dantrolene, but this does not necessarily confirm the diagnosis of MH. Such confirmation requires a muscle biopsy.

One theory of the pathogenesis of MH suggests that MH-triggering xenobiotics interact with an abnormal RYR-1 channel, causing it to stay in a prolonged open state and leading to rapid efflux of calcium from the skeletal muscle sarcoplasmic reticulum into the myoplasm. Succinylcholine prolongs muscle depolarization, leading to elevated myoplasmic calcium concentration. This action initiates accelerated calcium-activated calcium release from the myoplasmic reticulum.[36] However, not all cases of MH can be explained by an RYR-1 mutation.[29] For example, MH is also associated with defects in the CACNA1S protein that encodes a subunit of the skeletal muscle L-type calcium channel (known as the dihydropyridine receptor) and possibly with certain disorders of sodium channels (observed in the myotonic disorders).[29,70]

The antidote for MH is dantrolene, and the key aspects of MH therapy are rapid initial diagnosis, discontinuation of triggering anesthetics, and immediate therapy with dantrolene (within minutes). By partially blocking calcium release from skeletal muscle sarcoplasmic reticulum, dantrolene rapidly reverses the signs and symptoms of hypermetabolism. Before the introduction of dantrolene, the mortality rate of MH was 64%.[52] When patients with acute MH are treated immediately with dantrolene, removal of triggering agents, and supportive measures (volume resuscitation, active cooling, control of hyperkalemia), the mortality rate is less than 5%.[52] Factors associated with an increase in mortality are a muscular body habitus, development of disseminated intravascular coagulation, and a longer duration of anesthesia before the peak in end-tidal carbon dioxide.[52] Even if administration is delayed for hours or days, dantrolene may still improve survival after an acute episode. Patients with significant dysrhythmias can be treated with standard antidysrhythmics; however, calcium channel blockers must *not* be given with dantrolene because they may precipitate hyperkalemia and severe hypotension[86] (Table 68–3).

Persons who have experienced a possible episode of MH or have a positive family history may be considered for muscle biopsy and muscle testing. The fresh tissue specimen is placed in a tissue bath perfused with Krebs solution, and halothane or caffeine is added. According to the North America Malignant Hyperthermia Group, an MH-susceptible individual is one who demonstrates a positive muscle contraction in response to either halothane or caffeine.

■ MUSCLE SPASMS

Masseter muscle rigidity (MMR) was observed in 0.3% to 1.0% of pediatric patients when general anesthesia was induced with succinylcholine and halothane (a technique now obsolete), and, at present, it is much less frequently encountered. MMR is clinically significant because it may complicate airway management and herald the onset of MH.[77]

When administered to persons genetically predisposed to myotonia, succinylcholine may precipitate tonic muscular contractions, ranging from trismus (which may prevent orotracheal intubation) to severe generalized myoclonus and chest wall rigidity[25] (which may prevent ventilation). Because the myotonic contractions are independent of neural activity, they cannot be aborted by an NDNMB. Usually the contractions are self-limited, but occasionally they can be life-threatening if an airway cannot be established and hypoxemia ensues.

PHARMACOLOGY OF NONDEPOLARIZING NEUROMUSCULAR BLOCKERS

Table 68–1 summarizes the pharmacology and toxicity of the NDNMB drugs.[42,66,67,73] Whereas atracurium is composed of 10 different isomers, each having its unique pharmacokinetic and pharmacodynamic profile, cisatracurium contains only the 1R-*cis* and 1′R-*cis* isomers. Both

TABLE 68–3. Suggested Therapy for Malignant Hyperthermia

Acute Phase Treatment of Malignant Hyperthermia (MH)

1. **Call for help.** Immediately summon experienced help when MH is suspected.
2. **Stop triggers such as xenobiotics,** volatile inhalational anesthetics, and succinylcholine.
3. **Mildly hyperventilate with 100% O$_2$** with flows ≥10 L/min and monitor end-tidal CO$_2$.
4. **Administer dantrolene sodium.** Give the initial IV bolus of 2.5 mg/kg rapidly followed by additional boluses (every 15 min), until signs of MH are controlled (tachycardia, rigidity, increased end-tidal CO$_2$, hyperthermia). Typically, a total dose of 10 mg/kg IV controls symptoms, but occasionally 30 mg/kg may be required.
5. **Monitor core temperature closely.**
6. **Actively cool the patient** with core temperature >39°C simultaneously with the above.
   - Immersion in ice-water slurry is best. Peritoneal or gastric lavage can also be useful.
   - Surface cool with ice and hypothermia blanket.
7. **Aggressively treat hyperkalemia.** Hyperkalemia is common and should be treated with hyperventilation, sodium bicarbonate, IV calcium gluconate or chloride, IV dextrose and insulin. Those with hypokalemia should be treated with great caution because hyperkalemia may occur because of rhabdomyolysis.
8. **Sodium bicarbonate.** Consider correcting metabolic acidosis guided by arterial blood gas analysis (Not currently recommended).
9. **Monitor** arterial and mixed venous blood gases, serum potassium and calcium, clotting studies, and urine output.
10. **Dysrhythmias** usually respond to dantrolene and correction of acidosis and hyperkalemia. If dysrhythmias persist or are life threatening, standard antidysrhythmics may be used.
    - **Calcium channel blockers are not to be used (especially verapamil) to treat dysrhythmias** because they may cause hyperkalemia and cardiac arrest.
11. Ensure adequate urine output by hydration and/or administration of mannitol or furosemide. Insert a urinary bladder catheter and consider central venous or pulmonary artery catheterization.
12. **For emergency consultation, refer to the Malignant Hypertension Association of the United States** at http://www.mhaus.org/. **Call the MH Emergency Hotline:**
    - Inside United States or Canada, call **800-MH-HYPER (800-644-9737)**
    - Outside the United States and Canada, call **001 315-464-7079**

Postacute Phase Treatment of Malignant Hyperthermia

1. **Observe the patient in an ICU setting for at least 24 hours** because recrudescence of MH occurs in 25% of cases, particularly after a fulminant case resistant to treatment.
2. **Administer dantrolene 1 mg/kg IV q4–6h or 0.25 mg/kg/hr by infusion for at least 24 hours after the episode.**
3. Follow arterial blood gases, creatine phosphokinase, potassium, calcium, phosphorus, urine and serum myoglobin, PT, PTT, platelet count, and core body temperature until they return to normal values (eg, q6h). Central temperature (eg, rectal, esophageal) should be monitored continuously.
4. Counsel the patient and family regarding MH and further precautions.
    - For nonemergency patient referrals, contact MHAUS at 800-986-4287, 11 East State Street, PO Box 1069, Sherburne, NY 13460-1069.
    - Report patients who have had an acute MH episode to the **North American MH Registry of MHAUS** at **412-692-5464.**
    - Alert family members to the possible dangers of MH and anesthesia.
5. Recommend an MH medical ID tag or bracelet for the patient, which should be worn at all times.

Notes:

1. Each vial of dantrolene contains 20 mg of dantrolene and 3 g of mannitol (to improve water solubility). Each vial should be reconstituted with at least 60 mL of sterile, preservative-free water. Dissolution of the lyophilized dantrolene in water is slow and requires thorough mixing. Prewarming the water to 38°C speeds dissolution.

2. The guideline above may not apply to every patient and of necessity must be altered according to specific patient needs.

3. Sudden unexpected cardiac arrest in children: Children younger than about 10 years old who experience sudden cardiac arrest after succinylcholine administration in the absence of hypoxemia and anesthetic overdose should be treated for acute hyperkalemia first. In this situation, calcium chloride should be administered along with means to reduce serum potassium. They should be presumed to have subclinical muscular dystrophy, and a pediatric neurologist should be consulted.

ICU, intensive care unit; IV, intravenous; PT, prothrombin time; PTT, partial thromboplastin time.

atracurium and cisatracurium exhibit organ-independent elimination and are rapidly metabolized by spontaneous (nonenzymatic) temperature- and pH-dependent Hoffmann degradation and, to a lesser extent, by ester hydrolysis. The latter is catalyzed by nonspecific plasma esterases distinct from the plasma ChE that hydrolyzes succinylcholine. In addition, significant drug metabolism or elimination occurs in the liver and kidney.[27]

TOXICITY OF NONDEPOLARIZING NEUROMUSCULAR BLOCKERS

The most important toxic effects of the NDNMBs are accumulation of laudanosine and persistent weakness. In general, limiting the drug dose and monitoring the drug effect with a portable nerve stimulator reduce the incidence of prolonged weakness.

■ LAUDANOSINE

Metabolism of atracurium and cisatracurium generates laudanosine which crosses the blood–brain and placental barriers and may cause neuroexcitation but has no neuromuscular blocking activity.[22] Metabolism of each atracurium molecule generates one molecule of laudanosine.[75] Cisatracurium is an improvement over atracurium because it produces one-third as much laudanosine (and is three times more potent).[31,47]

In the CNS, laudanosine has an inhibitory effect at the γ-aminobutyric acid, nACh, and opioid receptors. At high serum concentrations in experimental animals, laudanosine causes dose-related neuroexcitation, myoclonic activity (>14 μg/mL), and generalized seizures[11,31] (>17 μg/mL). In humans, the toxic serum laudanosine concentration is unknown, and seizures directly attributable to atracurium have not been observed even after prolonged infusion in the ICU.[31,101] In ICU patients who received a 72-hour infusion of atracurium (1 mg/kg/h), the highest serum laudanosine concentrations (10–20 μg/mL) were observed in patients with renal insufficiency.[58] Laudanosine is excreted primarily in the bile, and its elimination is prolonged in patients with liver disease, biliary obstruction, and renal insufficiency.[81]

■ PERSISTENT WEAKNESS ASSOCIATED WITH NONDEPOLARIZING NEUROMUSCULAR BLOCKERS

Short-term blockade with a NDNMB usually resolves promptly upon discontinuation. When an NDNMB is administered for more than 48 hours, there is a risk that weakness will persist longer than anticipated based on the kinetics of drug elimination. In addition, critical illness is associated with dysfunction of the peripheral nerve, NMJ, and muscle (Table 68–4). For instance, in the ICU, persistent weakness is observed in 68% to 100% of patients with sepsis or multiple organ failure[16,30,96] and in 20% to 30% of patients who receive NDNMB for only 48 to 72 hours.[60] Persistent weakness is multifactorial and associated with illness severity, sepsis, acute respiratory distress syndrome, multiorgan failure, hyperglycemia, NDNMB, use of systemic glucocorticoids, muscle injury, thermal injury, and electrolyte, endocrine, and nutritional disorders.[15,20,40,59] Many xenobiotics given to patients in the ICU can cause weakness by themselves or potentiate the effects of NDNMB.[41,79] Progressive weakness and acute respiratory failure have even been described after discharge from the ICU and may be life threatening if not immediately recognized.[54] Patients who develop persistent weakness have a 2.5- to 3.5-fold increase in ICU mortality[60] and ICU stay.

TABLE 68–4. Acute Neuromuscular Pathology Associated with Critical Illness or NDNMB

	Critical Illness Polyneuropathy	Residual Neuromuscular Block	Disuse (Cachectic) Myopathy	Critical Illness Myopathy
Sensory	Moderate to severe, distal > proximal	Normal	Normal	Normal
Motor	Symmetric weakness, lower > upper extremity, proximal > distal or diffuse, respiratory failure	Diffuse symmetric weakness, respiratory failure	Diffuse weakness, proximal > distal	Symmetric weakness, proximal > distal or diffuse, respiratory failure
Creatine phosphokinase	Normal	Normal	Normal	Elevated in ≤50%
Electrodiagnostic studies (EMG, NCV)	Axonal degeneration of motor > sensory, reduced sensory and motor compound action potentials, normal NCV	Fatigue at NMJ assessed by fade on repetitive nerve stimulation	Normal EMG and NCV	Myopathic changes, muscle membrane inexcitability, normal NCV
Muscle biopsy	Denervation atrophy	Normal	Atrophy of type 2 fibers, no myosin loss, no necrosis	Atrophy of type 2 (fast-twitch) fibers, myosin loss, mild myonecrosis, no inflammatory infiltration

Duration (min)	30–60	30–60
Elimination	Renal	Renal
Crosses blood-brain barrier	No	Yes

PHARMACOLOGY OF REVERSAL DRUGS

Termination of NMB effect initially results from drug redistribution and later from drug elimination, metabolism, or chemical antagonism. Pharmacologic antagonism of a partial NDNMB is achieved by giving a reversal agent that inhibits junctional AChE and increases ACh at the NMJ. This increase in ACh can overcome the competitive inhibition caused by residual NDNMB. The commonly used anti-ChEs are polar molecules that possess a quaternary ammonium (Table 68–5). Neostigmine and pyridostigmine are hydrolyzed by ChE and form short-lived carbamyl complexes (half-life, 15–20 minutes) with the esteratic site of the enzyme.[5] In contrast, edrophonium is not hydrolyzed by ChE; rather, it forms an electrostatic interaction and a hydrogen bond with the cationic site of ChE that is both competitive and reversible. Neostigmine and pyridostigmine, but not edrophonium, inhibit plasma ChE and thus prolong the effects of drugs metabolized by this enzyme, such as succinylcholine.[28]

TOXICOLOGY OF REVERSAL AGENTS

The most common and troublesome clinical side effect of ChE inhibition is bradycardia, which usually is prevented by coadministration of an antimuscarinic drug.[13] Bradydysrhythmias may be severe and lead to nodal or idioventricular rhythm, complete heart block, or even asystole.[61] These side effects occur more frequently in patients with preexisting bradycardia and those receiving chronic β-adrenergic antagonist therapy. They are not necessarily prevented by prior administration of atropine.[91] Other problems that may result from excess ChE inhibition are hypersalivation, bronchospasm, increased bronchial secretions, abdominal cramping from intestinal hyperperistalsis, cell division, tearing, and increased bladder tone. After general anesthesia, use of AChE may increase the incidence of nausea, vomiting, and abdominal cramps.[46] Because atropine crosses the blood–brain barrier, it may produce central anticholinergic syndrome.

DIAGNOSTIC TESTING

Quantitative methods for analysis of blood and tissue NDNMB and metabolite concentrations using high-performance liquid chromatography and mass spectrometry are described.[45,89]

Succinylcholine and succinylmonocholine can be assayed by gas chromatography and mass spectrometry in blood, urine, or the site of intramuscular injection.[76,90] Less than 3% of administered succinylcholine and 10% of its metabolite succinylmonocholine are excreted in the urine. However, both the parent drug and the metabolite undergo spontaneous hydrolysis, especially in alkaline conditions.[95] Historically, detection of succinylcholine has proven difficult because of its rapid hydrolysis. However, techniques for detecting this parent compound in tissues even after embalming have been described.[34] Because succinic acid is a product of intermediary metabolism, assay of this metabolite is not useful for positive identification of prior succinylcholine exposure.[69] Surprisingly, the presence of succinylmonocholine in forensic samples also cannot prove prior exposure to succinylcholine. Succinylmonocholine in concentrations of 0.01 to 0.20 μg/g has been detected in tissues of six autopsy cases with no history of succinylcholine exposure.[56]

SUMMARY

Succinylcholine is the only DNMB in current clinical use. Its immediate adverse effects include dose- and rate-related histamine release and modulation of autonomic tone. Acute and potentially fatal hyperkalemia may occur after succinylcholine administration, particularly in patients with certain myopathies (eg, Duchenne muscular dystrophy). The effect of succinylcholine is prolonged when there is an atypical genetic variant of plasma ChE, when it is inhibited (eg, organic phosphorus compounds, or donezepil), or when it is deficient (eg, from liver disease or plasmapheresis). In MH, acute onset of severe hypermetabolism causing acidosis, rhabdomyolysis, hyperkalemia, and death occurs if treatment with dantrolene and aggressive cooling is not rapidly administered.

The most important complications associated with use of NDNMBs are undetected hypoventilation and prolonged drug effect. NDNMBs have clinically important interactions with many xenobiotics and coexisting medical conditions. In most neuromuscular diseases, sensitivity to NDNMB is increased. In renal failure, active metabolites of pancuronium and vecuronium may accumulate and cause prolonged block.

ANTIDOTES IN DEPTH (A22)

DANTROLENE SODIUM

Kenneth M. Sutin

Dantrolene produces relaxation of skeletal muscle without causing complete paralysis, and is the only xenobiotic proven to be effective for both treatment and prophylaxis of malignant hyperthermia (MH). Although dantrolene is a hydantoin derivative that is structurally similar to local anesthetics and anticonvulsants, it possesses none of their properties.[14,29] The drug is available as Dantrium® and in generic forms.

MH should be considered when hyperthermia is associated with severe hypermetabolism, increased CO_2 production, metabolic acidosis with elevated lactate, hyperkalemia, and/or rhabdomyolysis, especially when the course is fulminating and refractory to supportive therapy.

HISTORY AND EPIDEMIOLOGY

Dantrolene was first synthesized in 1967.[25] Four years later, the xenobiotic was first used clinically to treat muscular spasticity caused by neurological disorders.[4] The ability of dantrolene to reverse MH was first reported in swine in 1975[8] and in humans in 1982.[13] The delay from dantrolene discovery to clinical use was in part because of the difficulty encountered in formulating a parenteral (water-soluble) solution of the lipid-soluble drug.

PHARMACOKINETICS

Dantrolene is highly lipophilic and relatively insoluble in water. Dantrolene exhibits variable absorption by the small intestine. Oral bioavailability is up to 70% and peak blood concentrations are achieved 3 to 6 hours after ingestion.[14] In plasma, dantrolene is reversibly bound to plasma proteins, especially albumin. Most of the drug is eliminated by the liver; however, dantrolene is first metabolized in the liver by 5-hydroxylation of the hydantoin ring or by reduction of the nitro group to an amine.[29] Up to 20% of administered dantrolene is excreted in the urine as the 5-hydroxydantrolene metabolite, which is half as potent as the parent drug.[29] In adults, elimination half-life is 6 to 9 hours for dantrolene and 15.5 hours for the 5-hydroxydantrolene metabolite.[29] In one study of children aged 2 to 7 years, the dantrolene elimination half-life was 10 hours and that for 5-hydroxydantrolene was 9 hours.[16]

Quantitative analysis of dantrolene and its metabolites has been performed using high-performance liquid chromatography.[15] After a 2.4 mg/kg intravenous (IV) dose, the mean serum dantrolene concentration is 4.2 μg/mL,[6] which results in a 75% reduction in skeletal muscle with contraction.[6] The therapeutic serum concentration in humans is estimated at 2.8 to 4.2 μg/mL.[6]

MECHANISM

At therapeutic concentrations, dantrolene inhibits binding of [³H] ryanodine to the ryanodine receptor type 1 (RYR-1).[7] [³H]Dantrolene and [³H]ryanodine appear to bind to the same sites on sarcoplasmic reticulum membrane fractions.[20] Dantrolene acts primarily at skeletal muscle RYR-1, causing a dose-dependent inhibition of both the steady and peak components of sarcoplasmic calcium release.[26] This reduces the free myoplasmic calcium, thereby directly inhibiting excitation–contraction coupling.[17] Dantrolene causes skeletal muscle weakness but not complete paralysis, and this plateau effect may be related to its low water solubility. This plateau effect occurs at approximately a 75% reduction of skeletal muscle twitch contraction.[6] Dantrolene does not change the electrical properties or excitation of nerve, neuromuscular junction (NMJ), or muscle, and it does not alter sarcoplasmic calcium reuptake. Because dantrolene does not bind to the cardiac ryanodine receptor (RYR-2), it has minimal cardiac effects[7,28,32] and no effect on smooth muscle.

INDICATIONS

Dantrolene is indicated for treatment of skeletal muscle hypermetabolism characteristic of MH and following an acute episode of MH to prevent recrudescence. Long-term oral dantrolene therapy is used rarely to treat chronic spasticity.[12] Historically, dantrolene was used prophylactically in MH-susceptible individuals; however, current practice is simply to avoid exposure to MH triggers during anesthesia in this patient population.

Dantrolene should be considered for patients who present with severe hyperthermia when the diagnosis of MH cannot be excluded with certainty, especially when there is coexisting respiratory or metabolic acidosis, coagulopathy, or rhabdomyolysis.[5] In typical fulminant MH, the diagnosis is not subtle, and the course of treatment is obvious once the diagnosis is considered. Atypical clinical presentations of MH in the presence or absence of triggering anesthetics are reported, especially in MH susceptible individuals.

Dantrolene has been used to treat acute hyperthermia other than that caused by MH, including neuroleptic malignant syndrome,[21] heat stroke,[1] serotonin syndrome,[9] monoamine oxidase inhibitor overdose,[10] methylenedioxymethamphetamine ("ecstasy") overdose,[18,23] intrathecal baclofen withdrawal,[11] and thyroid storm.[3] Given the lack of evidence-based support, dantrolene therapy is not recommended for indications other than MH. However, given that (1) the differential diagnosis of a hyperthermic syndrome does not necessarily exclude (and often includes) that of MH, (2) the definitive diagnosis of a hyperthermic syndrome may be subtle or delayed, and (3) MH may occur simultaneously with another hyperthermic syndrome,[19] consideration should be given to dantrolene therapy when MH cannot be specifically excluded since its use may be life-saving. It bears emphasizing that dantrolene given for hyperthermia is not a substitute for aggressive cooling.

DOSING

Dantrolene is supplied as a sterile lyophilized powder in a 70-mL vial that contains 20 mg dantrolene sodium, 3 g mannitol (to maintain tonicity), and sodium hydroxide (to maintain alkalinity). The dantrolene powder must be reconstituted in preservative-free sterile water for injection (and not NaCl or dextrose-containing solutions) as this hastens dissolution and prevents precipitation. Prewarming

the sterile water to less than or equal to 38°C may decrease the time to dissolve the powder. After addition of 60 mL sterile water, the dantrolene bottles are shaken until the solution becomes clear (indicating the powder is fully dissolved). The final solution is isotonic and has a pH of approximately 9.5. The alkalinity of the reconstituted solution can corrode glass and thus must not be transferred into a glass bottle.

The initial dose of dantrolene for treatment of acute MH is an IV bolus of 2.5 mg/kg in adults and children.[16] For a typical adult, 10 bottles of dantrolene may need to be reconstituted for the initial dose. The pharmacokinetics of dantrolene in obese patients are not determined.[6] Redosing of 2 to 3 mg/kg IV is repeated every 15 minutes until the signs of hypermetabolism are reversed or until a total dose of approximately 10 mg/kg has been administered. Occasionally, however, doses in excess of 10 mg/kg are required. The key point is that the total dose of dantrolene is determined by titration to a metabolic end point—resolution of skeletal muscle hypermetabolism. When an effective dose of dantrolene is given, signs of muscle hypermetabolism generally begin to resolve within 30 minutes.[13]

Following the initial treatment, it is recommended that dantrolene therapy be continued 1 mg/kg IV every 4 to 6 hours for at least for 24 hours to prevent recrudescence.

SIDE EFFECTS AND TOXICITY

The alkaline pH of the reconstituted dantrolene causes venous irritation (pain) and thrombophlebitis. Unintended extravasation can cause tissue necrosis, highlighting that dantrolene should only be given through a central vein or a large peripheral vein. There is no evidence to suggest allergic cross-reactivity with dantrolene in patients with prior phenytoin allergy.

Dantrolene and verapamil should not be used in combination because of the risk of hyperkalemia and hypotension; however, the mechanistic details of this drug interaction remain unclear.[14,22,24] Intravenous calcium salts are safe to administer with dantrolene if needed, such as for the treatment of cardiac dysrhythmias or hyperkalemia (during an episode of MH).

When given to healthy persons or for MH prophylaxis or treatment, dantrolene causes dizziness, skeletal muscle weakness (but not paralysis), and diaphragm weakness (dyspnea).[30,31] In healthy volunteers, dantrolene 2.5 mg/kg does not reduce respiratory rate, vital capacity, or peak expiratory flow rate.[6] However, in patients with diminished respiratory reserve (e.g., end-stage pulmonary disease or neuromuscular disease), dantrolene may precipitate respiratory failure.[14] Oral dantrolene may cause gastrointestinal upset, nausea, and vomiting. Other reported side effects include light-headedness, ptosis, difficulty focusing, and difficulty swallowing.[6,31]

When dantrolene is given orally for more than 2 months to treat skeletal muscle spasticity, there is a 1.8% risk of dose- and duration-related chronic hepatitis, including elevated aminotransferase concentrations, hyperbilirubinemia, or jaundice[27] that may not be fully reversible after dantrolene is discontinued.[2]

G.
PSYCHOTROPIC MEDICATIONS

CHAPTER 69
ANTIPSYCHOTICS

David N. Juurlink

Most antipsychotics produce toxicity by one of two mechanisms—dose related and idiosyncratic. Overdose, whether intentional or unintentional, causes dose-related toxicity, which reflects an extension of the pharmacologic effects of the drug on neurotransmitter systems and other biologic processes. Such features of antipsychotic overdose are therefore generally predictable. Idiosyncratic adverse reactions may also occur in the context of routine therapeutic use resulting from individual susceptibility, which usually is pharmacogenetic in nature and only partially correlated with dose. In both instances, the severity of illness may range from minor to life threatening, depending on a number of other factors, including concomitant drug exposures, comorbidity, and access to medical care.

HISTORY AND EPIDEMIOLOGY

Before the introduction of chlorpromazine in 1950, patients with schizophrenia were treated with nonspecific sedatives such as barbiturates. Highly agitated patients were housed in large mental institutions and often placed in physical restraints. By 1955, approximately 500,000 patients with psychotic disorders were hospitalized in the United States. The advent of antipsychotics in the 1950s revolutionized care. Originally termed *major tranquilizers* and subsequently *neuroleptics*, these drugs dramatically reduced the hallucinations, delusions, and paranoia, which are "positive" symptoms that characterize schizophrenia.

Shortly after their introduction, however, it became apparent that the xenobiotics had potential danger in an overdose and were also associated with serious adverse effects, principally involving the endocrine and nervous systems, even when properly prescribed. Neurological sequelae included the extrapyramidal syndromes (EPS), a constellation of disorders that were relatively common, sometimes irreversible, and occasionally life threatening.

The search for antipsychotics led to the development of new types of xenobiotics from several different chemical classes characterized by varying potencies and markedly different adverse effect profiles. One novel antipsychotic, clozapine, was first synthesized in 1959 but did not enter widespread clinical use until the early 1970s. Clozapine was unique in that it was not only relatively free of EPS, but it was also an extremely effective antipsychotic even in patients who had not responded well to other drugs. Moreover, unlike other antipsychotics available at the time, it often improved the "negative" symptoms of schizophrenia, such as avolition, alogia, and social withdrawal, symptoms that are not as readily apparent as the positive symptoms but that also cause significant disability. Reports of agranulocytosis, sometimes fatal, led to the withdrawal of clozapine from the market in 1974, although it was reintroduced in 1990.[9] The unique therapeutic and pharmacologic properties of clozapine make it an *atypical* antipsychotic, the forerunner and prototype of more than a dozen compounds that have collectively become the most widely used antipsychotics over the past decade.

Unfortunately, the true incidence of antipsychotic drug reactions is not known with certainty with some patients not seeking medical attention, and others may be misdiagnosed. Even among those who seek medical attention and are correctly diagnosed, notification of poison centers or other adverse event reporting systems is discretionary and incomplete (see Chaps. 135 and 139). With these limitations in mind, a few observations can be made.

In 2007, antipsychotic exposures were reported in combination with sedative–hypnotics, but these collectively represented 154,602 exposures annually. This group of xenobiotics was associated with more fatalities than any other ($n = 377$ deaths), and most antipsychotic exposures involved the atypical antipsychotics.[16] The vast majority of poison center calls for antipsychotics involve intentional overdoses in patients ages 19 years and older. Although most of these patients have a good outcome, dozens of fatalities were reported in 2007, and the majority of these occurred in patients with concomitant xenobiotic exposures (see Chap. 135). A substantial body of clinical experience and some observational data suggest that the older low-potency, typical antipsychotics, such as thioridazine, chlorpromazine, and mesoridazine, are associated with greater toxicity than other antipsychotics.[17,19] Inferences regarding relative toxicity derived from aggregated population data should be extrapolated to individual patients with caution,[17,39] but at least one study supports the notion that thioridazine is associated with greater cardiovascular toxicity than other antipsychotics.[19]

PHARMACOLOGY

■ CLASSIFICATION

Antipsychotics can be classified according to their chemical structure, their receptor binding profiles, or as "typical" or "atypical" antipsychotics. Table 69–1 outlines the taxonomy of some commonly used antipsychotics. Classification by chemical structure was most useful before the 1970s, when phenothiazines and butyrophenones constituted most of the antipsychotics in clinical use. Currently, the surfeit of different compounds and their structural heterogeneity renders this scheme cumbersome and of limited use to clinicians. It is worth noting, however, that the phenothiazine antipsychotics bear a high degree of structural similarity to the tricyclic antidepressants (TCAs) (Fig. 69–1) and share many of their manifestations in overdose. The phenothiazines can be further subclassified according to the substituent on the nitrogen atom at position 10 of the center ring as aliphatic, piperazine, or piperidine compounds.

TABLE 69–1. Classification of Commonly Used Antipsychotics

Classification	Compound	Usual Daily Adult Dose (mg)	Volume of Distribution (L/kg)	Half-Life (Range, h)	Protein Binding (%)	Active Metabolite
Typical Antipsychotics						
Butyrophenones	Droperidol	1.25–30	2–3	2–10	85–90	N
	Haloperidol	1–20	18–30	14–41	90	Y
Diphenylbutylpiperidines	Pimozide	1–20	11–62	28–214	99	Y
Phenothiazines						
Aliphatic	Chlorpromazine	100–800	10–35	18–30	98	Y
	Methotrimeprazine	2–50	23–42	17–78	NR	Y
	Promazine	50–1000	30–40	8–12	98	N
	Promethazine	25–150	9–25	9–16	93	Y
Piperazine	Fluphenazine	0.5–20	220	13–58[b]	99	NR
	Perphenazine	8–64	10–35	8–12	>90	NR
	Prochlorperazine	10–150	13–32	17–27	>90	NR
	Trifluoperazine	4–50	NR	7–18	>90	Y
Piperidine	Mesoridazine	100–400	3–6	2–9	98	Y
	Thioridazine	200–800	18	26–36	96	Y
	Pipotiazine	25–250 (monthly IM depot)	7.5	3–11	NR	N
Thioxanthenes	Chlorprothixene	30–300	11–23	8–12	NR	NR
	Flupenthixol	3–6	7–8	7–36	NR	NR
	Thiothixene	5–30	NR	12–36	>90	NR
	Zuclopenthixol	20–100	10	20	NR	NR
Atypical Antipsychotics						
Benzamides	Amisulpride	50–1200	5.8	12	16	N
	Raclopride	3–6	1.5	12–24	NR	N
	Remoxipride	150–600	0.7	3–7	80	Y
	Sulpride	200–1200	0.6–2.7	4–11	14–40	N
Benzepines						
Dibenzodiazepine	Clozapine	50–900	15-30	6–17	95	Y
Dibenzooxazepine	Loxapine[a]	20–250	NR	2–8	90–99	Y
Thienobenzodiazepine	Olanzapine	5–20	10–20	21–54	93	N
Dibenzothiazepine	Quetiapine	150–750	10	3–9	83	N
Indoles						
Benzisoxazole	Risperidone	2–16	0.7–2.1	3–20	90	Y
Imidazolidinone	Sertindole	12–24	20–40	24–200	99	Y
Benzisothiazole	Ziprasidone	40–160	2	4–10	99	N
Quinolinones	Aripiprazole	10–30	5	47–68	99	Y

[a]Loxapine's atypical profile is lost at doses >50 mg/d; hence it is sometimes categorized as a typical antipsychotic.

[b]For hydrochloride salt; enanthate and decanoate have ranges of 3–4 days and 5–12 days, respectively.

IM, intramuscular; NR, not reported.

FIGURE 69–1. Structural similarity between phenothiazines and cyclic antidepressants.

Of greater clinical utility is the classification of antipsychotics according to their binding affinities for various receptors (Table 69–2). However, by far, the most widely used classification system categorizes antipsychotics as either *typical* or *atypical*. Typical, *traditional* or *conventional* antipsychotics dominated the first 40 years of antipsychotic therapy. They were subcategorized according to their affinity for the D_2 receptor as either low potency exemplified by thioridazine and chlorpromazine or high potency exemplified by haloperidol. These xenobiotics ameliorated the "positive symptoms" of schizophrenia, such as hallucinations, delusions, paranoia, and disorganization of thought, but they were of little benefit for the also disabling "negative symptoms" of schizophrenia, which are avolition, alogia, flattening of affect, and social withdrawal. Moreover, they were associated with acute, subacute, and long-term motor disturbances collectively referred to as EPS.

The notion of antipsychotic atypicality has evolved over time with the introduction of new xenobiotics[83,102] and connotes different properties to pharmacologists and clinicians. From a clinical perspective, atypical antipsychotics or *second-generation antipsychotics* treat both the positive and negative symptoms of schizophrenia, are less likely than traditional antipsychotics to produce EPS at clinically effective doses, and cause little or no elevation of serum prolactin concentration.[53] From a pharmacologic perspective, most atypical antipsychotics also inhibit the action of serotonin at the $5\text{-}HT_{2A}$ receptor. More than a

TABLE 69–2. Toxic Manifestations of Selected Antipsychotics

dozen atypical antipsychotics are now in clinical use or under development. Despite their considerably higher cost, these drugs have largely supplanted traditional antipsychotics because of their effectiveness in treating the negative symptoms of schizophrenia and their more favorable adverse effect profile, in addition to the perception that they cause fewer long-term adverse effects than conventional antipsychotics, a belief that may result, in part, from the use of higher doses of older drugs in studies comparing the tolerability of typical and atypical antipsychotics.[45] It is worth noting that the use of antipsychotics for unapproved (off-label) indications is extremely common, particularly as adjunctive therapies for the management of agitation association with cognitive impairment in the elderly.

■ ANTIPSYCHOTIC MECHANISMS OF ACTION

Of the many contemporary theories of schizophrenia, the most enduring has been the *dopamine hypothesis.*[96] First advanced in 1967 and supported by in vivo data,[1] this theory holds that the "positive symptoms" of schizophrenia (hallucinations, delusions, paranoia, and disorganization of thought) result from excessive dopaminergic signaling in the mesolimbic and mesocortical pathways.[66] This hypothesis resulted in part from the observation that hallucinations and delusions could be produced in otherwise normal individuals by drugs that increase dopaminergic transmission, such as cocaine and amphetamine, and that these effects could be blunted by dopamine antagonists.

There are five subtypes of dopamine receptors (D_1 through D_5), but schizophrenia principally involves excess signaling at the D_2 subtype,[96] and antagonism of D_2 neurotransmission is the *sine qua non* of antipsychotic activity. Antipsychotics have different potencies at this receptor, reflected by the dissociation constant (K_d), which in turn reflects release from the D_2 receptor. For example, the receptor releases clozapine and quetiapine more rapidly than it does any other drugs.[94,96]

Dopamine receptors are present in many other areas of the central nervous system (CNS), including the nigrostriatal pathway (substantia nigra, caudate, and putamen, which collectively govern the coordination of voluntary movement); tuberoinfundibular pathway; hypothalamus and pituitary; and area postrema of the brainstem, which contains the chemoreceptor trigger zone (CTZ). Antipsychotic-related blockade of D_2 neurotransmission in these areas is associated with many of the beneficial and adverse effects of these xenobiotics. For example, whereas D_2 antagonism in the CTZ alleviates nausea and vomiting, blockade of hypothalamic D_2 receptors increases prolactin release by the pituitary, resulting in breast tenderness and galactorrhea. Blockade of nigrostriatal D_2 receptors underlies many of the movement disorders associated with antipsychotic therapy.[107,119]

Antipsychotics also interfere with signaling at other receptors, including acetylcholine M_1 and M_2 muscarinic receptors, H_1 histamine receptors, and α-adrenergic receptors. The extent to which these other receptors are blocked at doses that effectively block D_2 transmission varies among antipsychotics but can be used to predict the adverse effect profile of each drug.[21] For example, drugs that antagonize muscarinic receptors at clinically effective doses (primarily the aliphatic and piperidine phenothiazines along with clozapine, loxapine, olanzapine, and quetiapine) often cause bothersome anticholinergic effects with routine use and may produce pronounced anticholinergic manifestations after overdose (see Table 69–2). Similarly, blockade of peripheral α₁-adrenergic receptors by the aliphatic and piperidine phenothiazines, clozapine, risperidone, and several other drugs renders them more likely to cause postural hypotension during therapy and supine hypotension after overdose.

Several antipsychotics also block voltage-gated fast sodium channels (I_{Na}). Although this effect is of little consequence during therapy,

in the setting of overdose, this sodium channel blockade may slow cardiac conduction (phase 0 depolarization) and impair myocardial contractility. This effect, most notable with the phenothiazines, is both rate and voltage dependent and therefore is more pronounced at faster heart rates and less negative transmembrane potentials.[18] Blockade of the delayed rectifier potassium current (I_{Kr}) may produce prolongation of the QT interval, increasing the likelihood of developing torsade de pointes.[70] QT prolongation is sometimes evident during maintenance therapy, particularly in patients with previously unrecognized repolarization abnormalities or additional risk factors for QT prolongation. This effect is thought to contribute to dose-dependent increase in risk of sudden cardiac death among patients treated with typical and atypical antipsychotics.[81,82]

Several antipsychotics exhibit a relatively high degree of antagonism at the 5-HT_{2A} receptor, which conveys two important therapeutic properties: (1) greater effectiveness in treating of the negative symptoms of schizophrenia and (2) a significantly lower incidence of EPS. Several antipsychotics are also distinguished by unique effects at other receptors. For example, loxapine and clozapine interfere with reuptake of catecholamines and antagonize γ-aminobutyric acid $(GABA)_A$ receptors,[101] which may explain the apparent increase in seizures reported with these agents.[78]

Clozapine binds to dopamine receptors (D_1–D_5) and serotonin receptors ($5\text{-HT}_{1A/1C}$, $5\text{-HT}_{2A/2C}$, 5-HT_3, and 5-HT_6) with moderate to high affinity.[9,79,87] It also antagonizes α₁-adrenergic, α₂-adrenergic, and H_1 histamine receptors and has the highest binding affinity of any atypical antipsychotic at M_1 muscarinic receptors.[86] Despite this feature, clozapine paradoxically activates the M_4 genetic subtype of the muscarinic receptor and frequently produces sialorrhea during therapy.[85]

Olanzapine, binds avidly to serotonin ($5\text{-HT}_{2A/2C}$, 5-HT_3, and 5-HT_6) and dopamine receptors (D_1, D_2, and D_4), although its potency at D_2 receptors is lower than that of most traditional antipsychotics.[56,87] It is an exceptionally potent H_1 antagonist, binding more avidly than pyrilamine (see Chap. 50), which is a widely used antihistamine. It also has a high affinity for M_1 receptors and is a relatively weak α₁ antagonist.

Risperidone has high affinity for several receptors, including serotonin receptors ($5\text{-HT}_{2A/2C}$), D_2 dopamine receptors, and α₁ and H_1 receptors.[56,85,87] It has no appreciable activity at M_1 receptors. Its primary metabolite (9-hydroxyrisperidone) is nearly equipotent compared with the parent compound at D_2 and 5-HT_{2A} receptors.[56]

Quetiapine is a weak antagonist at D_2, M_1, and 5-HT_{1A} receptors, but it is a relatively potent antagonist of α₁-adrenergic and H_1 receptors.[56] Of its 11 different metabolites, at least two are pharmacologically active. However, they circulate at very low concentrations and likely contribute little to the clinical effect of the drug. A considerable proportion of fatalities involving antipsychotics reported to North American poison control centers involve quetiapine, usually in combination with other drugs (see Chap. 135).

Ziprasidone is a potent antagonist at dopaminergic D_2 and several serotonin ($5\text{-HT}_{2A/2C}$, 5-HT_{1D}, and 5-HT_7) receptors, but it also displays agonist activity at 5-HT_{1A} receptors.[56,57,87] Its α₁ antagonist activity is particularly strong, with a binding affinity approximately one-tenth that of prazosin. In addition, it exhibits considerable inhibition of the cardiac delayed rectifier channel and may significantly prolong repolarization.[57,64]

Aripiprazole is a novel compound that binds avidly to dopamine D_2 and D_3 receptors and serotonin 5-HT_{1A}, 5-HT_{2A}, and 5-HT_{2B} receptors.[69,87] Some evidence suggests that its efficacy in the treatment of schizophrenia and its lower propensity for EPS may reflect partial agonist activity at dopamine D_2 receptors. Aripiprazole also acts as a partial agonist at serotonin 5-HT_{1A} receptors but is an antagonist at serotonin 5-HT_{2A} receptors. Its principal active metabolite, dehydroaripiprazole,

has affinity for dopamine D_2 receptors and thus has some pharmacologic activity similar to that of the parent compound.[69]

Similar to aripiprazole, bifeprunox is a partial agonist at D_2 and $5-HT_{1A}$ receptors. It has been characterized as a third-generation antipsychotic and has no appreciable affinity for serotonin $5-HT_{2A}$ and $5-HT_{2C}$, histaminergic, or muscarinic receptors.[28,72,95] Clinical experience with this drug is limited.

Amisulpride an investigational drug preferentially binds to dopamine receptors in limbic rather than striatal structures. At low doses, it blocks presynaptic D_2 and D_3 receptors, thereby accentuating dopamine release, but at high doses, it blocks postsynaptic D_2 and D_3 receptors. It has relatively low affinity for serotonergic, histaminergic, adrenergic, and cholinergic receptors.

Sertindole is a second-generation antipsychotic that was recently reintroduced into the market after being voluntarily withdrawn in 1998 because of concerns about its effects on the QT interval. It binds to striatal D_2 receptors, although less avidly than olanzapine, and also exhibits antagonism at $5-HT_{2A}$ and α-adrenergic receptors.[55,76,100]

PHARMACOKINETICS AND TOXICOKINETICS

With a few exceptions, the antipsychotics have similar pharmacokinetic characteristics regardless of their chemical classification. Most are lipophilic, have a large volume of distribution, and are generally well absorbed, although anticholinergic effects may delay absorption of some antipsychotics. Serum concentrations generally peak within 2 to 3 hours after a therapeutic dose, but this can be prolonged after overdose.

Most antipsychotics are substrates for various isoenzymes of the hepatic cytochrome P450 (CYP) enzyme system. For example, haloperidol, perphenazine, thioridazine, sertindole, and risperidone are extensively metabolized by the CYP2D6 system, which is functionally absent in approximately 7% of white patients and overexpressed in 1–25% of other patients, depending on their ethnicity.[53] These polymorphisms appear to influence the tolerability and efficacy of treatment with these antipsychotics during therapeutic use[15,29,30,52,112] but are unlikely to significantly alter the severity of acute antipsychotic overdose.

Drugs that inhibit CYP2D6 (eg, paroxetine, fluoxetine, bupropion) may increase the concentrations of these antipsychotics and increase the risk of adverse effects. In contrast, metabolism of clozapine is primarily mediated by CYP1A2, and increased clozapine concentrations may result after exposure to CYP1A2 inhibitors, such as fluvoxamine macrolide and fluoroquinolone antibiotics, as well as after smoking cessation because smoking induces CYP1A2.[34] The kidney plays a relatively small role in the elimination of antipsychotics, and dose adjustment is generally not necessary for patients with renal disease.

PATHOPHYSIOLOGY AND CLINICAL MANIFESTATIONS

Table 69–3 lists the adverse effects of antipsychotics. Some of these effects develop primarily after overdose, but others may occur during the course of therapeutic use.

■ ADVERSE EFFECTS DURING THERAPEUTIC USE

The Extrapyramidal Syndromes The EPS (Table 69–4) are a heterogeneous group of disorders that share the common feature of abnormal muscular activity. Among the typical antipsychotics, the incidence of EPS appears to be highest with the more potent drugs, such as haloperidol and flupentixol, and lower with less potent drugs, such as chlorpromazine and thioridazine. Atypical antipsychotics are associated with an even

TABLE 69–3. Adverse Effects of Antipsychotics	
Cardiovascular	
Clinical	Tachycardia
	Hypotension (orthostatic or resting)
	Myocardial depression
Electrocardiographic	QRS complex widening
	Right deviation of terminal 40 msec of frontal plane axis
	QT interval prolongation
	Torsades de pointes
	Nonspecific repolarization changes
Central nervous system	Somnolence, coma
	Respiratory depression
	Hyperthermia
	Seizures
	Extrapyramidal syndromes
	Central anticholinergic syndrome
Dermatologic	Impaired sweat production
	Cutaneous vasodilation
Endocrine	Amenorrhea, oligomenorrhea, or metrorrhagia
	Breast tenderness, galactorrhea
Gastrointestinal	Impaired peristalsis
	Dry mouth
Genitourinary	Urinary retention
	Ejaculatory dysfunction
	Priapism
Ophthalmic	Mydriasis or miosis, visual blurring

lower incidence of EPS. Although the physiologic mechanisms for this observation are not fully understood, several hypotheses have been put forth. In addition to the aforementioned antagonism of $5-HT_{2A}$ receptors, some atypical drugs dissociate more rapidly from the D_2 receptor and incite a lower degree of nigrostriatal dopaminergic hypersensitivity during chronic use.[53,54,65] However, it is important to note that EPS may occur during treatment with any of the antipsychotics, typical or atypical, regardless of potency.

Acute Dystonia. Acute dystonia is a movement disorder characterized by sustained involuntary muscle contractions, often involving the muscles of the head and neck, including the extraocular muscles and the tongue but occasionally involving the extremities. These contractions are sometimes referred to as *limited reactions*, reflecting their transient nature rather than their severity. All of the currently available antipsychotics are associated with the development of acute dystonic reactions.[107] Spasmodic torticollis, facial grimacing, protrusion of the tongue, and oculogyric crisis are among the more common manifestations. Laryngeal dystonia is a rare but potentially life-threatening variant that is easily misdiagnosed because it may present with throat pain, dyspnea, stridor, and dysphonia rather than the more characteristic features of dystonia.[37]

Acute dystonia typically develops within a few hours of starting treatment but may be delayed for several days. Left untreated, dystonia resolves slowly over several days after the offending xenobiotic is

TABLE 69–4. The Extrapyramidal Syndromes

Disorder	Time of Maximal Risk	Features	Postulated Mechanism	Possible Treatments
Acute dystonia	Hours to a few days	Sustained, involuntary muscle contraction; torticollis, lingual protrusion, blepharospasm, oculogyric crisis	Imbalance of dopaminergic/cholinergic transmission	Anticholinergics, benzodiazepines
Akathisia	Hours to days	Restlessness and unease, inability to sit still	Mesocortical D_2 antagonism	Dose reduction, trial of alternate drug, propranolol, benzodiazepines, anticholinergics
Parkinsonism	Weeks	Bradykinesia, rigidity, shuffling gait, masklike facies, resting tremor	Postsynaptic striatal D_2 antagonism	Dose reduction, anticholinergics, dopamine agonists
Neuroleptic malignant syndrome	2–10 days	Altered mental status, motor symptoms, hyperthermia, autonomic instability (see Table 69-5)	D_2 antagonism in striatum, hypothalamus, and mesocortex	Cooling, benzodiazepines, supportive care, consider dantrolene, bromocriptine, or other direct-acting dopamine agonists
Tardive dyskinesia	3 months–years	Late-onset involuntary choreiform movements, orobuccal, lingual, masticatory stereotypic movements	Excess dopaminergic activity	Recognize early and stop offending drug; addition of other antipsychotics; cholinergics

Data adapted from Pierre JM. Extrapyramidal symptoms with atypical antipsychotics: incidence, prevention and management. *Drug Saf.* 2005;28:191-208 and van Harten PN, Hoek HW, Kahn RS. Acute dystonia induced by drug treatment. *Br Med J.* 1999;319:623-626.

withdrawn. Risk factors for acute dystonia include male gender, young age (children are particularly susceptible), a previous episode of acute dystonia, and recent cocaine use.[108,119] Although the reaction may appear dramatic and sometimes is mistaken for seizure activity, it is rarely life threatening. Of note, xenobiotics other than antipsychotics, particularly metoclopramide, the antidepressants, some antimalarials, histamine H_2 receptor antagonists, anticonvulsants, and cocaine, may sometimes cause acute dystonia.[108]

Treatment of Acute Dystonia. Acute dystonia is generally more distressing than serious, but in rare cases, it may compromise respiration, necessitating supplemental oxygen and, occasionally, assisted ventilation.[37,108] The response to parenteral anticholinergics often is rapid and dramatic, and every effort should be made to administer benztropine as the first-line agent (2 mg intravenously [IV] or intramuscularly [IM] in adults; 0.05 mg/kg up to 2.0 mg in children). Often, diphenhydramine is more readily available and can be used instead (50 mg IV or IM in adults; 1 mg/kg up to 50 mg in children). Parenteral benzodiazepines such as lorazepam (0.05–0.10 mg/kg IV or IM) or diazepam (0.1 mg/kg IV) should be considered if patients do not respond to anticholinergics, but it may also be used effectively as initial therapy. It is important to recognize that because the elimination half-lives of most anticholinergics are shorter than those of most antipsychotics, dystonia may recur, and administering additional doses of anticholinergics may be necessary over the subsequent 48 to 72 hours.[27] Patients in whom acute dystonia jeopardizes respiration should be observed for at least 12 to 24 hours after initial resolution.

Akathisia. Akathisia (from the Greek phrase "not to sit") is characterized by a feeling of inner restlessness, anxiety, or sense of unease, often in conjunction with the objective finding of an inability to sit still. Patients with akathisia frequently appear uncomfortable or fidgety. They may rock back and forth while standing or may repeatedly cross and uncross their legs while seated. Akathisia can be difficult to diagnose and is easily misinterpreted as a manifestation of the underlying psychiatric disorder rather than an adverse effect of therapy.

Akathisia is common and may be an important determinant of a failure to adhere to therapy. Similar to acute dystonia, akathisia tends to occur relatively early in the course of treatment and coincides with peak serum antipsychotic concentrations.[119] The incidence appears highest with typical, high-potency antipsychotics and lowest with atypical antipsychotics. Although most cases develop within days to weeks after initiation of treatment or an increase in dose, a delayed-onset (tardive) variant is also recognized.

The pathophysiology of akathisia is incompletely understood but appears to involve antagonism of postsynaptic D_2 receptors in the mesocortical pathways.[65,107] Interestingly, a similar phenomenon has been described in patients after the initiation of treatment with antidepressants, particularly the selective serotonin reuptake inhibitors.[8,62]

Treatment of Akathisia. Akathisia may be difficult to treat. A reduction in the antipsychotic dose is sometimes helpful, as is substitution of another (generally atypical) antipsychotic. Treatment with lipophilic β-adrenergic antagonists such as propranolol may reduce the symptoms of akathisia, but there is little evidence supporting their use.[60,77] Benzodiazepines produce short-term relief, and anticholinergics such as benztropine or procyclidine may reduce symptoms of akathisia, but they are more likely to be effective for akathisia induced by antipsychotics with little or no intrinsic anticholinergic activity.[20,61]

Parkinsonism. Parkinsonism is thought to result from antagonism of postsynaptic D_2 receptors in the striatum[107] and is characterized by rigidity, akinesia or bradykinesia, and postural instability. It is similar to idiopathic Parkinson's disease, although the classic "pill-rolling" tremor is often less pronounced.[77] The syndrome typically develops during the first few months of therapy, particularly with high-potency antipsychotics. It is more common among older women, and in some patients, it may represent iatrogenic unmasking of latent Parkinson's disease.

Treatment of Xenobiotic-Induced Parkinsonism. The risk of xenobiotic-induced parkinsonism may be minimized by using the lowest effective

dose of an antipsychotic. The addition of an anticholinergic often attenuates symptoms at the expense of additional side effects. This strategy often is effective in younger patients, although the routine use of prophylactic anticholinergics is not recommended. Addition of a dopamine agonist, such as amantadine, is sometimes used, particularly in older patients who may be less tolerant of anticholinergics, but this may aggravate the underlying psychiatric disturbance.[63]

Tardive Dyskinesias. The term *tardive dyskinesia* was coined in 1952 to describe the delayed onset of persistent orobuccal masticatory movements occurring in three women after several months of antipsychotic therapy.[107] The adjective *tardive*, or late, was used to distinguish these movement disorders from the parkinsonian movements described above. The incidence of tardive dyskinesia in younger patients is approximately 3% to 5% per year but increases considerably with age. A prospective study of older patients treated with high-potency typical antipsychotics identified a 60% cumulative incidence of tardive dyskinesia after 3 years of treatment.[50] Potential risk factors for tardive dyskinesia include alcohol use, affective disorder, prior electroconvulsive therapy (ECT), diabetes mellitus, and various genetic factors.[107]

Several distinct tardive syndromes are recognized, including the classic orobuccal lingual masticatory stereotypy, chorea, dystonia, myoclonus, blepharospasm, and tics. The atypical antipsychotics are generally believed to be responsible for a lower incidence of tardive dyskinesia and other drug-related movement disorders. However, whether this is true of all atypical antipsychotics is unclear. Among the atypical antipsychotics, clozapine is associated with the lowest incidence of tardive dyskinesia and risperidone with the highest incidence (when higher doses are used), but the reasons for this observation are uncertain.[104,105,107]

Treatment of Tardive Dyskinesia. Tardive dyskinesia is highly resistant to the usual pharmacologic treatments for movement disorders. Anticholinergics do not alleviate tardive dyskinesia and may worsen it. Calcium channel blockers, β-adrenergic antagonists, benzodiazepines, and vitamin E have all been used with only limited supporting evidence.[35] Clozapine appears to temporarily suppress tardive dyskinesia. Although discontinuation of the causative drug may not produce total relief of symptoms, when possible, the antipsychotic should be discontinued as soon as signs or symptoms begin.

Neuroleptic Malignant Syndrome. Neuroleptic malignant syndrome (NMS) is a potentially life-threatening drug-induced emergency. First described in 1960 in patients treated with haloperidol, this syndrome has been associated with virtually every antipsychotic [31] because the reported incidence of NMS ranges from 0.2% to 1.4% of patients receiving antipsychotics,[2,23,103] but less severe episodes may go undiagnosed or unreported. As a result, much of the epidemiology and treatment of NMS is speculative and based only on case reports and case series.

The pathophysiology of NMS is incompletely understood but appears to involve abrupt reductions in central dopaminergic neurotransmission in the striatum and hypothalamus, altering the core temperature "set point"[41] and leading to impaired thermoregulation and other manifestations of autonomic dysfunction. Blockade of striatal D_2 receptors contributes to muscle rigidity and tremor.[13,25,109] In some cases, a direct effect on skeletal muscle may play a role in the pathogenesis of hyperthermia.[41] Altered mental status is multifactorial and may reflect hypothalamic and spinal dopamine receptor antagonism, a genetic predisposition, or the direct effects of hyperthermia and other drugs.[42] Serotonin also appears to play a role in the pathogenesis of NMS because antipsychotics that antagonize 5-HT$_{2A}$ receptors seem to be associated with a lower incidence of NMS.[4]

Although NMS most often occurs during treatment with a D_2 receptor antagonist, withdrawal of dopamine agonists may produce an indistinguishable syndrome. The latter typically occurs in patients with long-standing Parkinson's disease who abruptly change or discontinue treatment with dopamine agonists such as levodopa/carbidopa, amantadine, or bromocriptine.[13] The resulting disorder is sometimes referred to as the *parkinsonian-hyperpyrexia syndrome*, and mortality rates of up to 4% are reported.[71] Hospitalization for aspiration pneumonia, a common occurrence in older patients with Parkinson's disease, is a particularly high-risk setting for this complication and is particularly dangerous because the cardinal manifestations of NMS are easily misattributed to the combined effects of pneumonia and the underlying movement disorder.

The vast majority of NMS cases occur in the context of therapeutic use of antipsychotics rather than after overdose. Postulated risk factors for the development of NMS include young age, male gender, extracellular fluid volume contraction, use of high-potency antipsychotics, use of depot preparations, cotreatment with lithium, use of multiple drugs in combination, and rapid dose escalation.[2,24,58]

The manifestations of NMS include the tetrad of altered mental status, muscular rigidity or "lead pipe" rigidity, hyperthermia, and autonomic dysfunction. These symptoms may appear in any sequence, although in a review of 340 NMS cases, mental status changes and rigidity usually preceded the development hyperthermia and autonomic instability.[110] Signs typically evolve over a period of several days, with the majority occurring within 2 weeks of starting treatment. However, it is important to recognize that NMS may occur even after prolonged use of an antipsychotic, particularly after a dose increase, the addition of another xenobiotic, or the development of intercurrent illness. It is also worth noting that the clinical course of NMS may fluctuate with remarkable rapidity, sometimes waxing and waning dramatically over a few hours.

There are no universally accepted criteria for the diagnosis of NMS, and at least four different sets of criteria have been proposed.[3,23,33,58] The operating characteristics of these criteria have not been formally evaluated partly because of the absence of a gold standard. The criteria set forth by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) are perhaps the most widely cited, but their principal limitation is that they make no provision for a causal relationship with xenobiotics other than antipsychotics.[33] Because NMS is an uncommon and potentially life-threatening disorder with highly variable clinical manifestations, an algorithmic approach to diagnosis in inadvisable. Rather, clinicians should be aware of its many possible clinical and laboratory features (Table 69–5) and entertain the possibility of NMS in any unwell patient receiving an antipsychotic, particularly when altered mentation, unexplained fever, or muscle rigidity is present, particularly in the setting of recent modifications to the antipsychotic regimen.

It may be difficult to distinguish NMS from other toxin-induced hyperthermia syndromes, such as the anticholinergic (antimuscarinic) syndrome (see Chap. 50) and the serotonin syndrome (see Chap. 72), all of which share the common features of elevated temperature, altered mental status, and neuromuscular abnormalities. The most important differentiating feature is the medication history, with dopamine antagonists, antimuscarinics, and direct or indirect serotonin agonists (often in combination) as the most likely causes, respectively. Other helpful distinguishing features include the time course (NMS typically develops more gradually than serotonin syndrome and the antimuscarinic syndrome, both of which are characterized by a rapid onset) and the nature of neuromuscular abnormalities. Specifically, serotonin syndrome is characterized by myoclonus (spontaneous or inducible), shivering, and hyperreflexia, which occur rarely in patients with NMS. Because skeletal muscle contraction is governed by nicotinic rather than muscarinic acetylcholine receptors, patients with the

TABLE 69–5. Clinical and Laboratory Features of the Neuroleptic Malignant Syndrome[2,24,58,110]

Feature	Potential Manifestations
Altered mental status	Delirium, lethargy, confusion, stupor, catatonia, coma
Motor symptoms	"Lead pipe" rigidity, cogwheeling, dysarthria or mutism, parkinsonian syndrome, akinesia, tremor, dystonic posture, dysphagia, dysphonia, choreiform movements
Hyperthermia	Temperature >100.4°F (38°C)
Autonomic instability	Tachycardia, diaphoresis, sialorrhea, incontinence, respiratory irregularities, cardiac dysrhythmias, hypertension or hypotension
Laboratory findings	Increased muscle enzymes (creatine phosphokinase, lactate dehydrogenase, aldolase), leukocytosis, renal insufficiency (reflecting volume contraction and pigment nephropathy), acidemia, myoglobinuria, aminotransferase elevation, hypoxia, hyponatremia, increased prothrombin time/partial thromboplastin time

antimuscarinic syndrome have few muscular abnormalities. However, patients with prominent CNS features may be highly resistant to physical restraint, giving the appearance of increased muscle tone.

Treatment of Neuroleptic Malignant Syndrome: General Measures. Treatment recommendations are largely based on general physiologic principles, case reports, and case series. Therapy should be individualized according to the severity and duration of illness and the modifying influences of comorbidity.[13,84,111]

Good supportive care is the cornerstone of treatment of NMS. It is essential to recognize the condition as an emergency and to withdraw the offending xenobiotic immediately. When NMS ensues after abrupt discontinuation of a dopamine agonist such as levodopa, the drug should be reinstituted promptly. All patients with NMS should be admitted to an intensive care unit. Supplemental oxygen should be administered, and assisted ventilation may be necessary in cases of respiratory failure, which may result from central hypoventilation, loss of protective airway reflexes, or rigidity of the chest wall muscles.

The hyperthermia associated with NMS is multifactorial in origin and, when present, should be treated aggressively. For patients with severe hyperthermia, it is difficult to overstate the importance of normalizing body temperature. Submersion in an ice-water bath is the most rapidly efficient technique, although this may be impractical in some settings (see Chap. 15). Other strategies include the use of active cooling blankets; the placement of ice packs in the groin and axillae; or evaporative cooling, which can be accomplished by removing the patient's clothing and exposing the patient to cooled water or towels immersed in ice water while maintaining constant air circulation with the use of fans.[115]

Hypotension should be treated initially with volume resuscitation with 0.9% sodium chloride solution followed by vasopressors if necessary. Alkalinization of the urine with sodium bicarbonate may reduce the incidence of myoglobinuric renal failure in patients with high

creatine phosphokinase concentrations, but maintenance of intravascular volume and adequate renal perfusion are of far greater importance. Tachycardia does not require specific treatment, but bradycardia may necessitate the use of transcutaneous or transvenous electrical pacing. Venous thromboembolism is a major cause of morbidity and mortality in patients with NMS, and prophylactic doses of low-molecular-weight heparin should be considered in patients who likely will be immobilized for more than 12 to 24 hours.

Pharmacologic Treatment of Neuroleptic Malignant Syndrome. Benzodiazepines are the most widely used pharmacologic adjuncts for treatment of NMS and are considered first line-therapy. Despite the length of time that they have been available and recommended by many, dantrolene and bromocriptine are not well studied, and their incremental benefit over good supportive care is debated.[84,89] However, these drugs are associated with relatively little toxicity, and the absence of definitive evidence should not preclude their use, particularly in patients with moderate or severe NMS.

Benzodiazepines are frequently used in the management of patients with NMS because of their rapid onset of action, which is particularly important when patients are agitated or restless. Benzodiazepine actions are nonspecific in nature, but they presumably attenuate the sympathetic hyperactivity that characterizes NMS by facilitating GABA-mediated chloride transport and producing neuronal hyperpolarization in a fashion analogous to their beneficial effects in cocaine toxicity.[42] The primary disadvantage of benzodiazepines is that they may cloud the assessment of mental status.

Dantrolene reduces skeletal muscle activity by inhibiting ryanodine receptor calcium release channels, thereby interfering with calcium release from the sarcoplasmic reticulum. In theory, this process should reduce body temperature and total oxygen consumption and lessen the risk of myoglobinuric renal failure. Dantrolene may be particularly useful when muscular rigidity is a prominent feature of NMS.[13] It may be given by mouth (50–100 mg/d) or by IV infusion (2–3 mg/kg/d or ≤10 mg/kg/d in severe cases), although the latter requires laborious reconstitution. A recent review of 271 published cases of NMS that included information regarding drug treatment found that combination therapy including dantrolene was associated with a prolonged clinical recovery but also found that dantrolene monotherapy was associated with higher mortality rate than other treatment modalities including supportive care.[84] However, it is extremely difficult to draw meaningful conclusions regarding the effectiveness of dantrolene from this study in light of its design. Dantrolene is a relatively nontoxic drug suggested by some to be a reasonable therapeutic agent in patients with NMS, particularly those with prominent rigidity, although there is inadequate supportive evidence (see Antidote in Depth A22: Dantrolene).

Bromocriptine is a centrally acting dopamine agonist that is given orally or by nasogastric tube at doses of 2.5 to 10 mg three to four times a day. The rationale for its use rests in the belief that reversal of antipsychotic-related striatal D_2 antagonism will ameliorate the manifestations of NMS. Other dopamine agonists anecdotally associated with success include levodopa[74,99] and amantadine.[40,49,103] An important consideration with dopaminergic agents, however, is that their use may be associated with exacerbation of the underlying psychiatric illness. There is no current evidence to support their use at this time.

Electroconvulsive Therapy. ECT has been reported to dramatically improve the manifestations of NMS, presumably by enhancing central dopaminergic transmission. In one report, five patients received an average of 10 ECT treatments, and resolution generally occurred after the third or fourth session.[73] Whether this result represents a true effect of ECT or simply the natural course of NMS with good supportive care alone is not clear. As with drug therapies for NMS, the efficacy of ECT

remains unclear and its indications speculative, but its use seems reasonable in patients with severe, persistent, or treatment-resistant NMS and for those with residual catatonia or psychosis after resolution of other manifestations.[13,74]

Adverse Effects on Other Organ Systems. Sedation, dry mouth, and urinary retention occur commonly with the antipsychotics, particularly during the initial period of therapy. These symptoms occur most commonly with drugs that have potent antihistaminic and antimuscarinic activity. All antipsychotics can lower the seizure threshold, but seizures rarely complicate therapeutic use in patients without additional risk factors. Because hypothalamic dopamine normally inhibits prolactin release by the pituitary gland, hyperprolactinemia and galactorrhea may occur, although these are more common with atypical antipsychotic drugs.

All antipsychotics are associated with weight gain, dyslipidemia, steatohepatitis, and rare but dramatic instances of glucose intolerance, including fatal cases of diabetic ketoacidosis.[6,44,80,106] The mechanisms of the lipid and carbohydrate effects are incompletely understood and not adequately explained solely by the weight gain associated with antipsychotic therapy because glucose disturbances often develop shortly after therapy is instituted. Other idiosyncratic reactions reported with use of antipsychotics include photosensitivity, skin pigmentation and cholestatic hepatitis (which occur with the phenothiazines), myocarditis, and agranulocytosis (which occurs with several drugs but most notably clozapine, ie, between 0.38% and 2% of patients).[68] Most of these conditions result from an immunologically based hypersensitivity reaction and develop during the first month of therapy.

■ ACUTE OVERDOSE

Antipsychotic overdose may produce a spectrum of manifestations affecting multiple organ systems, but most serious toxicity involves the CNS and cardiovascular system. Some of these manifestations are present to a minor degree during therapeutic use. They tend to be most pronounced during the early period of therapy but dissipate with continued use.

Impaired consciousness is a common and dose-dependent feature of antipsychotic overdose, ranging from somnolence to coma. It may be associated with impaired airway reflexes, but significant respiratory depression is uncommon. Many antipsychotics, including several of the atypical drugs, are potent muscarinic antagonists and may produce dramatic anticholinergic manifestations in overdose.[11,21,26] Peripheral manifestations include tachycardia, decreased production of sweat and saliva, flushed skin, urinary retention, diminished bowel sounds, and mydriasis, although miosis also occurs. These findings may be present in isolation or coexist with central manifestations, which may be highly variable and may be mistakenly attributed to the underlying psychiatric illness. These manifestations include agitation, delirium, psychosis, hallucinations, and coma.

Mild elevations in body temperature are common and reflect impaired heat dissipation because of impaired sweating and increased heat production in agitated patients. Elevations in body temperature should always prompt a search for other manifestations of NMS. Tachycardia is a common finding in patients with antipsychotic overdose and reflects peripheral anticholinergic effects as well as a compensatory response to hypotension. Bradycardia is distinctly uncommon. Although it may be a preterminal event, its presence should prompt a search for alternate causes, including β-adrenergic antagonists, calcium channel blockers, cardioactive steroids, opioids, and myocardial ischemia. Hypotension is a common feature of antipsychotic overdose. Peripheral α_1-adrenergic blockade reduces vasomotor tone. Central maintenance of vasomotor tone may be impaired, albeit by an unknown mechanism.

The electrocardiographic (ECG) manifestations of antipsychotic overdose are similar to those of CA toxicity (see Chaps. 22 and 73) and include prolongation of the QRS complex and a rightward deflection of the terminal 40 msec of the QRS complex (T_{40}msec, a tall, broad terminal component of the QRS complex in lead aVR). These changes reflect blockade of the inward sodium current (I_{Na}). Prolongation of the QT interval results from blockade of the delayed rectifier potassium current (I_{Kr}), creating a substrate for development of torsades de pointes.[70] This situation is sometimes evident during maintenance therapy and may underlie the apparent increase in sudden cardiac death among users of antipsychotics.[81,83] A published meta-analysis of the operating characteristics of the ECG in patients with cyclic antidepressant toxicity found the ECG was a relatively poor predictor of seizures, dysrhythmia, and death.[7] However, the ECG is a dynamic instrument, particularly in the initial hours after overdose, and few studies have evaluated longitudinal changes in the ECG.[59]

DIAGNOSTIC TESTS

The diagnosis of antipsychotic poisoning is supported by the clinical history, the physical examination, and a limited number of adjunctive tests. Both the clinical and ECG findings are nonspecific and can occur after overdose of several different drug classes, including CAs, skeletal muscle relaxants, carbamazepine, and first-generation antihistamines such as diphenhydramine. Moreover, the absence of typical ECG changes does not exclude a significant antipsychotic ingestion, particularly early after overdose, and at least one additional ECG should be performed in the following 2 to 3 hours.

Serum concentrations of antipsychotics are not widely available, do not correlate well with clinical signs and symptoms, and do not help guide therapy. Comprehensive urine drug screens using high-performance liquid chromatography, gas chromatography–mass spectrometry, or tandem mass spectrometry may indicate the presence of antipsychotics, but these tests are available at only a few hospitals and in most instances provide only a qualitative result. Blood and urine immunoassays for CAs may yield a false-positive result in the presence of phenothiazines.[5,88]

MANAGEMENT

The care of a patient with an antipsychotic overdose should proceed with the recognition that other drugs, particularly other psychotropic agents, may have been prescribed and coingested and may confound both the clinical presentation and management. Regularly encountered coingestants include other psychotropic drugs such as antidepressants, sedative–hypnotics, anticholinergics, valproic acid, and lithium, as well as ethanol and nonprescription analgesics such as acetaminophen and aspirin.

Supportive care is the cornerstone of treatment for patients with antipsychotic overdose. Supplemental oxygen should be administered if hypoxia is present. Patients with altered mental status should receive thiamine and parenteral dextrose as clinically indicated. Intubation and ventilation are rarely required for patients with single drug ingestions but may be necessary for patients with very large overdoses of antipsychotic agents or ingestion of other CNS depressants. All symptomatic patients should undergo continuous cardiac monitoring. In addition, an ECG should be recorded upon presentation and reliable venous access obtained. Asymptomatic patients with a normal ECG 6 hours after overdose have an exceedingly low risk of complications and no longer require cardiac monitoring. Symptomatic patients and those with an abnormal ECG should be continuously monitored for a minimum of 24 hours.

GASTROINTESTINAL DECONTAMINATION

Gastrointestinal decontamination with activated charcoal (1 g/kg by mouth or nasogastric tube) should be considered for patients who present after a large or polydrug overdose. Although this intervention is time sensitive, many antipsychotics exhibit significant antimuscarinic activity and slow gastric emptying, thereby increasing the likelihood that activated charcoal will be beneficial. Although improvement in clinically important, outcomes cannot be attributed to activated charcoal at present. A Bayesian analysis of pharmacokinetic data from 54 quetiapine overdoses (19 of whom received activated charcoal) concluded that charcoal reduced absorption by 35%.[47] Orogastric lavage and whole-bowel irrigation likely will not improve clinical outcomes and should not be routinely used in the management of those with antipsychotic overdoses. Induction of emesis using syrup of ipecac is absolutely contraindicated because of the high potential for pulmonary aspiration.

TREATMENT OF CARDIOVASCULAR COMPLICATIONS

Vital signs should be monitored closely. Hypotension may result from peripheral α-adrenergic blockade and is most likely to occur with older, low-potency antipsychotics such as thioridazine. The hypotension should be treated initially with appropriate titration of 0.9% sodium chloride solution (30–40 mL/kg). If vasopressors are required, direct-acting agonists such as norepinephrine or phenylephrine are preferred over dopamine, which is an indirect agonist and likely will be ineffective. Vasopressin or its analogs may also be used, although direct-acting vasopressors should be used with great caution in patients who have coingested a negative inotropic drug such as a β-adrenergic antagonist or calcium channel blocker. Continuous, intraarterial blood pressure monitoring may be warranted in such cases. Central venous pressure monitoring and pulmonary artery catheterization rarely influence treatment decisions and should be used only if the patient's clinical status is obfuscated by significant coingestion or comorbidity.

Sodium bicarbonate (1–2 mEq/kg) is the first-line therapy for ventricular dysrhythmias and should be considered for patients with dysrhythmias or QRS prolongation above 0.12 seconds. The rationale for this strategy is based on the treatment of cyclic antidepressant overdose (see Antidotes in Depth A5: Sodium Bicarbonate and Chap. 73). At least two mechanisms underlie the beneficial effects of sodium bicarbonate: (1) the degree of sodium channel blockade is partially overcome by an increase in extracellular sodium; indeed, hypertonic saline alone may be beneficial and (2) the binding of these drugs to the sodium channel is pH dependent, with less extensive binding at higher pH.

Repeated boluses of bicarbonate may be administered to achieve a target blood pH of 7.5, although many toxicologists recommend continuous infusions.[98] If the patient is intubated, hyperventilation may also be used but is not comparably efficacious and should not be used for alkalinization. When significant conduction abnormalities or ventricular dysrhythmias persist despite the use of sodium bicarbonate, lidocaine (1–2 mg/kg followed by continuous infusion) is a reasonable second-line antidysrhythmic agent. Although lidocaine is also a sodium channel antagonist, it exhibits rapid on/off sodium channel binding with preferential binding in the inactivated state and may lessen the cardiotoxicity associated with antipsychotic drug overdose.[97] Class IA antidysrhythmics (procainamide, disopyramide, and quinidine), class IC antidysrhythmics (propafenone, encainide, and flecainide), and class III antidysrhythmics (amiodarone, sotalol, and bretylium) may all aggravate cardiotoxicity and should not be used. When administering sodium bicarbonate to patients with antipsychotic overdose, caution must be taken to avoid hypokalemia because many of these antipsychotics block cardiac potassium channels, thereby prolonging

the QT interval. Hypokalemia may exacerbate this blockade, potentially leading to torsade de pointes.

Sinus tachycardia related to anticholinergic activity should not be treated unless it is associated with ischemia. Prolongation of the QT interval requires no specific treatment other than monitoring and correction of potential contributing causes such as hypokalemia and hypomagnesemia. Torsade de pointes should be treated with IV magnesium sulfate, taking care to prevent hypotension, which is dose and rate dependent. Overdrive pacing with isoproterenol or transcutaneous or transvenous pacing should be considered if the patient does not respond to magnesium sulfate, although in theory this therapy may worsen the rate-dependent sodium channel blockade.

Many antipsychotics, including olanzapine, quetiapine, and sertindole, exhibit a high degree of lipophilicity in addition to significant cardiovascular toxicity. Recently, considerable enthusiasm has emerged for the use of high-dose lipid emulsion therapy for patients with significant overdoses of drugs displaying these characteristics. The rationale for this therapy depends, in part, in the concept that highly lipophilic drugs will selectively partition into the exogenous lipid, thereby minimizing toxicity at the biophase. This treatment has been extensively studied in animal models of bupivacaine toxicity,[32,113,114] but published experience with antipsychotic drugs is extremely limited.[38] Dosing for lipid "rescue" is not well established, but the current recommended protocol involves 20% lipid emulsion given as a bolus (1.5 mL/kg) followed by an infusion of 0.25 mL/kg/min for 30 to 60 minutes with adjustment of therapy according to the individual response (see Antidote in Depth: A22: Intravenous Fat Emulsion).

TREATMENT OF SEIZURES

Seizures associated with an antipsychotic overdose are generally short lived and often require no pharmacologic treatment. Multiple or refractory seizures should prompt a search for other causes, including hypoglycemia and ingestion of other proconvulsants. When treatment is necessary, benzodiazepines such as lorazepam or diazepam generally suffice, although phenobarbital may be necessary. Although phenytoin may be part of the standard algorithm for treating those with status epilepticus, it is of limited effectiveness for xenobiotic-induced seizures; and in this situation, barbiturates are preferred. Patients with refractory seizures typically respond to propofol infusion or general anesthesia. Seizures complicated by hyperthermia are considerably more ominous and warrant aggressive lowering of body temperature with aggressive rapid cooling measures. Finally, seizures may abruptly lower serum pH and may abruptly increase the cardiotoxicity of these drugs; therefore, an ECG should be obtained after resolution of seizure activity.

TREATMENT OF THE CENTRAL ANTIMUSCARINIC SYNDROME

Many of the older- and newer-generation antipsychotics have pronounced anticholinergic properties. Case reports and observational studies suggest that the cholinesterase inhibitor physostigmine (see Antidotes in Depth A12: Physostigmine Salicylate) can safely and effectively ameliorate the agitated delirium associated with the central anticholinergic syndrome by indirectly increasing synaptic acetylcholine levels.[25,91-93] Although benzodiazepines control agitation, they further impair alertness, obfuscating the assessment of mental status and increasing the risk of complications.[22]

Physostigmine has been used successfully in patients with antipsychotic overdose[22,90,93,116,117] but should be used with caution and not in patients with dysrhythmias, any degree of heart block, or widening of the QRS complex. If physostigmine is used, it should be given in 0.5-mg increments every 3 to 5 minutes with close observation of the

patient. Subsequent bradycardia, bronchospasm, or bronchorrhea can be treated with 0.2 to 0.4 mg of IV glycopyrrolate. Although atropine is often more widely available and could be used, it crosses the blood–brain barrier and may aggravate any associated delirium. The clinical effects of physostigmine are transient, typically ranging in duration from 30 to 90 minutes, and additional doses are often necessary. Physostigmine does not prevent other complications of antipsychotic overdose, particularly those involving the cardiovascular system.

Other commonly used cholinesterase inhibitors, such as edrophonium, neostigmine, or pyridostigmine, should not be used to treat anticholinergic delirium because they do not cross the blood–brain barrier. Case reports involving other anticholinergics suggest that cholinesterase inhibitors used for treatment of dementia (eg, tacrine, donepezil, and galantamine) may be alternatives to physostigmine for patients who are able to take medications orally.[48,67,75]

ENHANCED ELIMINATION

No pharmacologic rationale supports the use of multiple-dose charcoal or manipulation of urinary pH to increase the clearance of antipsychotics. One volunteer study found that urinary acidification may increase remoxipride elimination,[118] but this practice is impractical and possibly dangerous. Because most antipsychotics exhibit large volumes of distribution and extensive protein binding (see Table 69–1), neither hemodialysis nor hemoperfusion is warranted. These modalities should be considered only if the patient has concomitantly ingested other xenobiotics amenable to extracorporeal removal, such as lithium.

SUMMARY

Over the past decade, the atypical antipsychotics have largely supplanted traditional (typical) antipsychotics, which are associated with greater toxicity in overdose and a higher incidence of EPS.

However, significant toxicity may occur either during the course of therapy or after overdose with both typical and atypical antipsychotics. Of the various toxicities that arise during therapeutic use, NMS is the most dangerous. Its manifestations are protean, and it may be difficult to recognize. Altered mental status, muscle rigidity, fever, and autonomic instability are its hallmarks, but the diagnosis should be considered in any unwell patient treated with antipsychotics, particularly in the 2 weeks after a change in therapy or in a patient with severe intercurrent illness. Treatment of NMS is largely supportive and often involves the use of benzodiazepines. Dantrolene, dopamine agonists such as bromocriptine or entacopone, and ECT are anecdotally associated with dramatic clinical improvement.

The principal manifestations of antipsychotic overdose involve the CNS and cardiovascular system. Depressed mental status, hypotension, and anticholinergic signs are nonspecific features that support the diagnosis of antipsychotic overdose, particularly in conjunction with typical ECG findings of sodium channel blockade and QT prolongation. However, these signs and symptoms vary considerably among the available antipsychotics. Most fatalities after antipsychotic overdose occur in the setting of coingestions of other CNS depressants or cardiotoxic medications. Supportive care is the mainstay of therapy for patients with antipsychotic overdose, although selective use of nonspecific antidotes, such as activated charcoal, sodium bicarbonate, and physostigmine, may improve outcomes in some patients. Particularly severe or refractory cardiovascular toxicity may warrant a trial of lidocaine or IV lipid emulsion, although these interventions are not well studied in the context of antipsychotic drug overdose.

CHAPTER 70
LITHIUM

Howard A. Greller

MW	=	6.94 daltons
Lithium concentration (serum):		
Therapeutic concentration for bipolar depression	=	0.6–1.2 mEq/L (mmol/L)

Lithium is the most efficient long-term therapy for treatment and prevention of bipolar affective disorders,[57,89,211] with a demonstrated antisuicidal effect and an ability to improve both the manic and depressive symptoms of the illness.[15–17,51,59,86,87,145,192,212] Investigations on the use of lithium for compulsive gambling have also demonstrated beneficial results.[99] In most industrialized nations, approximately one in 1000 persons is prescribed one or more of the various lithium formulations.[8,187]

HISTORY

The Swedish chemistry student Arfwedson discovered lithium in 1817.[145] Lithium derives its name from the Greek word for stone, *lithos*, from which it was first isolated. Lithium has a long history of therapeutic use beginning in the mid 19th century, when lithium salts were used to treat individuals with gout. The therapy also improved symptoms of mania and depression.[16,120,212] The soft drink 7-Up was originally formulated with lithium as its "active ingredient."[5] During the 1930s and 1940s, lithium was used as a salt substitute ("Westsal") for patients with heart failure but was discontinued after several cases of acute lithium poisoning were described.[61,68,92,188] The beneficial effects of lithium on bipolar disorder were "rediscovered" by Cade in 1949, when he noticed the calming effect of lithium carbonate on guinea pigs.[48,49] The same year, however, the Food and Drug Administration (FDA) banned the use of lithium in response to reported poisonings.[48,172,188] The FDA lifted the ban in 1970 and approved the use of lithium for the treatment of mania.

PHARMACOLOGY

The simplicity of the lithium molecule belies the complexity of its mechanism of action. Although lithium has been used therapeutically for almost 50 years, the precise pharmacology of its therapeutic effects has not yet been fully elucidated.[80] Part of the difficulty in defining the precise mechanism of lithium is the difficulty in defining the precise pathophysiology of bipolar disorder.[192] Early efforts focused on dysfunctional neurotransmitter systems, particularly the role of biogenic amines. Lithium increases basal and stimulation-induced serotonin release and receptor sensitivity to serotonin.[45,213] Lithium modulates the effect of norepinephrine through its interactions with the G-protein–mediated β-adrenergic receptor, stabilizing fluctuations in the intracellular pool of cyclic adenosine monophosphate (cAMP). It performs this function by inhibiting not only the inhibitory subunit G_i, which increases basal concentrations of cAMP but also the stimulatory subunit, G_s, preventing fluctuations from adrenergic stimulation.[45] Clinically, the therapeutic effects of lithium and other mood-stabilizing pharmaceuticals become evident only after chronic administration, so their mechanism of action is likely not solely the result of acute biochemical interactions. Postulated mechanisms go beyond simple neurotransmitter function or dysfunction and focus on altered cellular signaling, neuronal plasticity, and neurogenesis. Rather than trying to identify any single neurotransmitter system as responsible for the complexity of depressive illness, efforts now are directed at elucidating the functional balance between interacting systems. Additionally postulated is a neuroprotective effect of lithium, with evidence to support benefit in neurodegenerative illnesses such as Alzheimer's disease.[26] Along with these advances, a clearer understanding of the action of lithium is developing.[22,45,80,95,120,121,192]

Among the first proposed mechanisms of action of lithium is the inositol-depletion hypothesis. Inositol is a six-carbon sugar that forms the backbone of a number of cellular signaling mechanisms. Lithium treatment results in decreased myoinositol (the most biologically active stereoisomer of inositol) concentration in the cerebral cortex.[6,26,95,114] Abnormalities in regional brain myoinositol concentrations are thought to occur in bipolar patients. This theory is partially supported by experimental magnetic resonance spectroscopy data.[195,229] Myoinositol is phosphorylated to form phosphatidyl inositol (PIP), which is further phosphorylated and combined with diacylglycerol (DAG) to form phosphatidyl 4,5 bisphosphate (PIP_2). Upon stimulation of a cell, G-protein–coupled receptors activate phospholipase C (PLC), which hydrolyzes PIP_2 to release the secondary messengers DAG and inositol 1,4,5 trisphosphate (IP_3).[95,191,195,229] Each of these secondary messengers in turn initiates a cascade of events, including activation of protein kinase C (PKC), which is important for calcium homeostasis and neurotransmitter release,[140,142,157,195] as well as independent mobilization and regulation of intracellular calcium.[18,55,152,174,195] Many extracellular signals, including some serotonin receptor subtypes, activate PLC to exert their actions.[88,139,162]

Serial dephosphorylation of IP_3 leads to regeneration of myoinositol and recycling of the inositol pool. Two enzymes involved in this pathway are inhibited by lithium. The first enzyme, inositol 1,4-bisphosphate 1-phosphatase (IPPase), dephosphorylates the bisphosphate to inositol monophosphate (IMP). The second enzyme, inositol-1-monophosphatase (IMPase), dephosphorylates IMP to myoinositol.

The inhibition of IMPase is interesting and important. First, the mechanism of inhibition is uncommon. Lithium noncompetitively inhibits IMPase by binding to the enzyme–substrate complex and preventing the release of a phosphate. It performs this function by displacing a magnesium ion from the active site after hydrolysis. Essentially, noncompetition means the higher the concentration of the substrate, the more the enzyme is inhibited.[9] This supports a theory about the pathophysiology of bipolar disorder involving an excess of myoinositol and is one reason why the mood-stabilizing effects of lithium are thought to occur only in bipolar patients.[95] That is, the noncompetitive nature of the action of lithium serves as a regulator to preferentially block pathologic signaling caused by excessive myoinositol while leaving the normal signaling intact. As described, IMPase is an important step in the cellular recycling of the inositol pool. Lithium inhibits the last step in this cycle.

Myoinositol is also generated de novo from glucose-6-phosphate by inositol synthase, which forms IMP. The inhibition of IMPase by lithium subsequently leads to myoinositol depletion by preventing the conversion of the newly synthesized IMP to inositol. Interestingly, valproic acid (VPA) also inhibits inositol synthase, illustrating a potential mechanism for the synergy of these complementary mood stabilizers.[160] A third mechanism of intracellular diminution of inositol by lithium (as well as VPA and carbamazepine) is the effect of lithium on reducing activity and transcription of the sodium myoinositol transporter (SMIT), preventing the uptake of exogenous myoinositol by the cell. This mechanism of inhibition may be overcome by increased extracellular concentration of myoinositol.[95,224]

The result of these effects is depletion of the inositol pool available to the cell, causing a series of events at different points in the signal transduction cascade that leads to differential gene transcription and expression. This sequence ultimately is responsible for the observed clinical effects of lithium on the central nervous system (CNS).[45,191] Experimental data using dextroamphetamine as a model for clinical mania demonstrate increased regional inositol signaling in the human brain, that is, attenuated by pretreatment with lithium, lending support to the hypothesis.[35]

The inositol depletion hypothesis represents an original attempt to explain in molecular terms the therapeutic effects of lithium. However, experimentally, this model does not fully elucidate nor replicate the clinical disease or response to therapy. In vivo studies with more drastic inositol depletion than from lithium therapy fail to replicate predicted behavioral patterns. Studies in knockout mice lacking various isoforms of inositol monophosphatase fail to replicate the antidepressant or antimanic effects of lithium. The model remains an attractive one, and the flaws may represent species variation with validity more in humans with bipolar disorder than the mouse model illustrates.[25,26,145]

A second compelling mechanism for the action of lithium is inhibition of the family of glycogen synthase kinase-3 (GSK3) kinases. GSK-3β overactivity is associated with neuronal degeneration and sensitivity to apoptotic stimulation. Dysregulation of GSK-3β is implicated in tumor growth and the neurofibrillary tangles of Alzheimer's disease.[225,226] GSK-3β is a key regulator of neuronal cell fate, with a proapoptotic effect in many settings.[3,25,27,62,73,98,107-109,145,178] GSK-3β is involved in regulating the activity of β-catenin, Jun and cAMP response element-binding protein (CREB), transcription factors important in embryonic patterning, cell proliferation, neuronal modeling and plasticity, neuronal signal transduction, and cytoskeletal remodeling. Lithium inhibits GSK-3β enzymatic activity directly through magnesium mimicry. Lithium also leads to indirect inhibition of GSK-3β through its interaction with the serine/threonine kinase Akt, which phosphorylates and inhibits GSK-3β. Lithium seems to accomplish this disparate inhibition by preventing the formation of a protein complex that is involved in G-protein–coupled receptor signaling. Dopaminergic neurotransmission through G-protein–coupled receptors is mediated through a protein complex that involves Akt, β-arrestin, and protein phosphatase 2A (Fig. 70–1). The complex, when active, dephosphorylates (deactivates) Akt in response to dopamine, leading to the activation of GSK-3β. Lithium disrupts assembly of the complex, which has the downstream effect of inactivation of GSK-3β, and the disruption of dopaminergic signaling. Lithium appears to be specific for this particular protein complex and seems to exert its inhibitory influence through displacement of the magnesium cofactor required for complex assembly. Evidence for this pathway is derived from in vivo models of mood-altering xenobiotics, such as phencyclidine models of schizophrenia, as opposed to in vitro biochemical studies.[31,159,165,228]

Inhibition of GSK-3β by lithium is thought to be neuroprotective.[3,26,45,91,96,169,179,180,231] Lithium is implicated in the neuroprotective modulation of the *bcl-2* gene, which is known for its role in preventing apoptosis and in downregulation of the proapoptotic protein *p53*. Lithium increases *bcl-2* levels in cultured nervous tissue of both rats and humans.[53,141,147] Additional support comes from patients undergoing long-term therapy with either lithium or VPA who show prefrontal cortex volumes significantly greater than in patients not treated with
FIGURE 70–1. Lithium influences myriad signals of commonly encountered xenobiotics that affect the dopamine (D) and serotonin (5-HT) neurotransmitter systems through the common pathway of Akt/GSK-3 signaling, cumulating in an observable behavioral response. Lithium exerts these effects through direct inhibition of GSK-3 signaling and indirectly through upstream disruption of the Akt Pathway. 8-OH-DPAT = 8-Hydroxy-N,N-dipropyl-2-aminotetralin; DOI = 2,5-dimethoxy-4-iodoamphetamine; D2, D3, D4 = dopamine receptors; Akt = serine/threonine kinase Akt; GSK-3 = glycogen synthesis kinase -3.

either agent, suggesting a protective effect in humans.[45,56,66] Further evidence points toward a protective effect of lithium and possible therapeutic role in such neurodegenerative conditions as Parkinson's disease (in a mice model of Parkinson's disease using N-methyl-4-pheynyl-1, 2, 3, 6-tetrahydropyridine [MPTP]),[230] Huntington's disease,[52,190] amyotrophic lateral sclerosis (ALS),[77] and Alzheimer's disease.[3,22,23,26,47,122,123,135,145,149,158,170,206]

A link between GSK-3β activity and bipolar disorder and depression is supported by the finding that serotonergic activity inhibits GSK-3β in vivo.[125] Additional evidence of an interaction between serotonergic neurotransmission and inhibition of GSK-3β by specific serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), and atypical antipsychotic agents lends further behavioral support to this theory.[27,124,125] Evidence from in vivo models of depression and mania implicate that GSK-3β is involved in regulation of behavioral stimulus by dopaminergic and serotoninergic neurotransmission.[25–33] Hypoxia contributes to increased GSK-3β activity, which may be counteracted or inhibited through mood-stabilizing drugs. Vascular depression, or depression after stroke, is an organic model of major depression.[148] The finding that this depressive state responds similarly to intervention with mood stabilizers lends further support to the GSK-3β hypothesis.[110] Thus, the diminished serotonergic activity associated with depression, or the hypoxic-induced activation of GSK-3β, may lead to impaired inhibition of GSK-3β. Mood stabilizers counteract this dysregulation and may explain their effectiveness in depression.[45,88,95,96,169,222]

In summary, although the precise mechanism of action is unknown, some common features of investigation have emerged. The potential targets, widely found and disparate in function, all seem to be inhibited by lithium in a noncompetitive fashion, most commonly through displacement of a divalent cation, usually Mg^{2+}. The systems affected by this inhibition vary widely. Downstream targets seem to modulate secondary cell messengers and intracellular signal transduction, transcription factors and gene expression, and neuronal plasticity and cellular differentiation. Further study is needed to elucidate the complex interaction of these pathways with the action of lithium to form an integrated hypothesis.

PHARMACOKINETICS AND TOXICOKINETICS

The volume of distribution of lithium is between 0.6 and 0.9 L/kg. It has no discernable protein binding and distributes freely in total body water, except the cerebrospinal fluid (CSF), from which it is actively extruded.[69,163,182,197] The extrusion is believed to occur through an active transport process involving sodium/lithium exchange at the arachnoid processes.[70] The immediate-release preparations of lithium are rapidly absorbed from the gastrointestinal (GI) tract. Peak serum concentrations are achieved within 1 to 2 hours.[105] Sustained-release products demonstrate variable absorption, with a delay to peak of 6 to 12 hours. In overdose, a longer delay to reach peak concentrations or multiple peaks may occur.[67] Chronic therapy prolongs the elimination of lithium, as does advancing age.[163] Although lithium is rapidly absorbed, tissue distribution is a complex phenomenon, with a significant delay in reaching a steady-state. Lithium exhibits preferential uptake into the kidney, thyroid, bone and other organs and tissues such as the liver and muscle. Lithium distribution into the brain can take up to 24 hours to reach equilibrium. Lithium is concentrated in red blood cells (RBCs) by both passive diffusion and active transport. The RBC concentration may correlate closely with the brain concentration, although this does not appear to be clinically useful.[50,71,173] The pharmacokinetic profile of lithium is described as an open, two-compartment model.[76,106]

Each 300-mg lithium carbonate tablet contains 8.12 mEq of lithium.[212] Ingestion of a single 300-mg tablet is expected to acutely increase the serum lithium concentration by approximately 0.1 to 0.3 mEq/L (assuming a volume of distribution of approximately 0.6–0.9 L/kg and a patient weight 50–100 kg).

Lithium is eliminated almost entirely (95%) by the kidneys, with a small amount eliminated in the feces.[105] Lithium is also found in sweat, saliva, and breast milk.[64,102,153] In an adult with normal renal function, lithium clearance ranges from 25 to 35 mL/min.[34,208,209] At steady-state equilibrium, total body clearance equals renal clearance.

Lithium is handled by the kidneys much in the same way as sodium. Lithium is freely filtered, and more than 60% is reabsorbed by the proximal tubule. Evidence also indicates a small amount of reabsorption by the loop of Henle and distal tubule.[10,40,41,65,79,119,163,212] Lithium excretion is therefore dependent on factors that affect the glomerular filtration rate (GFR) or decrease sodium concentration. Any condition that makes the kidney sodium avid such as volume depletion or salt restriction increases lithium reabsorption in the proximal tubule.[10] Thus, risk factors for development of lithium toxicity include advanced age with its decrease in GFR; use of thiazide diuretics, nonsteroidal antiinflammatory drugs (NSAIDs, or angiotensin-converting enzyme (ACE) inhibitors; decreased sodium intake; and low-output heart failure.[105,119]

The therapeutic to toxic index of lithium is narrow. The generally accepted steady-state therapeutic range of serum lithium concentrations is 0.6 to 1.2 mmol/L, although much disagreement exists about whether this serum concentration truly reflects therapeutic efficacy.[83,84,181] Both in therapeutic and overdose situations, clinical signs and symptoms seem to be a more valuable indicator of brain lithium concentrations.[181]

CLINICAL MANIFESTATIONS

Similar to other substances having prolonged redistributive phases and tissue burdens, lithium exposure can be divided into three main categories of toxicity: acute, acute-on-chronic, and chronic. In acute lithium toxicity, the patient has no body burden of lithium present at the time of ingestion. The toxicity that develops depends on the rate of absorption and distribution. In chronic toxicity, the patient has a stable body burden of lithium as serum concentration is maintained in the therapeutic range, and then some factor disturbs this balance, either by enhancing absorption, or more commonly, decreasing elimination. For chronic users of lithium, small perturbations in the equilibrium between intake and elimination may lead to toxicity. In acute-on-chronic toxicity, the patient ingests an increased amount of lithium (intentionally or unintentionally) in the setting of a stable body burden. With tissue saturation, any additional lithium leads to signs and symptoms of toxicity.

◼ ACUTE TOXICITY

Acute ingestions of lithium-containing preparations produce clinical findings similar to that of ingestions of other metal salts, with predominant early GI symptoms. Nausea, vomiting, and diarrhea are prevalent. Significant volume losses may result from these symptoms. Patients may complain of lightheadedness and dizziness, and they may be orthostatic. Neurologic manifestations are a late finding in acute toxicity as the lithium redistributes slowly into the CNS.

Lithium is associated with a number of electrocardiographic (ECG) abnormalities, although the evidence for significant effects is lacking. Most reports are uncontrolled case reports without corroborating experimental data or biologic plausibility. The most commonly reported manifestation has been T-wave flattening or inversion, primarily in the precordial leads.[44,167,211] Lithium is also associated with prolongation of

the QT interval.[227] One study associated elevated serum lithium concentrations with QT prolongation above 440 msec, although the number of patients studied was small.[101] Associations have been made between lithium and sinoatrial dysfunction, with resultant bradycardia.[85,166,194,205] Theoretically, this condition may result from the effect of lithium on G-protein–mediated cAMP generation and subsequent modification of calcium channel opening and calcium influx in the pacemaker cells.[44,101,167,211] Additional reports attempt to link lithium therapy with cardiomyopathy and unmasking of a Brugada pattern.[4,63,111] For the most part, lithium has few consequential effects on cardiac function, even in overdose, and malignant dysrhythmias or significant dysfunction is uncommon.[133,155,163]

CHRONIC TOXICITY

Lithium is primarily a neurotoxin. The earliest case reports of lithium toxicity described predominantly neurologic symptoms.[61,220] Of note, neurotoxicity does not correlate with serum concentrations. The initial clinical condition of the patient and the duration of exposure to an elevated concentration seem to be more closely predictive of outcome than the initial serum lithium concentration.[2,8,20,93,117,155,186,217]

Tremor, a common finding in patients undergoing chronic therapy, may increase with toxicity. Other findings of chronic toxicity include fasciculations, hyperreflexia, choreoathetoid movements, clonus, dysarthria, nystagmus, and ataxia.[163,212] Mental status is often altered and may progress from confusion to stupor, coma, and seizures.[46] Electroencephalographic changes are most frequently reported as "slowing."[193] The progression of these symptoms follows no order, and any patient undergoing chronic therapy may have one or any combination of these features.

The syndrome of irreversible lithium-effectuated neurotoxicity (SILENT) is a descriptive syndrome of the irreversible neurologic and neuropsychiatric sequelae of lithium toxicity.[2,171] SILENT is defined as neurologic dysfunction caused by lithium in the absence of prior neurologic illness, persists for at least 2 months after cessation of the drug. Case reports in the literature support these findings and this definition. However, as is true in most case reports, confounders make wide applicability of the findings difficult. Because of the polypharmacy prevalent in psychiatric treatment, long-term neurologic sequelae attributed to lithium are frequently described in patients using lithium in combination with other xenobiotics, such as haloperidol, chlorpromazine, carbamazepine, phenytoin, aspirin, VPA, amitriptyline, β-adrenergic antagonists, calcium channel blockers, ACE inhibitors, diuretics, and NSAIDs.[2,12,58,75,76,94,138,151,217] However, there are reports of patients using lithium without coingestants who had no comorbid illness and sustained lasting dysfunction as a result of lithium toxicity.[8,115,154,164,186,217] Cerebellar findings seem to predominate in patients with SILENT.[2,90,112,115,143] One of the predictors of persistent neurologic dysfunction seems to be the concomitant finding of hyperpyrexia, an ominous finding in patients with lithium toxicity.[90,143] The mechanism of the persistent dysfunction is unclear, but demyelination and cellular loss are proposed.[2,143,155,185]

ACUTE-ON-CHRONIC TOXICITY

Patients undergoing chronic therapy who acutely ingest an additional amount of lithium (either intentionally or unintentionally) are at risk for signs and symptoms of both acute and chronic toxicity. These patients may display prominent GI and neurologic symptoms and may be difficult to diagnose and manage. Serum lithium concentrations in cases of acute or chronic toxicity may be difficult to interpret, and therapy should be guided by the patient's clinical status.

OTHER SYSTEMIC MANIFESTATIONS OF CHRONIC LITHIUM THERAPY

The most common adverse effect of chronic lithium therapy is the development of nephrogenic diabetes insipidus. The process thought to be involved is the interference of lithium on magnesium-dependent G proteins that activate vasopressin-sensitive adenylate cyclase, leading to decreased generation of cAMP in the cell membranes of distal tubular cells.[54,143,198,218] Decreased cAMP leads to reduced expression and translocation of the vasopressin-regulated water channel aquaporin-2 (AQP2), making the distal tubules resistant to the action of vasopressin.[7,60,113,144,146,184,221] Lithium also inhibits the transport of sodium through the amiloride-sensitive Na^+ channel.[208]

Another theory proposed for the mechanism of lithium-induced nephrogenic diabetes insipidus suggests that lithium inhibits GSK-3β directly and through a phosphorylation pathway. GSK-3β exhibits tonic inhibition of cyclooxygenase-2 (COX-2). When this inhibition is removed by lithium, COX-2 activity leads to increased prostaglandin expression in the renal medulla. Increased prostaglandin expression is believed to be important in nephrogenic diabetes insipidus through regulation of glomerular blood flow.[136,175]

Chronic lithium therapy is also associated with chronic tubulointerstitial nephropathy, as manifested by the development of renal insufficiency with little or no proteinuria and biopsy findings of tubular cysts. This association was demonstrated in a biopsy-based study of 24 chronically treated patients, although the overall prevalence of this condition is low.[144]

Lithium is associated with a number of endocrine disorders. The most prevalent endocrine manifestation of chronic lithium therapy is hypothyroidism.[38,39,81,154] The causative etiology is multifactorial. Lithium is selectively concentrated in the thyroid gland and impairs iodine uptake, synthesis of triiodothyronine (T_3), responsiveness of the gland to thyroid-stimulating hormone (TSH), release of T_3 and tetraiodothyronine (T_4), and peripheral conversion of T_4 to T_3. Additionally, lithium decreases responsiveness of peripheral tissues to T_3 and leads to the development of antithyroglobulin antibodies (see Fig. 49-1).[13,161,223] Although hypothyroidism is most common, hyperthyroidism and frank thyrotoxicosis are also reported.[19] However, hyperthyroidism, by altering proximal tubule function, leads to decreased lithium excretion.[24] Thus, hyperthyroidism may lead to chronic lithium toxicity through impaired elimination, and the elevated lithium concentrations may mask the manifestations of hyperthyroidism.[161]

The combination of hyperparathyroidism and hypercalcemia is frequently reported with chronic lithium therapy, most commonly in women. The mechanism is thought to be modification of calcium feedback on parathyroid hormone release, although stimulation of parathyroid hyperplasia and adenomas is suggested.[1,11,37,118,196,212]

Developmentally, in utero exposure to lithium increases the incidence of congenital heart defects, specifically Ebstein anomaly.[102,169,196] Additionally, many effects similar to those that occur in patients undergoing chronic therapy are found in infants exposed in utero, including thyroid disease and neurotoxicity.[102]

Lithium causes a leukocytosis and an increase in neutrophils. It has been proposed as an adjunct to chemotherapy-induced neutropenia, other marrow suppressive therapies, and acquired immunodeficiency syndrome (AIDS). Although lithium increases the total neutrophil count, no improved clinical outcomes are documented, and its use has been superseded by recombinant colony-stimulating factors.[42,169,177,196,200]

DIAGNOSTIC TESTING

Because of the prevalence of lithium use, therapeutic drug monitoring is ready available in most settings, and concentrations should be readily

obtainable. A lithium concentration should be requested upon patient presentation and serial measurements requested or considered in most instances, especially after ingestion of sustained-release preparations. Emphasis should be placed on the lithium concentration as a marker of exposure and response to therapy but not necessarily as a determinant of toxicity or treatment. The history, clinical signs, and symptoms rather than the absolute lithium concentration should guide therapy. The sample must be sent in an appropriate lithium-free tube, because use of lithiated-heparin tubes may lead to clinically false-positive results. Serum electrolyte concentrations and renal function should be monitored because renal function is important in determining the need for more aggressive therapy, including enhanced elimination techniques such as hemodialysis. If the patient is hypernatremic, nephrogenic diabetes insipidus should be suspected, and determinations of serum and urine osmolarity and electrolytes help confirm the diagnosis (see Chap. 16). If clinical thyroid disease is suspected, thyroid function tests should be obtained. If a deliberate ingestion, a serum acetaminophen concentration should be obtained. An ECG is also indicated. The complete blood count may indicate a leukocytosis, as a stress response or due to the hematologic effects of lithium.

MANAGEMENT

The initial management and stabilization should begin with assessment and, if necessary, support of airway, breathing, and circulation. Lithium rarely, if ever, affects the patient's airway or breathing, although coingestants may. Emesis, which occurs with significant frequency after acute exposure, may lead to aspiration and respiratory compromise. After the patient is stable, the characteristics of the exposure should be determined while the physical examination and laboratory assessment commence. The formulation and nature of the product should be ascertained and most importantly, identified as immediate-release or sustained-release. Also, whether or not lithium is part of the patient's medication regimen may help determine whether the ingestion is acute, acute-on-chronic, or chronic.

◼ GASTROINTESTINAL DECONTAMINATION

For patients who present after an acute overdose or an acute-on-chronic overdose, a risk benefit analysis of GI decontamination must be undertaken. Two factors should be considered. With an acute overdose and predominance of early GI symptoms, including emesis, self-decontamination may already have started. Second, immediate-release preparations are often rapidly absorbed and may not lend themselves to GI evacuation.

Few GI decontamination options are available. Although syrup of ipecac is no longer generally recommended as a standard decontamination choice, because activated charcoal is not an effective adsorbent for lithium, emesis may still be useful in certain instances after ingestion of sustained-release lithium preparations when care may be delayed or is distant, as in remote or rural areas. Whereas immediate-release preparations of lithium are rapidly absorbed and typically produce emesis, sustained-release formulations of lithium (ie, controlled-release tablets) compounded in a slowly dissolving film-coated formulation often make the tablet too large to fit through even the largest lavage tube. Thus, orogastric lavage has essentially no role in the acute management of a patient with an lithium overdose unless indicated for a coingestant.

Lithium is a monovalent cation that does not bind readily to activated charcoal.[130] Because no beneficial effect from activated charcoal is expected, the danger of a depressed level of consciousness, potential loss of protective airway reflexes, and prominent emesis and the possible need for subsequent endoscopy for a coingestant-related problem contraindicate activated charcoal use except for treatment of a potential coingestant.

Sodium polystyrene sulfonate (SPS) is a cationic exchange resin often used for the treatment of severe hyperkalemia. It binds potassium in exchange for sodium, allowing elimination of excess potassium in the feces. Because of the similarity between potassium and lithium, use of SPS has been proposed for decontamination of patients being treated for lithium toxicity. A number of models have examined the effectiveness of this technique.[126–134] Use of SPS has many theoretical benefits, including demonstrated effectiveness of lithium binding compared with activated charcoal and the ability of orally administered SPS to reduce serum concentrations of intravenously administered lithium in mice.[128–130] Unfortunately, the finding that doses used to increase lithium elimination also lead to significant hypokalemia in human subjects limits the application of this technique.[129,183] In a murine model, potassium supplementation with SPS was found to mitigate this process but only at the expense of elevating lithium concentrations.[134] Two reports in the literature demonstrate increased lithium elimination with SPS, one in a healthy volunteer and another in a patient with an acute overdose. However, the serum potassium concentration was not reported in either case.[82,176] At present, use of SPS in the management of the lithium-poisoned patient cannot be routinely recommended.

Whole-bowel irrigation (WBI) is the only GI decontamination modality that has shown any efficacy in eliminating lithium from human subjects. In one of the few clinical trials of WBI, the serum lithium concentrations of 10 normal volunteers who had ingested sustained-release lithium carbonate were plotted against time over a 72-hour period. In the second phase of the trial, the volunteers received 2 L/h of polyethylene glycol solution 1 hour after the ingestion with a significant reduction (67%) in the serum concentration, even as early as 1 hour after the therapeutic intervention.[199] Thus, use of WBI is recommended for sustained-release preparations.

◼ FLUID AND ELECTROLYTES

The critical initial management of the lithium-poisoned patient should focus on restoration of intravascular volume, both in acute poisonings with GI losses and in chronic poisonings with toxic effects that are often the result of disturbances of renal function and lithium elimination. Many patients with lithium toxicity have volume-responsive decreases in renal function,[163] which can be managed by infusion of 0.9% sodium chloride solution at 1.5 to two times the maintenance rate. This therapy increases renal perfusion, increases the GFR, and lithium elimination. Urine output must be closely monitored and any electrolyte abnormalities corrected. Caution must be used in patients with renal insufficiency, renal failure, and congestive heart failure. Monitoring for the development of hypernatremia in patients suspected of having nephrogenic diabetes insipidus is critical.[212]

Lithium-induced nephrogenic diabetes insipidus may be reversed by discontinuation of the drug and repletion of electrolytes and free water. However, nonreversible effects have been reported.[137,144,207] Clinical application of amiloride to mitigate lithium-induced polyuria has been described, although the potential for volume contraction and stimulation of lithium reabsorption limits recommendation of this drug as a routine adjunct to acute care.[21,74,78,116]

Any attempt to enhance elimination of lithium by forced diuresis using loop diuretics (furosemide), osmotic agents (mannitol), carbonic anhydrase inhibitors (acetazolamide), or phosphodiesterase inhibitors (aminophylline) should be avoided. An initial small increase in elimination may be achieved, but typically salt and water depletion subsequently develop followed by increased lithium retention. Sodium

bicarbonate for urinary alkalinization should also be avoided because it does not significantly increase elimination over volume expansion with sodium chloride and may lead to hypokalemia, alkalemia, and fluid overload.

■ EXTRACORPOREAL DRUG REMOVAL

Debate surrounds the efficacy and practicality of using enhanced elimination techniques in cases of lithium poisoning. Lithium does have physiochemical properties that make it amenable to extracorporeal removal,[97,104,105,119] and with these characteristics, it would seem to be an ideal candidate for hemodialysis. In fact, hemodialysis is often recommended for treatment of acute, acute-on-chronic, and chronic lithium toxicity.[14,103–105,143,168,204,212,219] However, some characteristics of lithium make extracorporeal elimination difficult. Lithium is predominantly localized intracellularly and diffuses slowly across cell membranes.[163] When traditional intermittent hemodialysis is used for chronic exposures, clearance of the blood compartment is often followed by a rebound phenomenon of redistribution from tissue stores, leading to increased serum concentrations, in some cases approaching predialysis concentrations.[43] An additional complicating factor is that the brain, the "target organ" of toxicity, is not amenable to a rapid artificial elimination process. Attempts have been made to correlate the serum concentration with the lithium concentration in the CSF and brain. But in the few studies where CSF concentrations were obtained, although serum and CSF lithium concentrations seemed to correlate, brain concentrations and toxicity did not.[105,189] Magnetic resonance spectroscopy studies of bipolar patients with steady-state lithium concentrations demonstrated a significant variability between brain and serum concentrations, especially within the therapeutic range.[105,181,189] No consensus recommendation on the appropriate time to initiate therapy is available.[14,105,183] In addition, because of the toxicokinetic profile of lithium, serum concentrations do not correlate well with toxicity.[68,105,201,212]

Hemodialysis or an alternative extracorporeal technique is clearly indicated for three groups of patients. The first group consists of patients who are manifesting severe signs and symptoms of neurotoxicity, such as alterations in mental status. The second group consists of patients who have renal failure and show signs or symptoms of lithium toxicity. Such patients are unable to eliminate their lithium burden on their own and should undergo hemodialysis. The third group consists of patients who show little or no sign of toxicity but who cannot tolerate sodium repletion therapy; patients who should be considered for early hemodialysis includes patients with congestive heart failure or such "redistributive diseases" as liver failure, pancreatitis, or sepsis.

For a patient who belongs to this last group, the next step is to determine the probability that the patient will develop toxicity if elimination is not enhanced. Although serum concentrations do not necessarily correlate with toxicity, they can nevertheless be a useful aid to making the decision for hemodialysis. As an adjunct to the clinical presentation, an absolute lithium concentration above 4.0 mEq/L (mmol/L) with any type of overdose or a concentration of greater than 2.5 mEq/L with chronic toxicity should prompt dialysis. These criteria originate from a case series of 23 patients and a review of 100 other patients published in 1978, which was before the introduction of sustained-release products.[93] Although this recommendation has never been prospectively evaluated (or subsequently reevaluated), it still can serve as a useful guide in the management of lithium-poisoned patients.[14,34]

The dialysate bath should contain bicarbonate rather than acetate to help lessen the intracellular sequestration of lithium that occurs from the activation of the sodium/potassium antiporter and preferential intracellular transport of lithium.[168,204]

Whether hemodialysis diminishes or enhances the risk of permanent neurologic sequelae is a subject of debate.[202,203] Although no controlled studies have analyzed this important management question, the preponderance of evidence suggests a reduced risk.[2,8,14,73,100,105,143,150,163,168,186,212]

Continuous venovenous hemodialysis and continuous venovenous hemodiafiltration are two continuous renal replacement therapies (CRRTs) commonly used in the treatment of patients with acute renal failure or volume overload and for elimination of xenobiotics.[34,119,214–216] Both techniques are effective in patients who are hemodynamically unstable because blood flow through the filter is pump driven and is not dependent on the arterial blood pressure.[97] Other continuous techniques that use patient blood pressure as the basis of flow through the system also may have application here.[215] Traditional intermittent hemodialysis offers clearance rates that vary between 50 and 170 mL/min.[34,36,119,163,168,215] Although CRRT techniques offer lower clearance per hour than does intermittent hemodialysis, their overall daily clearances are similar.[34,119] With continued improvements in techniques, use of high volumes, and high dialysate flow rates, clearances are improving, approaching more than half the clearance per hour achieved by intermittent hemodialysis in some studies.[34,97,119,215] Although one case of a rebound concentration was reported in a patient treated with continuous arteriovenous hemodiafiltration,[36] no cases with use of the venovenous techniques have been reported, offering a clear advantage over intermittent hemodialysis. Unfortunately, CRRT requires prolonged anticoagulation with its inherent risks. Nevertheless, these techniques may be beneficial in patients who are hemodynamically unstable, or they may be used in series with traditional dialysis in other patients to prevent redistribution of lithium and rebound of serum concentrations (see Chap. 9).

Peritoneal dialysis (PD) offers no increased efficacy of clearance of lithium over the natural clearance of normal kidneys.[14,97,105,183] Although recommended in the past, given its lack of efficacy coupled with its infrequent use and potential for serious complications such as bowel perforation, PD has no role in the management of lithium-poisoned patients.

SUMMARY

Lithium is a simple ion with extensive current usage and extremely varied and complex clinical and pathophysiologic effects. It is available in multiple formulations, both immediate release and sustained release, and is an essential part of the pharmacologic arsenal of clinical psychiatry. Because of the complexity of the pharmacokinetic profile of lithium, toxicity may develop in a wide range of conditions and may be precipitated by both intentional overdose and therapeutic misadventure. The care of lithium-poisoned patients should be predicated on rapid clinical evaluation of the patient's condition coupled with identification of the poisoning and followed by management that includes the use of volume resuscitation and, when indicated, WBI and hemodialysis or other extracorporeal techniques to prevent or treat severe neurologic morbidity and to prevent mortality.

CHAPTER 71
MONOAMINE OXIDASE INHIBITORS

Alex F. Manini

Monoamine oxidase (MAO) inhibitors (MAOI) have a unique history, pharmacology, and toxic syndromes associated with their use. This drug class has fallen in and out of favor with scientists and clinicians over the past several decades. While toxicity from MAOI ingestion is becoming less common due to more limited clinical usage of the traditional nonselective MAOIs, an understanding of MAOI toxicity is fundamental to any clinician who takes care of patients with acute poisoning and xenobiotics overdoses. In this chapter, an overview of clinical manifestations from MAOI toxicity is presented along with an approach to management.

HISTORY

Monoamine oxidase was discovered in 1928 and named by Zeller when the enzyme was recognized to be capable of metabolizing primary, secondary, and tertiary amines such as tyramine and norepinephrine.[126] Subsequently, the monoamine hypothesis postulated depression as a monoamine deficiency state and MAOI drugs were used to target monoamine metabolism for therapeutic benefit. In the early 1950s iproniazid, a drug previously used to treat tuberculosis, was found to produce favorable behavioral side effects. By the mid-1950s, it was demonstrated that iproniazid inhibited MAO, and it then became the first antidepressant used clinically.[46]

Another crucial finding in the late 1960s was the existence of two MAO isoforms, each with their own substrate and inhibitor specificity. This paved the way for future development of selective MAOIs in attempts to minimize the many food and drug interactions that occur with the traditional nonselective MAOIs. Nonselective MAOIs proved to be potent and efficient antidepressants and at one point were utilized as first-line therapy for depression. In the 1970s, MAOIs were competing with alternative therapies for depression, such as tricyclic antidepressants, which were achieving good clinical results without as many food interactions.

EPIDEMIOLOGY

Intentional MAOI overdose is relatively uncommon and accounts for a dwindling number of annual exposures reported to the American Association of Poison Control Centers. In 2006, there were only 268 exposures reported[16] or 0.3% of all antidepressant exposures. Of the reported exposures in 2006, there were only three cases of "major toxic effect" (defined as life-threatening signs or symptoms) and no deaths were reported. Over the past two decades, annual reported MAOI exposures have decreased 34% since 1985 (see Chap. 135). Global MAOI exposure rates most likely mirror the decline occurring in the United States, with the possible exception of exposures to moclobemide, a drug which is not approved by the United States FDA.[33]

PHARMACOLOGY

■ CHEMISTRY

Monoamines, also known as biogenic amines, are a group of neurotransmitters including norepinephrine, dopamine, and serotonin that have in common the presence of a single amine group and the ability to be metabolized by MAO. Monoamine oxidase is a flavin-containing enzyme present on the outer mitochondrial membrane of central nervous system (CNS) neurons, hepatocytes, and platelets. In a two-step reaction, MAO catalyzes the oxidative deamination of its various substrates. Importantly, the reaction liberates H_2O_2, a reactive oxygen species. Deamination by MAO is one of two major routes of elimination of monoamines, the other being extracellular degradation by catechol-O-methyltransferase (COMT). Serotonin is the monoamine exception to this rule, as it is not metabolized by COMT.

■ MONOAMINE NEUROTRANSMITTER STORES

Monoamine neurotransmitter synthesis, vesicle transport, vesicle storage, uptake, and degradation are described in detail in Chap. 13 ("Neurotransmitters and Neuromodulators"). In the neuron, MAO functions as a "safety valve" to metabolize and inactivate any excess monoamine neurotransmitter molecules. Once monoamines undergo reuptake back into the cytoplasm from the synaptic cleft, they can either be transported back into vesicles for further storage and release, or can be quickly enzymatically degraded by MAO which is expressed on the outer mitochondrial membrane. Thus, under normal conditions, MAO degradation of monoamines helps regulate presynaptic neurotransmitter stores.

■ MAO ISOFORMS

There are two MAO isoforms, each with their own substrate and inhibitor specificity (Table 71–1). MAO-A preferentially metabolizes norepinephrine and serotonin, and MAO-B preferentially metabolizes benzylamine in vitro. Both isoforms metabolize tyramine and dopamine equally efficiently, but they are localized to differing regions of mammalian anatomy, with MAO-A more concentrated in intestine and liver whereas MAO-B is more concentrated in the basal ganglia region of the brain.[22]

■ MECHANISM OF ACTION

Monoamine oxidase inhibitors are transported into the neuron by the Na^+-dependent membrane norepinephrine-reuptake transporter.[73] Inhibition of MAO prevents presynaptic degradation of monoamines, thus increasing the concentration of monoamine neurotransmitters available for synaptic storage and subsequent release (Fig. 71–1). Inhibition of MAO also results in some indirect release of norepinephrine into the synapse, via displacement from presynaptic vesicles by raising pH in a manner similar to amphetamines.[112]

Elevated synaptic concentration of serotonin is most closely correlated with the antidepressant therapeutic effects of MAOIs. As with other antidepressants, the enzymatic inhibitions produced by MAOIs precede their clinical effects by as long as 2 weeks. This finding may relate to relatively slow downregulation of postsynaptic CNS serotonin receptors.[90]

Monoamine oxidase inhibitors impair norepinephrine synthesis due to dopamine-β-hydroxylase inhibition. Impaired norepinephrine synthesis leads to eventual depletion of norepinephrine stores. Additionally, indirect dopamine agonism occurs via elevated synaptic concentrations of dopamine. Dopamine agonism results in β-adrenergic stimulation, peripheral vasodilation, and direct α-adrenergic stimulation at high doses.

TABLE 71–1. Monoamine Oxidase (MAO) Isoforms: Substrate Affinities and Localization

	MAO Isoforms	
	MAO-A	MAO-B
Substrate Affinity		
Dopamine	Moderate	Moderate
Epinephrine	Moderate	Moderate
Norepinephrine	High	Low
Serotonin	High	Low
Tyramine	Moderate	Moderate
Localization		
Brain	Low	High
Intestine	Moderate	Low
Liver	Moderate	Moderate
Placenta	High	Absent
Platelets	Absent	High

The hydrazide MAOIs (eg, phenelzine, isocarboxazid) are thought to be cleaved to liberate pharmacologically active products (eg, hydrazines) which are cleared by acetylation in the liver (see Chap. 117).

■ FIRST-GENERATION MAOIs: NONSELECTIVE AND IRREVERSIBLE

Monoamine oxidase inhibitors are a chemically heterogeneous group of xenobiotics (Fig. 71–2). First-generation MAOIs (ie, irreversible and nonselective) in clinical use include the reactive hydrazine derivatives (phenelzine, isocarboxazid) and an amphetamine derivative (tranylcypromine).[45] First-generation MAOIs bind covalently to MAO and irreversibly inhibit the enzyme's function. Thus, patients taking these MAOIs are depleted of the enzyme until new MAO is synthesized, a process that typically takes up to 3 weeks. Patients taking first-generation MAOIs remain at risk for food and xenobiotic interactions during much of this period. Because nonselective MAOIs inhibit both isoforms of MAO (ie, MAO-A and MAO-B), inhibition of intestinal and hepatic degradation of biogenic amines occurs. As a result, patients taking these xenobiotics must be placed on a restrictive diet to prevent adverse events resulting from the absorption of undigested tyramine from the gut.
FIGURE 71–1. Sympathetic nerve terminal. Dopamine is synthesized in the sympathetic nerve cell and transported into vesicles where it is converted to norepinephrine (NE); and stored in vesicles (⊙). An action potential causes the vesicles to migrate to and fuse with the presynaptic membrane. NE diffuses across the synaptic cleft and binds with and activates postsynaptic α- and β-adrenergic receptors. Neuronal NE reuptake occurs via the monoamine transporter. NE is transported back into vesicles by the vesicular monoamine transporter (VMAT; inset) or metabolized to 3, 4 dihydroxyphenyl acetic acid (DOPAC) by mitochondrial monoamine oxidase (MAO). NE that diffuses away from the synaptic cleft is inactivated by catechol-O-methyl transferase (COMT). AADC = aromatic L-amino acid decarboxylase; DBH = Dopamine beta-hydroxylase; HR= heart rate; NET = NE transporter.
FIGURE 71–2. Structural similarities between amphetamine and the monoamine oxidase inhibitors. The words in parentheses are the chemical classes of the MAOI.

Phenelzine, isocarboxazid, and tranylcypromine are currently FDA approved for treatment of refractory depression.[58,77] Pargyline, previously approved for use as an antihypertensive due to chronic effects to generally decrease sympathetic outflow, is no longer routinely used.[122] Metabolites of amphetamine, such as phentermine, are also nonselective MAO inhibitors.[118]

Other enzyme systems inhibited by first generation MAOIs include amine oxidases such as diamine oxidase and semicarbazide-sensitive oxidases, arylamine *N*-acetyltransferase (by tranylcypromine), ceruloplasmin, alcohol dehydrogenase (by tranylcypromine), dopa decarboxylase, L-glutamic acid decarboxylase, γ-aminobutyric acid (GABA) decarboxylase and GABA transaminase (by hydrazide MAOIs), alanine aminotransferase (by phenelzine), and other pyridoxine (B$_6$)-containing enzyme systems.[49] The clinical implications of inhibiting these diverse enzyme systems, other than cytochrome P450,[99] are poorly understood.

■ SECOND-GENERATION MAOIs: SELECTIVE AND IRREVERSIBLE

Selective MAOIs preferentially inhibit one of the two MAO isoforms, although isoform selectivity is lost as the dose is increased.

MAO-A Inhibitors Clorgyline is an MAO-A inhibitor which is structurally related to pargyline. Once thought to be useful for treatment of depression, it has not found a widespread therapeutic niche.

MAO-B Inhibitors Selegiline is a selective MAO-B inhibitor that is FDA approved for the treatment of Parkinson disease,[58] although it does exhibit weak MAO-A inhibition at therapeutic doses.[68] Selegiline transdermal system is FDA approved for treatment of major depressive disorder in adults as an alternative to the traditional oral delivery system.[6,58,94] Rasagiline is another MAO-B selective MAOI that is FDA approved to treat Parkinson disease.[19]

■ THIRD-GENERATION MAOIs: SELECTIVE AND REVERSIBLE

Reversible inhibitors of monoamine oxidase (RIMA) are reversible and thus do not bind to MAO for the "lifetime" of the enzymes, such

that high concentrations of substrate can displace the RIMA.[58] These drugs were developed in an effort to compensate for the limitations of first- and second-generation MAOIs (see Clinical Manifestations). RIMAs can be displaced by tyramine from the active site of the enzyme MAO-B, thereby enabling the amine to be metabolized peripherally. Because tyramine is not present in high concentrations in the brain, MAO-A continues to be inhibited and the antidepressant effects are achieved.[58] Moclobemide is the most widely studied RIMA and is approved as an antidepressant in Europe and other parts of the world but not currently in the United States.[33] Brofaromine and toloxatone are other RIMAs that were recently introduced but are less well studied.

■ NATURALLY OCCURRING MAOIs

The plant extract St. John's wort (*Hypericum perforatum*) is licensed in Germany for use as an antidepressant. Although hypericin or hyperforin have weak MAOI activity, it is debated whether this is responsible for its antidepressant effect. However, MAOI activity explains sporadic reports of hypertensive crises, cardiovascular collapse during anesthesia, and serotonin syndrome associated with use of this herbal product.[53,83]

Ayahuasca, a hallucinogenic beverage used by South American natives, uses an ethnobotanical mixture to circumvent gastrointestinal MAO. Dimethyltryptamine, which is derived from several local plant species, is a potent visual hallucinogen[27] that alone is not orally bioavailable because of its first-pass metabolism by MAO.[74] *Banisteriopsis caapi*, a plant containing the MAO-inhibiting harmala alkaloids, is mixed with dimethyltryptamine-containing plants to improve the bioavailability of this hallucinogenic amine.[74,75]

MAO-B activity in tobacco plants has prompted studies to find a link between the lower platelet MAO-B activity of smokers and their lower rate of Parkinson disease in this group.[18] This has led to interest in studying other MAO-B inhibitors for potential applications as neuroprotective xenobiotics.[125]

■ MISCELLANEOUS AND EXPERIMENTAL MAOIs

Some other xenobiotics with nonselective MAO inhibitory properties are used for purposes unrelated to MAO inhibition. Furazolidone is an antimicrobial used to treat protozoan-related diarrhea and bacterial enteritis. Procarbazine is a hydrazine derivative indicated as a chemotherapeutic agent for the treatment of Hodgkin lymphoma and some brain tumors. Linezolid is an antibiotic that produces weak, nonselective MAO inhibition.[30,108,116]

Research is active for novel MAO combination drugs that target multiple mechanistic approaches for the treatment of dementia and parkinsonism.[28] Ladostigil combines the cholinergic effects of a carbamate with the aminergic effects of MAO-B inhibition.[100] M30 is an actively researched drug that combines iron chelation and radical scavenger effects with irreversible, nonselective MAO inhibition.[35] Neither drug has been approved by the FDA.

PHARMACOKINETICS AND TOXICOKINETICS

Monoamine oxidase inhibitors are absorbed readily when given by mouth, and peak plasma concentrations are reached within 2–3 hours. Like other antidepressants, these xenobiotics are lipophilic and readily cross the blood–brain barrier. MAOIs are hepatically metabolized by both oxidation (various CYP450 isoenzymes including 2D6 and 2C19) and acetylation (*N*-acetyltransferase), and the metabolites are excreted in the urine.[8]

Phenelzine and isocarboxazid are hydrazides, as is the original MAOI, iproniazid. Hydrazides are metabolized to hydrazines.

The rate of metabolism of the hydrazide MAOIs is dependent on the *N*-acetyltransferase phenotype (ie, "acetylator status") of the patient (ie, fast or slow). About one-half of US populations are so-called slow-acetylators, which may contribute to exaggerated clinical effects despite standard therapeutic dosing or even mild overdose.

The clinical effects of MAOI inhibition occur rapidly and are usually maximal within a few days. First-generation (ie, irreversible) MAOIs have durations of effect that far surpass their pharmacologic half-lives, and recovery from their effects requires the synthesis of new enzyme over a period of up to 3 weeks ("washout period").[113] Thus, when switching from one serotonergic (ie, MAOI, SSRI, cyclic antidepressant), a sufficient washout must be allowed to prevent an adverse drug interaction.

PATHOPHYSIOLOGY

Increasing the concentration of norepinephrine, serotonin, and dopamine that are available for synaptic storage and release contributes to the majority of MAOI toxicity. Indirect release of monoamine neurotransmitters into the synapse as well as displacement of monoamine neurotransmitters (eg, norepinephrine) from vesicles (similar to amphetamines) also occurs.[112] These effects contribute to adrenergic stimulation that may lead to hyperadrenergic crisis. Furthermore, there is a synergistic effect on elevated presynaptic monoamine stores in the setting of coadministration with foods or xenobiotics that serve as substrates for, or enhancers of, monoamine formation, such as tyramine.[63]

Phenelzine and tranylcypromine are capable of stimulating the release of norepinephrine (and presumably other monoamines) from sympathetic nerve endings.[64] Norepinephrine release combined with MAO inhibition may result in so-called autopotentiation, or synergistic sympathomimetic effects. Autopotentiation may be responsible for paradoxical or hypertensive reactions sometimes observed following therapeutic doses of these xenobiotics.[5,23]

Hydrazide MAOIs, phenelzine and isocarboxazid are metabolized to hydrazines, which to some extent inactivate pyridoxal 5' phosphate, the cofactor necessary for neuronal decarboxylation of glutamic acid to the inhibitory neurotransmitter GABA. In addition, hydrazides may complex with pyridoxine, the precursor of pyridoxal 5' phosphate, thus enhancing its urinary elimination and further inhibiting the formation of neuronal GABA.[82] Decreased availability of neuronal GABA stores may lead to CNS excitation following overdose of hydrazide MAOIs (see Chap. 117 and Chap. 57).[61]

Impaired $GABA_A$ activity may contribute to symptoms of CNS excitation such as seizures which occur in MAOI overdose. In animal models, isocarboxazid and tranylcypromine directly inhibit GABA-mediated Cl^- influx at $GABA_A$ receptors.[109] The exact binding site of MAOIs on the $GABA_A$ receptor complex is unknown. Localization of GABA effects appears to be most pronounced in the caudate-putamen and nucleus accumbens areas in one animal model.[82] In addition, elevated neuronal glutamate concentrations due to MAOI effects may synergistically enhance CNS excitation.[102]

CLINICAL MANIFESTATIONS

The prescription of nonselective MAOIs is currently limited to resistant or atypical depression with prominent neurovegetative symptoms.[31] However, selective and reversible MAOIs are becoming the subject of renewed clinical applicability and basic science research interest. MAO-B selective drugs, such as selegiline, are used for the treatment of Parkinson disease. Reversible inhibitors of MAO, such as

moclobemide, are used in Europe for depression, phobias, anxiety, and other select indications.[124] Current applicability of a new generation of experimental MAOIs is being investigated as neuroprotective drugs used in a broadening variety of neurodegenerative diseases.[125]

■ HYPERADRENERGIC CRISIS WITH FOOD

Hyperadrenergic crisis occurs in patients with MAO-A inhibition when tyramine-containing food is ingested, such as aged cheeses and fermented drinks (see Table 71–2 for a complete list).[125] Tyramine is an indirect-acting sympathomimetic amine with an amphetamine-like mechanism of action.[127] Under normal circumstances, MAO-A present in the intestinal wall and liver extensively metabolizes dietary amines preventing them from entering the circulation. In the presence of irreversible MAO-A inhibition, however, this protective mechanism is lost, allowing tyramine and other dietary monoamines to enter the circulation.[12] The result is the amphetamine-like induction of a significant release of norepinephrine from peripheral adrenergic neurons and provocation of hyperadrenergic crisis. A meal that contains 6–8 mg of tyramine per serving can potentially precipitate this reaction, and ingestion of a total of 25–50 mg can produce a severe and possibly life-threatening reaction.[29,114,120] Additionally, despite compliance with diet, chronically elevated cytoplasmic and synaptic concentrations of norepinephrine due to therapeutic MAOI administration can lead to occasional and unpredictable adrenergic crisis in some patients. Dietary restrictions and recommendations for patients prescribed first-generation MAOIs are summarized in Table 71-2.[29,114,120] A "washout" period of 3 weeks is sufficient to allow the inhibition caused by the irreversible MAOIs to end and a normal diet may then be resumed.[115]

The clinical syndrome of tyramine-related hyperadrenergic crisis is characterized by hypertension, headache, flushing, diaphoresis, mydriasis, neuromuscular excitation, and potential cardiac dysrhythmias.[117] This reaction is subjectively reported in up to 10% of patients taking MAOIs chronically,[88] and can occur up to 3 weeks following discontinuation of the drug.[123] Monoamine oxidase inhibitors specific for the MAO-B isoform are less likely to predispose to food or drug interactions by maintaining significant hepatic MAO-A activity, however isoform specificity is lost as dose is increased.

TABLE 71–2. Dietary Restrictions for Patients Taking MAOIs

LOW Tyramine Content (0–4 mg/serving)	MODERATE Tyramine Content (4–8 mg/serving)	HIGH Tyramine Content (>8 mg/serving)
Cottage cheese, cream cheese, yogurt, sour cream	Avocado/guacamole	Aged, mature cheeses
Chocolate	Meat extracts	Broad beans or fava beans
Distilled alcohol	Pasteurized light and pale beers	Red wines, selected beers
Non-overripe fruit	Overripe fruit/ figs	Smoked, pickled, aged, putrefying meats or fish, caviar
Soy sauce	Banana peels or stewed whole bananas	Yeast and meat extracts
		Fermented sausage
		Liver

Recommendation: Foods with *high* tyramine content should be avoided, those with *moderate* content should be consumed in restricted moderation, and those with *low* content may be cautiously consumed.

■ SEROTONIN SYNDROME

Any xenobiotic with serotonin-potentiating activity can interact with the MAOIs to produce serotonin syndrome. Combinations of xenobiotics commonly implicated in this reaction are involved with serotonin synthesis (eg, L-tryptophan), release (eg, amphetamines), agonism (eg, triptans that are metabolized by MAO), neuromodulation (eg, lithium), or reuptake inhibition (eg, selective serotonin reuptake inhibitors, meperidine, dextromethorphan). Animal studies have demonstrated that both meperidine[104] and dextromethorphan[105] administration can lead to fatal serotonin syndrome. Serotonin syndrome most commonly occurs in patients receiving combination therapy with two or more serotonergic agents; however, it may rarely occur with just one serotonergic agent.[81]

Clinically, this syndrome runs a spectrum of severity,[13] and is described in detail in Chap. 72. Minor findings can include akathisia, myoclonus, hyperreflexia, diaphoresis, penile erection, shivering, hyperactive bowel sounds, and tremor. Tremor and hyperreflexia are typically greater in the lower extremities. Shivering classically described with this syndrome is visually similar to "wet dog shakes," which may be analogous to serotonergic-mediated behavior in rodents,[43] and can occur at a range of body temperatures.[80] Severe signs and symptoms can include life-threatening autonomic instability, muscular rigidity, and hyperthermia.

Several diagnostic schemes for serotonin syndrome exist.[13,25,47,89,110] However, the key diagnostic criterion is exposure to a serotonergic. Because no diagnostic test is yet available, the diagnosis of serotonin syndrome must be established on clinical grounds. The onset of clinical symptoms may occur within minutes after a change in medication or self-poisoning.[69] The majority of patients with serotonin syndrome develop symptoms within 6 hours. Serotonin syndrome is not thought to resolve spontaneously if the serotonergic exposure is ongoing. Key clinical features of MAOI-induced serotonin syndrome are summarized in Table 71-3.

■ OVERDOSE

Monoamine oxidase inhibitor overdose may result in severe and life-threatening clinical manifestations, especially if the MAOI is a first-generation drug such as phenelzine. Classically, the clinical course involves a biphasic response characterized by initial CNS excitation and peripheral sympathetic stimulation which terminates in coma and cardiovascular collapse.[66] This biphasic model is hypothesized to result from an initial adrenergic crisis followed by inhibition of norepinephrine release,[127] and is supported by animal studies.[37,41] Additionally, depletion of norepinephrine stores may be partially or fully responsible for late hypotension observed in MAOI overdose. Toxic dose-response relationships in man are unclear, but overdose of 5 mg/kg of a first-generation MAOI is potentially life threatening.[11,66] Clinical manifestations of MAOI overdose are summarized in Table 71–3.

Patients with MAOI overdose are initially asymptomatic for several hours. Delays in clinical toxicity are well described.[70,72,92] Unstudied hypotheses that might explain this phenomenon include all of the following: initial reversible binding to MAO, cumulative effects, time-dependent alterations to MAO substrate stores, individual acetylator status, and hydrolysis of the hydrazide MAOIs. However, it must be highlighted that clinical toxicity should generally occur within the first 24 hours after overdose.[66]

Neurologic effects can be categorized as neuropsychiatric effects, neuromuscular effects, mental status effects, seizures, and chronic effects. *Neuropsychiatric* effects include agitation, akathisia, and hallucinations. *Neuromuscular* effects include flailing and tremor of the extremities, nystagmus, opsoclonus, fasciculation, myoclonus, hypertonia, hyperreflexia, muscular irritability, and muscular rigidity, the latter of which may lead to secondary effects such as hyperthermia and rhabdomyolysis. Effects on *mental status* include a variable spectrum from confusion to coma, the latter of which is a typically end-stage finding. Seizures may be either partial or generalized, and decorticate or decerebrate rigidity may alternate with periods of flaccid paralysis. Chronic use of phenelzine is also associated with and isoniazid-like peripheral neuropathy,[42] possibly explained by pyridoxine deficiency.[111]

Severe hyperthermia (40.5°C or 105°F)[103] due to MAOI toxicity may have a multifactorial etiology and is an ominous sign. Temperature dysregulation may be due to adrenergic crisis, muscular hypertonia, or CNS effects. Rigors may be present. Secondary effects from severe hyperthermia include disseminated intravascular coagulation and metabolic acidosis.[72]

Cardiovascular effects follow the previously described initial hyperadrenergic crisis followed by cardiovascular collapse. Thus, initially, hypertension, tachycardia, palpitations, and tachydysrhythmias are to be expected.[56] In severe poisoning, late toxicity can include development of hypotension, reflex tachycardia or bradycardia, bradydysrhythmias, and sudden death.[70,93] Alterations in myocardial supply/demand dynamics may lead to myocardial injury with elevations of serum cardiac biomarkers (eg, troponin I). Myonecrosis[84] and myocarditis[121] are also attributed to MAOI overdose.

TABLE 71–3. Comparison of Clinical Manifestations due to MAOI Toxicity

Clinical Category	Hyperadrenergic Crisis	Serotonin Syndrome	MAOI Overdose
Onset	Minutes–hours	Minutes–hours	Up to 24 hours
Duration	Hours	Hours	Days
Temperature	Normal	Elevated	Elevated
Neurological	Headache, hemorrhagic stroke Neuromuscular excitation	Akathisia, hyperreflexia, shivering, tremor, seizures, autonomic instability, coma Myoclonus, "wet dog shakes," muscular rigidity	Neuropsychiatric effects, neuromuscular effects, headache, seizures Myoclonus, muscular rigidity
Cardiovascular	Hypertension, dysrhythmias, myocardial injury	Hypertension, hypotension, tachycardia, palpitations, dysrhythmias	Hypertension (early), hypotension (late), tachycardia, palpitations, dysrhythmias, myocardial injury
Gastrointestinal	Nausea	Hyperactive bowel sounds	Nausea, vomiting, diarrhea
Dermatological	Flushing, diaphoresis	Diaphoresis	Flushing, piloerection, diaphoresis
Ophthalmologic	Mydriasis	Mydriasis	Mydriasis, ocular clonus

Electrocardiographic (ECG) abnormalities may include ischemic ECG changes (contiguous lead findings of T-wave inversion or ST-segment depression/elevation). Peaked T waves, in the presence[66] or absence[87] of hyperkalemia, are also noted. Myocardial manifestations associated with catastrophic CNS processes (eg, intracranial hemorrhage) can also lead to T wave inversions.

In addition to the effects mentioned above and listed in Table 71–3, reported complications of MAOI overdose include acute renal failure,[66,70,84,93] fetal demise,[93] and hemolysis.[66,72]

SELEGILINE OVERDOSE

Selegiline is metabolized to L-methamphetamine, which may result in hypertension and tachycardia, even at therapeutic doses.[1,7,97] Because selegiline overdose has not been reported in the routinely accessible medical literature, the clinical consequences of such an event are unknown.

MOCLOBEMIDE OVERDOSE

Moclobemide overdose typically produces mild to moderate CNS depression (drowsiness, disorientation), GI effects (nausea), and cardiovascular effects (tachycardia and mild hypertension).[33,76] Serotonin syndrome due to the ingestion of moclobemide, alone[51] and in combination with other serotonergics,[24,50,78,119] is well described. In massive overdose, fatalities attributed solely to the toxic effects of moclobemide have been reported.[17,34,40]

OTHER ADVERSE DRUG REACTIONS

Clinically significant drug interactions with MAOIs can be due to serotonergic effects (see Serotonin Syndrome earlier) as well as alterations to drug metabolism. Administration of opioids with serotonergic properties (eg, meperidine, dextromethorphan) is absolutely contraindicated due to risk of precipitating the serotonin syndrome.[13,39,96,104,105] Adverse drug reactions with other coadministered drugs that are metabolized by cytochrome P450 may be problematic, as first-generation MAOIs have an extensive inhibitory effect on hepatic cytochrome P450 enzymes 2C9, 2C19, and 2D6.[8,99] Thus, barbiturates (eg, phenobarbital) and benzodiazepines (eg, diazepam, lorazepam) that are metabolized by hepatic cytochrome P450 may produce prolonged sedation and respiratory depression. Table 71–4 summarizes analgesic safety in combination with MAOI drugs.[39]

TABLE 71–4. Adverse Drug Events Associated with Monamine Oxidase Inhibitors

Analgesic Class	Safe	Monitor Closely and Consider Alternative	Avoid Combination (*Contraindicated*)
Nonprescription	Acetaminophen Aspirin NSAIDs		Dextromethorphan
Opioids	Buprenorphine Codeine Morphine Oxycodone	Fentanyl Propoxyphene Remifentanil	Meperidine Methadone Pentazocine
Nonopioids	Inhalational anesthetics Nitroglycerin	Barbiturates[†] Benzodiazepines[†] Ethchlorvynol	Cyclobenzaprine Tramadol
Local anesthetics	Lidocaine		Cocaine

† Drugs that are metabolized by hepatic cytochrome P450 may produce prolonged sedation and respiratory depression when combined with MAOIs.

WITHDRAWAL REACTIONS

Monoamine oxidase inhibitor withdrawal may be severe, beginning 24–72 hours after discontinuation. Classically, MAOI withdrawal symptoms are the worst following discontinuation of high therapeutic doses of tranylcypromine and isocarboxazid.[9] Symptoms range from nausea, vomiting, and malaise, to CNS symptoms such as agitation, psychosis, and convulsions. Treatment is generally supportive and typically involves a benzodiazepine such as diazepam and restarting the medication if clinically indicated.

DIAGNOSTIC TESTING

The clinical utility of therapeutic drug monitoring in the routine use of MAOIs is limited. Evaluation of MAO activity is not routinely available, requires a fresh specimen (preferably jejunal biopsy),[65] and is therefore not recommended. Experimental evidence suggests that inhibition of human platelet MAO-B activity by at least 85% may be associated with a favorable clinical antidepressant response to phenelzine.[32,36]

Evaluation of MAOI toxicity remains a clinical diagnosis. Serum concentrations of MAOIs that correlate meaningfully with clinical effects are not well established. In addition, serum concentrations of any antidepressant, in general, can be misleading when obtained postmortem for forensic purposes.[86,95] Hyperglycemia and leukocytosis may be present. Elevations in serum lactate concentrations and metabolic acidosis may be present from seizures, muscular hypertonia, or hyperthermia.

Measurement of blood and urinary concentrations of MAO substrates may provide indirect evidence of MAOI effects. MAOIs may cause increase serum serotonin, increase or decrease serum norepinephrine, increase urinary epinephrine and norepinephrine, and decrease urinary serotonin metabolites. Due to the indirect nature of this testing and the fact that its interpretation is frought with confounding factors (eg, if the patient is receiving vasopressors), the routine measurement of plasma and urinary MAO substrates is not recommended in the assessment of MAOI toxicity. Of note, patients taking selegiline[101] and tranylcypromine[128] may test positive for amphetamines on drug screens due to their metabolites.

MANAGEMENT

OUT OF HOSPITAL

Decisions regarding referral to the emergency department (ED) must take into account factors such as patient age, intent of exposure, symptoms, as well as timing of exposure. All patients with MAOI exposures who display suicidal intent should be referred to an ED for evaluation. Children with exposure to even one adult formulation MAOI tablet or selegiline patch should be referred to the ED due to the potential for late-onset significant toxicity.[3] Patients who exhibit more than mild headache, minimal diaphoresis following an acute MAOI ingestion should be referred to an ED. Observation at home is warranted in patients who are asymptomatic and more than 24 hours have elapsed since the time of ingestion. Due to paucity of data at this time, patients with selegiline patch ingestions should be referred to the ED for observation, even if suicidal intent is absent.

PRE-HOSPITAL

Induction of emesis is not recommended.[3] Activated charcoal can be administered to asymptomatic patients who have ingested overdoses of MAOI if no contraindications are present.[2] Transportation to the hospital should not be delayed in order to administer activated charcoal. Use of intravenous benzodiazepines for seizures and external cooling

measures for severe hyperthermia (40.5°C [105°F])[103] should be performed in consultation/authorization with EMS medical direction, by a written treatment protocol or policy, or with direct medical oversight.

■ INITIAL APPROACH IN THE EMERGENCY DEPARTMENT

As with any serious ingestion, initial stabilization must include rapid assessment of the airway, breathing, and circulation as well as establishment of intravenous access, supplemental oxygen, and cardiac monitoring. Evidence of hyperthermia or hemodynamic instability following MAOI ingestion may be a manifestation of significant toxicity. Intravenous volume repletion should begin while gastrointestinal decontamination is considered. In any patient with altered mental status who will likely deteriorate progressively, early orotracheal intubation may facilitate safe gastric decontamination measures. Subsequent management should focus on stabilization of hyperthermia, seizures, and muscular rigidity.

■ GASTRIC DECONTAMINATION

Patients who overdose with MAOIs are more likely to benefit from gastrointestinal decontamination than most other overdose patients because of their high potential for morbidity/mortality.[59,85] Orogastric lavage with a large bore orogastric tube (36-40 French) should be considered if a life-threatening ingestion is suspected to have occurred within several hours prior to presentation.[39,59,85] Single-dose activated charcoal should be orally administered for ingestions presenting within several hours, unless contraindications are present. Whole bowel irrigation with oral polyethylene glycol has limited utility unless there are co-ingestions with other sustained-release preparation medications. The lack of early clinical findings of poisoning should not dissuade the use of gastrointestinal decontamination given the potential for delayed clinical deterioration.

■ COOLING MEASURES

Severe hyperthermia must be treated aggressively. Use of ice baths (first choice for life-threatening hyperthermia),[106] cold water, and fans are the mainstay of treatment (see Chap. 15). Indications for ice bath immersion to treat MAOI toxicity include rectal temperature greater than 40.5°C (105°F),[103] rigidity, and altered mental status. If an ice bath is unavailable, ice packs should be placed in both the axillae and the groin. Benzodiazepines help control muscular rigidity, seizures, and agitation that may contribute to amelioration of hyperthermia and tachycardia. Patients with refractory hyperthermia despite the above measures may require neuromuscular blockade, using nondepolarizing paralytics, in conjunction with tracheal intubation and ventilation. The depolarizing paralytic succinylcholine should be avoided in severe MAOI toxicity due to the risk of precipitating lethal dysrhythmia due to hyperkalemia in the setting of rhabdomyolysis. Neuromuscular blockade eliminates hyperthermia that results from muscular rigidity, and can be employed if first-line treatments are unsuccessful. Antipyretics such as acetaminophen are unlikely to be efficacious because the hyperthermia is not due to alterations in the hypothalamic temperature set point.[103]

■ BLOOD PRESSURE CONTROL

Because there is characteristic fluctuation in vital signs associated with MAOI overdose, hemodynamic monitoring should be instituted even for patients who initially are stable. When supporting the patient's blood pressure, preference should be given to titratable drugs with a rapid onset and termination of action because of the potential for rapid hemodynamic changes. Use of β-adrenergic antagonists is relatively contraindicated for control of hypertension in MAOI-related toxicity because the action of monoamines (eg, norepinephrine) at the neuronal synapse in the autonomic nervous system could result in refractory hypertension due to unopposed α-adrenergic agonism.[91]

Patients who are normotensive at baseline and who experience MAOI-related severe *hypertension* can be treated with a short-acting α-adrenergic antagonist such as phentolamine (2–5 mg IV) for effective control.[12] Xenobiotics such as nitroprusside and nitroglycerin may be preferred because they allow for titratable blood pressure control.[21] Tyramine-related hypertensive crises can successfully be controlled with the dihydropyridine calcium channel blockers such as nifedipine and possibly the oral α-adrenergic antagonists such as terazosin but should be used with caution.[20,48] Particular caution must be exercised in patients with baseline hypertension because overly aggressive blood pressure lowering may reduce cerebral perfusion pressure sufficiently to cause cerebral ischemia.

Patients who are *hypotensive* may require aggressive support with intravenous fluid resuscitation and vasopressors. Direct-acting sympathetic agents (eg, epinephrine, norepinephrine) can be used safely in patients taking MAOIs.[14] Rather than causing release of a stored pool of norepinephrine, these xenobiotics bind directly with postsynaptic α- and β-adrenergic receptors.

Dopamine is relatively contraindicated in hypotensive patients who have overdosed on MAOIs for several reasons. The indirect action of dopamine administration may produce a synergistic effect with MAOI, resulting in excessive adrenergic activity and exaggerated rises in blood pressure. In addition, most of dopamine's α-adrenoceptor–mediated vasoconstriction is secondary to norepinephrine release; in the presence of MAOIs, norepinephrine synthesis may be impaired from concomitant dopamine-β-hydroxylase inhibition, and dopamine may not reliably raise blood pressure if cytoplasmic and vesicular neuronal stores have been depleted. Finally, in the presence of impaired norepinephrine release or α-adrenergic blockade by any cause, unopposed dopamine-induced vasodilation from action on peripheral dopamine and β-adrenoceptors may paradoxically lower blood pressure further.

■ DYSRHYTHMIAS

Due to the unique pharmacological and toxicokinetic considerations of MAOI toxicity, adherence to advance cardiac life support (ACLS) protocols may not provide optimal results.[4] In any stable patient, removal of the offending xenobiotic as well as correction of hypoxia, hypokalemia, and hypomagnesemia, if present, is a rational initial step.

Patients with immediately *life-threatening dysrhythmias* require rapid cardioversion. In the presence of the nonperfusing dysrhythmias such as ventricular fibrillation, pulseless ventricular tachycardia, and torsades de pointes unsynchronized electrical defibrillation is the treatment of choice.

Stable patients with *ventricular tachycardia* may benefit from a trial of antidysrhythmic drugs such as amiodarone or lidocaine. High-quality studies evaluating the use of these xenobiotics in the setting of MAOI overdose are not available.

Hemodynamically significant *supraventricular tachycardia* from MAOI toxicity should be corrected to prevent myocardial ischemia/infarction, ventricular dysrhythmia, and high-output heart failure. Benzodiazepines are safe and effective to treat sinus tachycardia, as long as respiratory status remains monitored. Adenosine and synchronized cardioversion are unlikely to be useful in the setting of ongoing presence of the MAOI, but may be considered in rare cases that are unresponsive to benzodiazepines. In patients with borderline hypotension, nondihydropyridine calcium-channel antagonists such as diltiazem and verapamil are relatively contraindicated because they may further lower blood pressure.

Hemodynamically significant *bradycardia* from MAOI toxicity may be refractory to standard ACLS protocols. An initial approach with intravenous atropine is a rational first-line therapy to temporize the patient with bradycardia and hypotension. Epinephrine and isoproterenol may also be considered. Multiple boluses of atropine in conjunction with intravenous fluid resuscitation may be necessary, while a pacemaker (transcutaneous or transvenous) is considered.

MANAGEMENT OF CNS MANIFESTATIONS

In acute altered mental status, hypoglycemia should be rapidly excluded.[15,98] Mild to moderate CNS excitation may be treated with small incremental doses of parenteral diazepam. Seizures should be treated with benzodiazepines such as lorazepam in standard incremental doses. Empiric administration of pyridoxine (vitamin B$_6$), intravenously at 70 mg/kg, up to 5 g in adults) should be considered in patients with status epilepticus, particularly following massive ingestions of hydrazine-derived MAOIs such as phenelzine which may deplete endogenous pyridoxine stores (see A-15 Pyridoxine).[111] Theoretically, phenytoin is not likely to be useful for treatment of MAOI-induced seizures because there is no distinct seizure focus, but rather generalized presence of MAOI (and metabolites) in the CNS.

CYPROHEPTADINE

Cyproheptadine is a nonselective serotonin antagonist that is recommended as third-line therapy (after benzodiazepine administration and cooling measures) for MAOI-induced serotonin syndrome.[13] Cyproheptadine prevents lethality in animal models of serotonin syndrome[79] and reportedly is beneficial in humans with serotonin syndrome although its efficacy has not been rigorously established.[38,44] It should be strongly considered when the diagnosis of serotonin syndrome is likely, especially if incomplete response has been achieved with aggressive cooling and benzodiazepine therapy.[62] In addition, its use to treat neuromuscular rigidity and hyperthermia associated with MAOI overdose has been reported.[10,26]

The recommended initial dose in adults is 12 mg orally, to be followed by 2 mg every 2 hours while symptoms continue.[13] Maintenance dosing involves the administration of 8 mg of cyproheptadine every 6 hours. A dose of 12–32 mg will bind 85%–95% of serotonin receptors.[55] The dose of cyproheptadine used to treat the serotonin syndrome may cause sedation, but this effect is a goal of therapy and should not deter clinicians from using the drug. Relative contraindications to its use include acute asthma exacerbation, GI obstruction, and age less than 2 years (due to lack of safety information for this age group).

DANTROLENE

Use of dantrolene in patients with serotonin syndrome is not recommended (see Antidote in Depth A22: Dantrolene Sodium). Case reports citing its utility probably involved a misdiagnosis of serotonin syndrome.[13,54] Dantrolene is indicated for treatment of malignant hyperthermia, a disease generally considered to be unrelated to serotonin syndrome. In animal models of serotonin syndrome, dantrolene administration has no effect on survival.[52,79] Use of dantrolene in one report of serotonin syndrome was implicated with causing fatality.[57]

EXTRACORPOREAL ELIMINATION

The utility of extracorporeal measures, such as hemodialysis, to treat MAOI toxicity remains to be demonstrated. The ability to dialyze a xenobiotic depends largely on its protein binding the volume of distribution. Unfortunately, data regarding protein-binding and volumes of

distribution of the first generation MAOI drugs such as isocarboxazid are not well characterized. Use of peritoneal dialysis[67] and hemodialysis[71] to treat MAOI overdose has been reported in the literature. However, time to resolution of symptoms for all cases did not differ (~24 hours) from those in which hemodialysis was not employed. Therefore, extracorporeal elimination is not recommended in the management of MAOI overdose unless other indications are present such as severe acidemia or life-threatening hyperkalemia, or the need to eliminate dialyzable toxic co-ingestions.

DISPOSITION

Recommendations for the ideal time frame for observation of patients with suspected MAOI overdose are limited by a paucity of relevant studies in the clinical toxicology literature. Patients with presumed MAOI overdose should be observed with telemetry monitoring, preferably in an intensive care unit, for at least 24 hours regardless of the initial clinical findings. This recommendation takes into account the potential for delayed-onset of clinical toxicity as well as the potential for severe morbidity and mortality.[70,72,92] However, patients with MAOI–food or MAOI–xenobiotic interactions may not require hospital admission if the interaction is mild, resolution of symptoms is complete, and the patient has been observed for 4–8 hours.

SUMMARY

Toxicity from MAOI exposures is becoming less common due to more limited clinical usage of the traditional nonselective MAOIs; however, clinical and research use of selective MAOIs and RIMAs is increasing. Inhibition of MAO has effects on myriad neuronal neurotransmitters which are responsible for the majority of the therapeutic and toxic effects of MAOIs. The clinical effects of MAOI overdose may be life threatening and should be managed aggressively. Other consequential manifestations of MAOI toxicity may include hyperadrenergic crisis and the serotonin syndrome.

CHAPTER 72

SEROTONIN REUPTAKE INHIBITORS AND ATYPICAL ANTIDEPRESSANTS

Christine M. Stork

Antidepressants modulate the activity of serotonin and norepinephine to achieve their effect. The class of selective serotonin reuptake inhibitors (SSRIs) includes citalopram, escitalopram (active enantiomer of citalopram), fluoxetine, fluvoxamine, paroxetine, and sertraline (Fig. 72–1). Atypical antidepressants expand the pharmacologic principles of SSRIs to achieve additional beneficial effects for patients with depression.

In a brief period of time these new xenobiotics have become the standard, with excellent profiles as compared to the monoamine oxidase inhibitors and the cyclic antidepressants. Like many new xenobiotics the appropriateness of their use and the associated morbidity and mortality have come into question as the patient population has aged and comorbidity profiles of those using the SSRIs have changed.

HISTORY AND EPIDEMIOLOGY

SSRIs initially were marketed in the United States in the early 1980s and still are considered a first-line therapy for treatment of depressive disorders in the United States and in Europe.[18,164,209] SSRIs are as effective as the cyclic antidepressants and monoamine oxidase inhibitors for treatment of major depression and have fewer significant side effects associated with therapeutic use and overdose (Chaps. 71 and 73).[67,135] SSRIs also are used to treat obsessive-compulsive disorders, panic disorders, alcoholism, obesity, and various medical and psychologic disorders such as migraine headache and chronic pain syndromes.[10,147,154]

An increased risk of suicidal behavior is reported with the use of many antidepressants compared with nondrug therapy or no therapy.[6,126] This is particularly true in children. The reason for this finding may be related to delayed onset of drug efficacy coupled with the increased energy associated with the initiation of drug therapy.

PHARMACOLOGY

Table 72–1 lists the pharmacology, therapeutic doses, and metabolism of the currently available SSRIs and the atypical antidepressants. Modulation of serotonin and norepinephrine neurotransmission has a significant role in the treatment of depression.[173] The selectivity of SSRIs for serotonin reuptake is structurally related to p-trifluoromethyl or p-fluoro substitution, which is present in many of these drugs.[218] Serotonin neurons are located almost exclusively in the median raphe nucleus of the brainstem, where they extend into and are in close proximity to norepinephrine neurons that are located primarily in the locus coeruleus (Fig. 72–2).[9] The interplay between norepinephrine and serotonin likely explains the effectiveness of other atypical antidepressants that do not directly modulate serotonin neurotransmission.

The exact etiology of depression and the mechanism by which increased serotonergic and norepinephrine neurotransmission modulates mood remain unclear. Some postulated causes of depression include decreased neuronal serotonin storage, decreased synaptic serotonin, increased serotonin receptor sensitivity, and serotonin overactivity resulting in depressed dopamine neurotransmission.[173,196,212,216] According to the first theory, desensitization and downregulation of serotonin of the somatodendritic and presynaptic inhibitory autoreceptors occur after extended use of SSRIs.[34] Ultimately these effects result in increased activity of raphe neurons, increased synthesis of serotonin, and increased release of serotonin. Unfortunately, no difference in the concentration of serotonin binding sites is reported between depressed patients who respond to SSRIs and those who do not respond.[182] In the second theory, SSRIs potentiate the activity of neuronally released serotonin at 5-HT$_{2A}$ receptors and subsequently decrease the sensitivity of the serotonin receptor.[34] In depressed patients, these receptors are downregulated after treatment, but no overall difference in receptor activity is observed between depressed and nondepressed populations. Finally, increased serotonergic activity, particularly at 5-HT$_{2A}$ receptors, is theorized to result in antidepressant activity through modulation of dopaminergic release.[216] Although the causes of depression are diverse and not well understood, recent data indicate that genetic polymorphisms of the serotonin transporter may play a role in individual response to SSRI therapy.[166]

Unlike cyclic antidepressants and other atypical antidepressants, SSRIs have little direct interaction with cholinergic receptors, γ-aminobutyric acid (GABA) receptors, sodium channels, or adrenergic reuptake (Table 72–2).

PHARMACOKINETICS AND TOXICOKINETICS

The SSRIs display diverse elimination patterns and have numerous active metabolites, which substantially increase both the duration of therapeutic effectiveness and the duration during which drug interactions and adverse drug effects can occur after the drug is discontinued (Table 72–1). Important pharmacokinetic and pharmacodynamic drug interactions are reported with therapeutic dosing (see Serotonin Syndrome). The SSRIs and their active metabolites are substrates for, and potent inhibitors of, CYP2D6 and other CYP enzymes.[89,174] For example, fluoxetine, fluvoxamine, citalopram, venlafaxine, mirtazapine, paroxetine, and sertraline are substrates for CYP2D6, whereas paroxetine, norfluoxetine, and fluoxetine inhibit the same enzyme (Table 72–1). Alternatively, mirtazapine induces CPY3A4 enzymes, while trazodone metabolism may be decreased after this same enzyme is inhibited.[191,197] The consequences of these interactions are manifest when the metabolism of xenobiotics that rely on these enzymes for metabolic transformation is altered (Chap. 12).

CLINICAL MANIFESTATIONS

■ ACUTE OVERDOSE

The majority of effects that occur following overdose are direct extensions of the pharmacologic activity of SSRIs in therapeutic doses. Excess serotonergic stimulation is prominent and nonselective. Acute signs and symptoms include nausea, vomiting, dizziness, blurred vision, and, less commonly, central nervous system (CNS) depression and sinus tachycardia.[28,30] Seizures and electrocardiographic changes including prolongation of the QRS complex and QT internal duration are reported, but rarely occur with most SSRIs, even after large overdoses (Table 72–3).[93,110,168]
FIGURE 72–1. Structures of common selective serotonin reuptake inhibitors. Citalopram is shown as the *S*-enantiomer (escitalopram).

Infrequently, SSRI overdose results in life-threatening effects. In two fatalities, the patients reportedly ingested 40–75 times the maximum daily dose of fluoxetine. Serum fluoxetine concentrations were 4500 and 6000 ng/mL, the latter with a measured norfluoxetine concentration of 5000 ng/mL—more than 10 times higher than therapeutic steady-state serum concentrations.[43,116]

Citalopram Citalopram and its enantiomer escitalopram cause QT interval prolongation and seizures in a dose-related manner. These effects are reported at doses as low as 400 mg for citalopram and 190 mg for escitalopram.[40,223] Larger case series found that these effects typically occur after exposure to doses exceeding 600 mg citalopram or in patients with serum concentrations more than 40 times the expected therapeutic concentrations.[90,160,161] In two large case series, seizures were an early finding, whereas the development of ECG abnormalities was delayed for as long as 24 hours following ingestion.[108,161] A recent case report documents prolongation of the QT interval and torsades de pointes occurring at 32.5 hours after ingestion with concentrations of citalopram and desmethylcitalopram of 477 mg/mL and 123.2 mg/mL, respectively.[205]

Although the mechanisms are unclear, experimental models suggest that the didesmethylcitalopram metabolite of citalopram prolongs the QT interval by blocking I_{Kr}, whereas high concentrations of both the parent drug and this metabolite result in seizures (Chaps. 22 and 23).[27,37] The elimination half-life of the *R*-enantiomer of citalopram appears to exceed that of the *S*-enantiomer.[213] The implications of this difference on the formation and effects of racemic forms of didesmethylcitalopram are unclear.

Management Treatment of patients with acute SSRI overdose is largely supportive. Dextrose and thiamine should be considered for patients who present with altered mental status when clinically warranted. Although cardiac manifestations after SSRI overdose are rare, a 12-lead ECG should be obtained to identify other cardiotoxic drugs such as cyclic antidepressants to which the patient may have access (Chaps. 22, 23 and 73). If overdose of citalopram or escitalopram is suspected, 24 hours of cardiac monitoring is recommended to exclude the possibility of QT prolongation and subsequent risk for ventricular dysrhythmias. In a single case, sodium bicarbonate was effective in reversing junctional bradycardia, and QT prolongation.[35]

After the patient is stabilized, oral activated charcoal (1 g/kg) may be useful to adsorb drug remaining in the gastrointestinal tract. In fact, pharmacokinetic lowering of blood concentrations and reduction in risk for QT prolongation is demonstrated when activated charcoal is given early after citalopram ingestion.[69,70] Because SSRI overdose is rarely life threatening, orogastric lavage is not generally indicated. Patients with small unintentional overdoses of SSRIs other than citalopram and escitalopram are not expected to develop significant signs and symptoms of poisoning. Fatalities resulting from SSRIs are rare and most commonly occur after multiple drug ingestions and manifestations of drug interactions resulting from excess serotonergic effects (see Serotonin Syndrome).[84] Forensic analysis suggests the minimum lethal concentrations of fluoxetine, paroxetine, and sertraline after isolated overdose are 0.63, 0.4, and 1.5 mg/L, respectively. Postmortem concentrations of citalopram include a heart blood concentration of 3.35 mg/L, a whole blood concentration of 11.6 mg/L, and urine concentrations of 32.43–149.67 mg/L.[105,131] When mono-n-desmethylcitalopram was measured, concentrations of 1.02 mg/L were found in the blood and 12.1 mg/L in the urine. A case of infant survival occurred with blood concentrations of 1.4 mg/L.[133]

Patients, frequently children, with well-defined small unintentional oral ingestions can be managed safely at home with close observation.[146]

■ ADVERSE EFFECTS AFTER THERAPEUTIC DOSES

Adverse effects commonly attributed to therapeutic doses of SSRIs that also may occur in overdose include gastrointestinal symptoms (anorexia, nausea, vomiting, diarrhea), sexual dysfunction in both men and women, headache, insomnia, jitteriness, dizziness, and fatigue.[220] Genetic polymorphism typing holds promise in identifying patients at highest risk for adverse drug events with therapeutic dosing.[23,98,195,222] However, pharmacokinetic polymorphisms do not appear to be important with fluoxetine.[80] Less common adverse effects include sedation, particularly following citalopram and paroxetine use as a result of their weak anticholinergic activity, and anxiety following fluoxetine treatment.[129]

Serotonin activity inhibits platelet secretory response, platelet aggregation, and platelet plug formation.[51] Although the effect increases in SSRIs with increased potency, clinical bleeding is rare and significant only in patients concurrently on other antiplatelet medications, most notably nonsteroidal antiinflammatory drugs such as aspirin.[51,137] This effect may be of potential benefit in patients at risk for cardiovascular events.[134] Other rarely reported adverse effects include new onset panic disorder, priapism, various cutaneous effects, bradycardia, hepatotoxicity, and urinary incontinence.[2,22,32,58,121,143,198] Movement disorders,

most commonly akathisia, parkinsonism, myoclonus, and dystonia, also occur after SSRI use.[7,185] These extrapyramidal side effects may be related to the complex interplay between serotonergic and dopaminergic activity. Predisposing factors for the development of movement disorders include concomitant use of dopamine antagonists such as the antipsychotics.[122]

The syndrome of inappropriate antidiuretic hormone (SIADH) (see Chap. 16), in which severe hyponatremia may occur rapidly, is associated with SSRI use. In an animal model, the effect appears to be serotonin mediated, with increased concentrations of serum cortisol, adrenocorticotropin (ACTH), and vasopressin.[72] Rat studies demonstrate that stimulation of $5HT_{1C}$ receptors increases antidiuretic hormone secretion.[159] However, human case control studies have not confirmed defects in osmoregulated release of vasopressin through normal water loading tests and measurement of vasopressin concentrations after 3–11 months of paroxetine use.[132] A review of the literature identified women older than 70 years who are concomitantly receiving diuretic therapy and have low baseline serum sodium concentrations to be at the greatest risk for developing SIADH.[24,112,117] Although reported to occur from 3 days to 4 months after initiation of therapy, a case-matched control study of 203 patients identified that SIADH occurs most frequently within the first 2 weeks of therapy.[142] Hyponatremia is demonstrated to occur when switching from one SSRI to another.[8] Efforts to predict risk through poor CYP2D6 genotype metabolizer status or high serum concentrations have not been successful.[200]

Patients older than 50 years of age using SSRIs may be at increased risk for bone fracture theorized due to a serotinergic effect on osteoblasts and osteocytes.[172] However, depression itself is also implicated in decreasing bone density in adults and children, and the implications of these findings are unknown.[214]

Buspirone[11,85]

Cocaine[206]

Lithium[119,144,151]

Mirtazapine[20,55,57]

Serotonin Syndrome The most common severe adverse effect associated with SSRIs is the development of the serotonin syndrome. This syndrome, also referred to as the serotonin behavioral or hyperactivity syndrome, was first described in patients treated with MAOIs who were given other drugs that enhance serotonergic activity.[42,88,153,194] However, ingestion of an MAOI is not required for this syndrome to develop, and its development is unpredictable (Table 72–4).

Pathophysiology. The pathophysiologic mechanism of the serotonin syndrome is not completely understood but involves excessive selective stimulation of serotonin 5-HT_{2A} and perhaps 5-HT_{1A} receptors.[29] Animal models demonstrate that specific stimulation of 5-HT_{1A} receptors results in signs and symptoms of serotonin syndrome even when 5-HT_{2A} receptors were inactivated using a specific antagonist.[48] However, a subsequent animal study and a human retrospective case series showed that the potency of 5-HT_{2A} antagonist therapy was directly related to resolution of symptoms attributed to serotonin syndrome.[81] 5-HT_{1D} receptors are not implicated in cases of serotonin syndrome.

Clinical Manifestations. Symptoms of serotonin syndrome include altered mental status, agitation, myoclonus, hyperreflexia, diaphoresis, tremor, diarrhea, incoordination, muscle rigidity, and hyperthermia (Table 72–5). The clinical manifestations of serotonin syndrome are diverse, and minor manifestations are common after initiation of SSRI and atypical antidepressant therapy. In fact, a prospective study of depressed inpatients given clomipramine demonstrated that 16 of 38 patients experienced symptoms consistent with the serotonin syndrome, 14 of whom spontaneously recovered within 1 week without discontinuation of therapy.[125]

Life-threatening effects invariably result from hyperthermia caused by excessive muscle activity which may be more prominent in the lower extremities. Sustained severe hyperthermia can lead to death through denaturation of essential protein and enzymatic function that ultimately results in elevated lactate and metabolic acidosis, rhabdomyolysis, myoglobinuria, renal and hepatic dysfunction, disseminated intravascular coagulation, or adult respiratory distress syndrome (Chap. 15).[138,201]

Diagnosis. The serotonin syndrome occurs most frequently following use of combinations of serotonergic agents (Table 72–4). Xenobiotic interactions resulting in serotonin syndrome can occur while switching serotonergic pharmacologic agents when an insufficient time lag occurs before initiating the alternative therapy.[179,180] Residual pharmacologic effect, receptor downregulation or upregulation, and the presence of active metabolites may be causative in these circumstances. For example, fluoxetine metabolism results in the active metabolite norfluoxetine, which has comparable pharmacologic effects and a half-life substantially longer than that of the parent xenobiotic. The metabolite persists and may result in serotonin syndrome when another serotonergic agent, usually another antidepressant, is given prior to complete clearance of norfluoxetine, which takes approximately 2 weeks.[44]

This syndrome is reported in patients following a single dose, high therapeutic dosing, or overdoses of certain serotonergic agents in adults and children.[47,78,94,114,126,157,169] Although sporadic reports occur, selective MAO subtype B (MAO-B) inhibitor drug combinations are rarely reported to result in serotonin syndrome at therapeutic doses.[61,140]

Currently no diagnostic test capable of determining whether a patient is experiencing serotonin syndrome is available. A single case report demonstrated increased urinary serotonin concentrations after serotonin syndrome.[36] Although fulminant life-threatening cases are easy to recognize, mild cases are more difficult to distinguish from other causes. In an effort to determine diagnostic criteria, a study that included 38 cases of presumed serotonin syndrome was performed. This trial led to suggested diagnostic criteria for serotonin syndrome that include three of the following signs and symptoms—altered level of consciousness, agitation, myoclonus, hyperreflexia, diaphoresis, tremor, diarrhea, and incoordination—when other etiologies are excluded.[202] A modification, the Hunter Serotonin Toxicity Criteria, which included the variables myoclonus, agitation, diaphoresis, hyperreflexia, hypertonicity, and fever, was validated in 473 patients and found to correlate best with a clinical toxicologic diagnosis of the serotonin syndrome.[63,201] The most comprehensive review of signs and symptoms in a literature review found altered mental status, other neurologic signs and symptoms, vital signs, and autonomic manifestations most commonly associated with the development of serotonin syndrome. Diagnostic criteria based on these clinical findings are given in Table 72–5.[167]

Management. Treatment of patients with serotonin syndrome begins with supportive care and focuses on decreasing muscle rigidity. Because muscular rigidity is thought to be partly responsible for hyperthermia and death, rapid external cooling in conjunction with aggressive use of benzodiazepines should limit complications and mortality. In severe cases, neuromuscular blockade should be considered to achieve rapid muscle relaxation. The time course of the serotonin syndrome is variable and related to the time required to offending drug effects. In most patients, the serotonin syndrome resolves within 24 hours after the offending drug is removed. However, the serotonin syndrome can be prolonged when it is caused by drugs with long half-lives, protracted duration of effects, or active metabolites.

Animal models indicate that pretreatment with serotonin antagonists can prevent development of the serotonin syndrome.[77,103,199] Several case reports indicate the successful use of 4 mg oral or intravenous cyproheptadine, an antihistamine with nonspecific antagonist effects at 5-HT$_{1A}$ and 5-HT$_{2A}$ receptors.[88,123] Current recommendation allows doses at 8–16 mg. Patients who responded typically had mild to moderate symptoms of serotonin syndrome and were not hyperthermic evidence supports the use of cyproheptadine in this patient group. Further research is warranted to determine the success of higher doses given to gain sufficient 5-HT$_{2A}$ antagonistic effects in more severely affected patients.[81] Other drugs that are anecdotally reported to be successful for treatment of symptoms caused by the serotonin syndrome include methysergide, chlorpromazine, atypical antipsychotics, and propranolol.[81,82,85,91,181] Because all of these drugs are of unproven utility and can be dangerous, aggressive cooling and sedation with a benzodiazepine remain the basis of therapy.

Differential Diagnosis of the Serotonin Syndrome from the Neuroleptic Malignant Syndrome Many features overlap between the serotonin syndrome and the neuroleptic malignant syndrome (NMS) (Chap. 68). Some authors call these "spectrum disorders" that can be caused by drugs with antidopaminergic and/or proserotonergic effects.[139,221] This position is supported by the finding that 5-HT$_{2A}$ agonism results

TABLE 72–5. Diagnostic Criteria for Serotonin Syndrome

Major	Minor
Mental Status	
Consciousness altered	Insomnia
Elevated mood	Restlessness
Other Neurologic Signs and Symptoms	
Coma	Akathisia
Hyperreflexia	Incoordination
Myoclonus	Mydriasis
Rigidity	
Shivering	
Tremor	
Vital Signs and Autonomic Manifestations	
Fever (Hyperthermia)	Hypertension or hypotension
Sweating	Tachycardia
	Tachypnea or Dyspnea
	Diarrhea

Serotonin syndrome is diagnosed by the presence of at least four major symptoms or three major plus two minor symptoms following the addition or an increase in a known serotonergic agent. Underlying psychiatric disorder should be excluded. Other etiologies must be excluded, including initiation of a neuroleptic or other dopamine antagonist or withdrawal from a dopamine agonist.

in an overall decrease in neuronal dopamine release. Some authors report NMS with use of serotonin-enhancing drugs. However, low concentrations of measured dopamine and normal concentrations of serotonin metabolites in the NMS patients reported support the hypothesis of central dopaminergic hypoactivity.[12,150] It now is clear that the implicated drugs, time course, pathophysiologic mechanism, and manifestations are distinct (Table 72–6).[81] Altered mental status, autonomic instability, and changes in neuromuscular tone that may result in hyperthermia are common to both syndromes. The development of NMS involves rapid blockade of dopaminergic neurons in the CNS, whereas the serotonin syndrome appears to result from acute overstimulation of serotonin receptors (5-HT$_{2A}$).

In addition to the associated medications, the time courses of the two syndromes are substantially different. Signs and symptoms of the serotonin syndrome develop within minutes to hours after exposure to the offending xenobiotics, whereas NMS typically develops days to weeks after daily exposure to the drug in question.[87] In addition, after symptoms develop and offending xenobiotics are discontinued, NMS can last for as long as 2 weeks, whereas the serotonin syndrome usually resolves quickly, directly correlated with the pharmacokinetic metabolic profile of the offending xenobiotic. A review of the literature indicates that patients presenting with serotonin syndrome were more likely to exhibit agitation, hyperactivity, clonus and myoclonus, ocular oscillations, (opsoclonus), shivering, tremors, and hyperreflexia, whereas patients presenting with NMS were more likely to exhibit bradykinesia and lead pipe rigidity.[81]

ATYPICAL ANTIDEPRESSANTS

Atypical antidepressants are defined as not belonging strictly to a set classification of antidepressants. They are not SSRIs, cyclic antidepressants, or MAOIs. In general, the atypical antidepressants are the newer antidepressants, most of which are derivatives of SSRIs and have additional pharmacologic effects that were selected in an attempt to decrease the undesirable side effects of traditional antidepressants.

■ SEROTONIN/NOREPINEPHRINE REUPTAKE INHIBITORS

Venlafaxine
In addition to inhibiting serotonin reuptake, venlafaxine inhibits norepinephrine reuptake. Venlafaxine produces rapid downregulation of central β-adrenergic receptors, which may result in a faster onset of antidepressant effect.[187] Patients with acute venlafaxine overdose may present with nausea, vomiting, dizziness, tachycardia, CNS depression, hypotension, hyperthermia, hepatic toxicity that include zone 3 necrosis, rhabdomyolysis and seizures.[104,187,215,217,224] (see Chap. 26). Sodium and potassium channel blocking effects are rarely clinically apparent; however, QRS prolongation, QT prolongation, and ventricular tachycardia have resulted in death.[16,26,128,178,224] One report indicated a positive association of toxicity to serum venlafaxine concentration.[136] Although no clinical data regarding efficacy are available, sodium bicarbonate may be helpful in attenuating the sodium channel blocking effects leading to QRS prolongation (Antidotes in Depth A5: Sodium Bicarbonate). Chronic reported adverse effects after venlafaxine include alopecia, yawning, focal myositis facial flushing, and dose-related increases in blood pressure.[54,59,65,109,158]

Duloxetine, a drug similar to venlafaxine, has similar effects.[62]

■ OTHER ATYPICAL ANTIDEPRSSANTS WITH REUPTAKE INHIBITION AS PART OF THEIR MECHANISM

Bupropion
The pharmacologic mechanism of action of bupropion, a unicyclic antidepressant, is unclear, but both the parent xenobiotic and an active metabolite inhibit the reuptake of dopamine and, to a lesser extent, serotonin and norepinephrine.[173] Extended-release formulations of bupropion are frequently used as adjuncts in smoking cessation therapy.[107] Chronic doses greater than 450–500 mg/d place the patient at risk for seizures.[50,112]

Frequent effects after overdose include tachycardia, hypertension, gastrointestinal symptoms, and agitation.[15,19] Large acute overdoses may result in seizures and/or QRS prolongation.[46,83,97,141,156,190,202] In some cases, effects were delayed for up 10 hours, particularly after ingestion of sustained-release preparations.[96,190] Symptoms can continue for up to 48 hours.

Several studies suggest that seizures following either bupropion overdose or high therapeutic doses are caused by its metabolite hydroxybupropion.[71,162] Elevated hydroxybupropion concentrations are documented after seizures when bupropion concentrations were

no longer detectable. The exact mechanism for the development of seizures caused by hydroxybupropion is unclear at this time.[50,71,176]

Treatment, when required for seizures, should be supportive and includes judicious use of benzodiazepines, followed by barbiturates if necessary. If QRS prolongation occurs, the patient should be treated with sodium bicarbonate (Antidotes in Depth A5: Sodium Bicarbonate). Intravenous fat emulsion therapy was used to successfully resuscitate a 17-year-old woman who ingested multiple drugs including bupropion after sodium bicarbonate and advanced life support failed and should be considered in similar cases (Antidotes in Depth A21: Intravenous Fat Emulsion).[190] Early after sustained-release bupropion overdose, activated charcoal should be considered, with use of multiple doses of activated charcoal or whole-bowel irrigation after large, potentially life-threatening ingestions.

Other serious adverse effects reported after bupropion use include cholestatic and hepatocellular hepatic dysfunction, and rhabdomyolysis, with isolated reports of chest pain, dystonia, trigeminal nerve dysfunction, mania, generalized erythrodermic psoriasis, erythema multiforme, dyskinesias, altered vestibular and sensory function, and serum sickness.[5,45,49,53,60,74,86,115,130,207,221]

Trazodone
Trazodone is a serotonin agonist that acts through inhibition of serotonin reuptake. In addition, trazodone has peripheral α-adrenergic antagonist activity. CNS depression and orthostatic hypotension are the most common complications after acute overdose of trazodone.[73] Trazodone is rarely reported to cause SIADH. This effect may be responsible for seizures, which also may occur after acute overdose.[13,210] Priapism, reported with trazodone, may also occur occasionally after overdose.[39,73] Management of hypotension includes supportive care and administration of fluids and vasopressors, if necessary.

Mirtazapine
The mechanism of mirtazapine action is unique. In addition to serotonin reuptake inhibition, mirtazapine increases neuronal norepinephrine and serotonin through α_2-adrenergic antagonism.[52] Mirtazapine also blocks some subtypes of 5-HT receptors, including 5-HT$_2$ and 5-HT$_3$, which appear to have antidepressant effects.[152] The main effects that occur after acute mirtazapine overdoses include altered mental status, tachycardia, and hypothermia.[33,171,211] Large overdoses may cause respiratory depression and prolongation of the QT interval.[33,76,102,172] Because more overdose data are required before a precise constellation of symptoms can be attributed to this xenobiotic, careful clinical monitoring is advised. Therapeutic use of mirtazapine causing serotonin syndrome, hepatitis, hypertension, and reversible agranulocytosis is reported.[1,100,106,149,208]

DRUG DISCONTINUATION SYNDROME

The term *drug discontinuation syndrome* is used to describe the physiologic manifestations that occur after antidepressant withdrawal. The choice of terminology is unclear, but may relate to the manifestations occurring after therapeutic use versus misuse of the drug. Drug discontinuation syndromes are commonly reported after withdrawal of conventional antidepressants, including cyclic antidepressants and MAOIs (Chaps. 71 and 73).[124] SSRIs cause a discontinuation syndrome that typically begins within 5 days after drug discontinuation and may last up to 3 weeks.[92] The most frequently reported symptoms include dizziness, lethargy, paresthesias, nausea, vivid dreams, irritability, and depressed mood.[185] The risk factors associated with development of a discontinuation syndrome are not fully clarified. The syndrome is more common with SSRIs that have shorter elimination half-lives (paroxetine > fluvoxamine > sertraline > fluoxetine). In addition, SSRIs with high-potency serotonin reuptake inhibition are more frequently implicated (paroxetine > sertraline > clomipramine > fluoxetine > venlafaxine > trazodone). Of the SSRIs, paroxetine most often results in discontinuation syndrome, which results in mild to moderate symptoms in 20%–40% of patients, respectively, receiving 20 mg daily.[14] Several studies demonstrate that the vast majority of cases are attributed to paroxetine with an approximately 20% risk with sertraline, and escitalopram and 10% decrease in risk with fluvoxamine.[14,25] Fluoxetine discontinuation syndrome occurs less frequently, at only two cases per million prescriptions.[165] The long elimination half-life of fluoxetine and its active metabolite norfluoxetine probably decrease the incidence of discontinuation syndrome by providing a tapered effect after cessation.

Because of difficulty in distinguishing symptoms of discontinuation syndrome from underlying disease, many authors have proposed diagnostic criteria for the SSRI discontinuation syndrome.[25] All proposed criteria include discontinuation of the SSRI in concordance with CNS effects, gastrointestinal distress, or anxiety.[205]

The biochemical basis of the discontinuation syndrome appears to be similar to tryptophan depletion, both of which result in an acute decrease in synaptic serotonin.[56] In fact, abrupt discontinuation versus drug taper was a noted risk factor in paroxetine cases when compared with those who did not suffer discontinuation symptoms.[101] Although postulated, antimuscarinic withdrawal seems an unlikely cause because the antimuscarinic effects of desipramine failed to protect against paroxetine withdrawal in a human model.[66]

Treatment of patients exhibiting discontinuation symptoms should include supportive care and reinitiation of the discontinued drug or administration of another SSRI if reinitiation of the drug is contraindicated.[184] The drug then should be tapered at a rate that allows for improved patient tolerance.

Many of the other antidepressants discussed in this chapter also result in discontinuation reactions. Symptoms appear similar to those reported after discontinuation of SSRIs and are treated in a similar manner.[21,111]

SUMMARY

In acute overdose, SSRIs or atypical antidepressants usually are not life threatening, although a few drugs produce seizures or cardiac toxicity. Treatment is generally supportive for all of these drugs. In particular, patients with citalopram or escitalopram overdoses should be monitored for 24 h for QT prolongation. However, significant drug interactions and adverse drug effects are associated with serotonin reuptake inhibitors and may lead to acute life-threatening events including

serotonin syndrome. In addition, the management of these patients frequently is complicated because they likely have concomitant access to more life-threatening antidepressants such as cyclic antidepressants and MAOIs.

CHAPTER 73
CYCLIC ANTIDEPRESSANTS

Erica L. Liebelt

The term *cyclic antidepressant* (CA) refers to a group of pharmacologically related xenobiotics used for treatment of depression, neuralgic pain, migraines, enuresis, and attention deficit hyperactivity disorder. Most CAs have at least three rings in their chemical structure. They include the traditional tricyclic antidepressants (TCAs) imipramine, desipramine, amitriptyline, nortriptyline, doxepin, trimipramine, protriptyline, and clomipramine, as well as other cyclic compounds such as maprotiline and amoxapine.

HISTORY AND EPIDEMIOLOGY

Imipramine was the first TCA used for treatment of depression in the late 1950s. However, the synthesis of iminodibenzyl, the "tricyclic" core of imipramine, and the description of its chemical characteristics date back to 1889. Structurally related to the phenothiazines, imipramine was originally developed as a hypnotic agent for agitated or psychotic patients and was serendipitously found to alleviate depression. From the 1960s until the late 1980s, the TCAs were the major pharmacologic treatment for depression in the United States. However, by the early 1960s, cardiovascular and central nervous system (CNS) toxicities were recognized as major complications of TCA overdoses.[99] The newer CAs developed in the 1980s and 1990s were designed to decrease some of the adverse effects of older TCAs, improve the therapeutic index, and reduce the incidence of serious toxicity. Other CAs include the tetracyclic drug maprotiline and the dibenzoxapine drug amoxapine.

The epidemiology of CA poisoning has evolved significantly in the last 20 years, resulting in great part from the introduction of the newer selective serotonin reuptake inhibitors (SSRIs) for the treatment of depression. Although the use of CAs for depression has decreased over the last 15 years, other medical indications, including chronic pain, obsessive-compulsive disorder, and, particularly in children, enuresis and attention deficit hyperactivity disorder have emerged, resulting in their continued use. The antidepressants are a leading cause of drug-related self-poisonings in the developed world, primarily because of their ready availability to people with depression who by virtue of the disease are at high risk for overdose. However, despite the increase in SSRI use and overdose, patients with TCA overdoses continue to have higher rates of hospitalization (78.7% versus 64.7%) and fatality (0.73% versus 0.14%) than do those with SSRI overdose.[73]

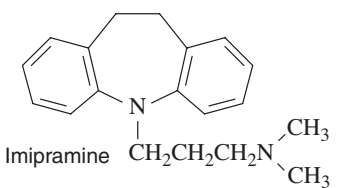
Children younger than 6 years have consistently accounted for approximately 12%–13% of all CA exposures reported to poison centers during each of the last 15 years (see Chap. 135). Despite the emergence of the SSRIs in the early 1990s, TCAs were still among the top five psychotropic drugs most frequently prescribed by pediatric office–based practices in 1995.[48] The use of TCAs has remained stable in adolescents but has declined in prepubertal children.[116] Thus CA poisoning likely will continue to be among the most lethal unintentional drug ingestions in younger children because only one or two adult-strength pills can produce serious clinical effects in young children.

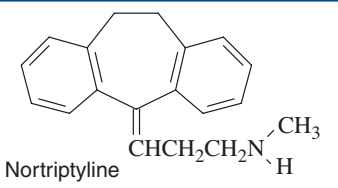
PHARMACOLOGY

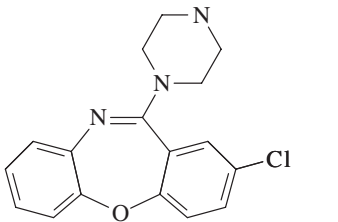
In general, the TCAs can be classified into tertiary and secondary amines based on the presence of a methyl group on the propylamine side chain (Table 73–1). The tertiary amines amitriptyline and imipramine are metabolized to the secondary amines nortriptyline and desipramine, respectively, which themselves are marketed as antidepressants. In therapeutic doses, the CAs produce similar pharmacologic effects on the autonomic system, CNS, and cardiovascular system. However, they can be distinguished from each other by their relative potencies.[118]

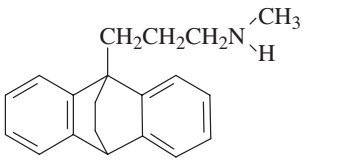
At therapeutic doses, CAs inhibit presynaptic reuptake of norepinephrine and/or serotonin, thus functionally increasing the amount of these neurotransmitters at CNS receptors. The tertiary amines, especially clomipramine, are more potent inhibitors of serotonin reuptake, whereas the secondary amines are more potent inhibitors of norepinephrine reuptake. Although these pharmacologic actions formed the basis of the monoamine hypothesis of depression in the 1960s, antidepressant actions of these drugs appear to be much more complex.

Extensive research has led to the "receptor sensitivity hypothesis of antidepressant drug action," which postulates that following chronic CA administration, alterations in the sensitivity of various receptors are responsible for antidepressant effects. Chronic TCA administration alters the number and/or function of central β-adrenergic and serotonin receptors. In addition, TCAs modulate glucocorticoid receptor gene expression and cause alterations at the genomic level of other receptors.[7,57] All of these actions likely play a role in the antidepressant effects of TCAs.

Additional pharmacologic mechanisms of CAs are responsible for their side effects with therapeutic dosing and clinical effects following overdose. All of the CAs are competitive antagonists of the muscarinic acetylcholine receptors, although they have different affinities. The CAs also antagonize peripheral α_1-adrenergic receptors. The most prominent effects of CA overdose result from binding to the cardiac sodium channels, which is also described as a membrane stabilizing effect (Fig. 73–1) (see Chap. 22). The tricyclic antidepressants are potent inhibitors of both peripheral and central postsynaptic histamine receptors. Finally, animal research demonstrates that the CAs interfere with chloride conductance by binding to the picrotoxin site on the GABA–chloride complex.[106]








Amoxapine is a dibenzoxapine CA derived from the active antipsychotic loxapine. Although it has a 3-ringed structure, this drug has little similarity to the other tricyclics. It is a potent norepinephrine reuptake inhibitor, has no effect on serotonin reuptake, and blocks dopamine receptors. Maprotiline is a tetracyclic antidepressant that predominantly blocks norepinephrine reuptake. Both of these CAs have a slightly different toxic profile than the traditional TCAs.[53,54,118]

PHARMACOKINETICS AND TOXICOKINETICS

The CAs are rapidly and almost completely absorbed from the gastrointestinal (GI) tract, with peak concentrations 2–8 hours after administration of a therapeutic dose. They are weak bases (high pK_a). In overdose, the decreased GI motility caused by anticholinergic effects and ionization in gastric acid delay CA absorption. Because of extensive first-pass metabolism by the liver, the oral bioavailability of CAs is low and variable, although metabolism may become saturated in overdose, increasing bioavailability.

The CAs are highly lipophilic and possess large and variable volumes of distribution (15–40 L/kg). They are rapidly distributed to the heart, brain, liver, and kidney, where the tissue-to-plasma ratio generally exceeds 10:1. Less than 2% of the ingested dose is present in blood several hours after overdose, and serum TCA concentrations decline biexponentially. The CAs are extensively bound to α_1-acid glycoprotein (AAG)

FIGURE 73–1. Effects of cyclic antidepressants on the fast sodium channel. **(A)** Sodium depolarizes the cell, which both propagates conduction; allowing complete cardiac depolarization; and opens voltage-dependent Ca^{2+} channels, producing contraction. **(B)** Cyclic antidepressants and other sodium channel blockers alter the conformation of the sodium channel, slowing the rate of rise of the action potential, which produces both negative dromotropic and inotropic effects. **(C)** Raising the Na^+ gradient across the affected sodium channel speeds the rate of rise of the action potential, counteracting the drug-induced effects. Raising the pH removes the CA from the binding site on the Na^+ channel. See Figure 73-3 for the effects noted on the ECG.

in the plasma, although differential binding among the specific CAs is observed.[2] Changes in AAG concentration or pH can alter binding and the percentage of free or unbound drug.[87,98] Specifically, a low blood pH (which often occurs in a severely poisoned patient) may increase the amount of free drug, making it more available to exert its effects. This property serves as the basis for alkalinization therapy (see below).

The TCAs undergo demethylation, aromatic hydroxylation, and glucuronide conjugation of the hydroxy metabolites. The tertiary amines imipramine and amitriptyline are demethylated to desipramine and nortriptyline, respectively. The hydroxy metabolites of both tertiary and secondary amines are pharmacologically active and may contribute to toxicity. The glucuronide metabolites are inactive.

Genetically based differences in the activity of the CYP2D6 enzymes, which are responsible for hydroxylation of imipramine and desipramine, account for wide interindividual variability in metabolism and steady-state serum concentrations.[17] "Poor metabolizers" may recover more slowly from an overdose or demonstrate toxicity with therapeutic dosing.[110] The metabolism of CAs also may be influenced by concomitant ingestion of ethanol and other medications that induce or inhibit the CYP2D6 isoenzyme (see Chap. 12 Appendix).[16] Patient variables such as age and ethnicity also affect CA metabolism.

Elimination half-lives for therapeutic doses of CAs vary from 7–58 hours (54–92 hours for protriptyline), with even longer half-lives in the elderly. The half-lives may also be prolonged following overdose as a result of saturable metabolism. A small fraction (15%–30%) of CA elimination occurs through biliary and gastric secretion. The metabolites are then reabsorbed in the systemic circulation, resulting in enterohepatic and enterogastric recirculation and reducing their fecal excretion. Finally, less than 5% of CAs are excreted unchanged by the kidney.

PATHOPHYSIOLOGY

The CAs slow the recovery from inactivation of the fast sodium channel, slowing phase 0 depolarization of the action potential in the distal His-Purkinje system and the ventricular myocardium[117,119]

(Fig. 73–1 and Fig. 22-2; see Chaps. 22 and 23 (Hemodynamic Principles)). Impaired depolarization within the ventricular conduction system slows the propagation of ventricular depolarization, which manifests as prolongation of the QRS interval on the electrocardiogram (Fig. 73–1). The right bundle branch has a relatively longer refractory period, and it is affected disproportionately by xenobiotics that slow intraventricular conduction. This slowing of depolarization results in a rightward shift of the terminal 40-millisecond (T40-ms) of the QRS axis and the right bundle-branch block pattern that is noted on the electrocardiogram of patients who are exposed to, or overdose with, a CA.[121]

Because CAs are weakly basic, they are increasingly ionized as the ambient pH falls, and less ionized as the pH rises. Changing the ambient pH therefore likely alters their binding to the sodium channel. That is, since it is probable that 90% of the binding of TCA to the sodium channel occurs in the ionized state, alkalinizing the blood facilitates the movement of the TCA away from the hydrophilic sodium channel and into the lipid membrane.

Sinus tachycardia is due to the antimuscarinic, vasodilatory (reflex tachycardia), and sympathomimetic effects of the CAs. Wide-complex tachycardia most commonly represents aberrantly conducted sinus tachycardia rather than ventricular tachycardia. However, by prolonging anterograde conduction, nonuniform ventricular conduction may result, leading to reentrant ventricular dysrhythmias.[117]

Electrophysiologic studies in a canine model demonstrate that QRS prolongation is rate dependent, a characteristic effect of the type I antidysrhythmics (Chap. 63). In these studies, when the heart rate could not accelerate because of a crushed sinus node the dogs never developed QRS prolongation. Furthermore, pharmacologic induction of bradycardia prevents or narrows wide-complex tachycardia by allowing time for recovery of the sodium channel from inactivation.[4,97] However, since bradycardia adversely affects cardiac output, induction of bradycardia is not recommended.

A Brugada electrocardiographic pattern, specifically Type 1 or "coved" pattern, is rarely associated with CA overdose. The Brugada syndrome originates from a structural change in the myocardial sodium channel that results in functional sodium channel alterations similar to those caused by the CAs.[10,78] It is possible that this small cohort of patients may have had subclinical Brugada syndrome that was uncovered by the CA.

QT interval prolongation can occur in the setting of both therapeutic use and overdose of CAs. This apparent prolongation of repolarization results primarily from slowed depolarization (ie, QRS prolongation) rather than altered repolarization.[93] Although QT prolongation predisposes to the development of torsades de pointes, this dysrhythmia is uncommon in patients with CA poisoning due to the prominent tachycardia.

Hypotension is caused by direct myocardial depression secondary to altered sodium channel function, which disrupts the subsequent excitation-contraction coupling of myocytes and impairs cardiac contractility. Peripheral vasodilation from α-adrenergic blockade by CAs also contributes prominently to postural hypotension. In addition, downregulation of adrenergic receptors may cause a blunted physiologic response to catecholamines.[77]

Agitation, delirium, and depressed sensorium are primarily caused by the central anticholinergic and antihistaminic effects. Hemodynamic effects are likely to contribute in only the most severely poisoned patients. Details regarding the exact mechanism of CA-induced seizures remain elusive.[65] CA-induced seizures may result from a combination of an increased concentration of monoamines (particularly norepinephrine), muscarinic antagonism, neuronal sodium channel alteration, and GABA inhibition.[65,79]

Acute lung injury may occur in the setting of CA overdose. In one study, amitriptyline exposure caused dose-related vasoconstriction and bronchoconstriction in isolated rat lungs.[109] Many substances implicated in acute lung injury, such as platelet-activating factor and protein kinase activation, were important in mediating amitriptyline-induced lung function impairment in this experimental model. Another animal model demonstrated that acute amitriptyline poisoning causes dose-dependent rises in pulmonary artery pressure, pulmonary edema, and sustained vasoconstriction that could be attenuated by either calcium channel inhibition or a nitric oxide donor.[64]

CLINICAL MANIFESTATIONS OF TOXICITY

The toxic profile is qualitatively the same for all of the first-generation TCAs, but is slightly different for some of the other CAs.[118] The progression of clinical toxicity is unpredictable and may be rapid. Patients commonly present to the emergency department (ED) with minimal apparent clinical abnormalities only to develop life-threatening cardiovascular and CNS toxicity within hours.

The CAs have a low therapeutic index, meaning that a small increase in serum concentration over the therapeutic range may result in toxicity. Acute ingestion of 10–20 mg/kg of most CAs causes significant cardiovascular and CNS manifestations (therapeutic dose 2–4 mg/kg/d). Thus, in adults, ingestions of more than 1 gram of a CA is usually associated with life-threatening effects. As few as two 50-mg imipramine tablets may cause significant toxicity in a 10-kg toddler (ie, 10 mg/kg). In a series of children with unintentional TCA exposure, all patients with reported ingestions of more than 5 mg/kg manifested clinical toxicity.[72]

■ ACUTE TOXICITY

Most of the reported toxicity from CAs derives from patients with acute ingestions, especially in patients who are chronically taking the medication. Clinical manifestations of these two cohorts do not appear to be different, and most studies do not distinguish between them.

Acute Cardiovascular Toxicity Cardiovascular toxicity is primarily responsible for the morbidity and mortality attributed to CAs. Refractory hypotension due to myocardial depression probably is the most common cause of death from CA overdose.[19,108] Hypoxia, acidosis, volume depletion, seizures, or concomitant ingestion of other cardiodepressant or vasodilating drugs can exacerbate hypotension.

The most common dysrhythmia observed following CA overdose is sinus tachycardia (rate 120–160 beats/min in an adult) and this finding is present in most patients with clinically significant TCA poisoning. The electrocardiogram typically demonstrates intraventricular conduction delay that manifests as a rightward shift of the T40-ms QRS axis and a prolongation of the QRS complex duration. These findings can be used to identify and risk-stratify, respectively, patients with CA poisoning (see Diagnostic Testing). PR, QRS, and QT interval prolongation can occur in the setting of both therapeutic and toxic amounts of TCAs.[67]

Wide-complex tachycardia is the characteristic potentially life-threatening dysrhythmia observed in patients with severe toxicity (Fig. 73–2A–C). Ventricular tachycardia may be difficult to distinguish from aberrantly conducted sinus tachycardia which occurs more commonly. In the former cases, the preceding P wave may not be apparent because of prolonged AV conduction, widened QRS interval, or both. Ventricular tachycardia occurs most often in patients with prolonged QRS complex duration and/or hypotension.[62,112] Hypoxia, acidosis, hyperthermia, seizures, and β-adrenergic agonists may also predispose

FIGURE 73–2. **(A)** ECG shows a wide-complex tachycardia with a variable QRS duration (minimum 220 ms). **(B)** ECG 30 minutes after presentation following sodium bicarbonate shows narrowing of the QRS interval to a duration of 140 ms and an amplitude of RaVR of 6.0 mm. **(C)** ECG 9 hours after presentation shows further narrowing of the QRS interval to 80 ms and decrease in the amplitude of RaVR to 4.5 mm. (Reproduced with permission from Liebelt EL, Targeted management strategies for cardiovascular toxicity from tricyclic antidepressant overdose: the pivotal role for alkalinization and sodium loading. *Pediatr Emerg Care* 1998;14:293–298.)

to ventricular tachycardia.[62,112] Fatal dysrhythmias are rare, as ventricular tachycardia and fibrillation occur in only approximately 4% of all cases.[39,90] Both the Brugada Type I electrocardiogram pattern and torsades de pointes are uncommon with acute TCA overdose.

Acute Central Nervous System Toxicity Altered mental status and seizures are the primary manifestations of CNS toxicity. Delirium, agitation, and/or psychotic behavior with hallucinations may be present and most likely result from antagonism of muscarinic and histaminergic receptors. These alterations in consciousness usually are followed by lethargy which is followed by rapid progression to coma. The duration of coma is variable and does not necessarily correlate or occur concomitantly with electrocardiographic abnormalities.[54]

Seizures usually are generalized and brief, most often occurring within 1–2 hours of ingestion.[26] The incidence of seizures is similar to ventricular tachycardia and occurs in an estimated 4% of patients presenting with overdose and 13% of fatal cases.[123] Status epilepticus is uncommon. Abrupt deterioration in hemodynamic status, namely, hypotension and ventricular dysrhythmias, may develop during or within minutes after a seizure.[26,62,112] This rapid cardiovascular deterioration likely results from seizure-induced acidosis that exacerbates cardiovascular toxicity. The risk of seizures with CA overdoses may be

increased in patients undergoing long-term therapy or who have other risk factors such as history of seizures, head trauma, or concomitant drug withdrawal.[104] Myoclonus and extrapyramidal symptoms may also occur in CA-poisoned patients.

Discontinuation of CAs may produce a withdrawal syndrome in some patients. The syndrome is typified by gastrointestinal and somatic distress, sleep disturbances, movement disorders, and mania.[35]

Other Clinical Effects Anticholinergic effects can occur early or late in the course of CA toxicity. Pupils may be dilated and poorly reactive to light. Other anticholinergic effects include dry mouth, dry flushed skin, urinary retention, and ileus. Though prominent, these findings are typically clinically inconsequential.

Reported pulmonary complications include acute lung injury, aspiration pneumonitis, and multisystem organ failure. Acute lung injury may be the result of aspiration, hypotension, pulmonary infection, and excessive fluid administration, along with the primary toxic effects of CAs.[101,103] Bowel ischemia, pseudoobstruction, and pancreatitis are reported in patients with CA overdose.[75]

Death directly caused by CA toxicity usually occurs in the first several hours after presentation and is secondary to refractory hypotension in patients who reach healthcare facilities. Late deaths (>1–2 days after

presentation) usually are secondary to other factors such as aspiration pneumonitis, adult respiratory distress syndrome from refractory hypotension, and/or infection.[19]

■ CHRONIC TOXICITY

Chronic CA toxicity usually manifests as exaggerated side effects, such as sedation and sinus tachycardia, or is identified by supratherapeutic drug concentrations in the blood in the absence of an acute overdose.[37] Unlike chronic theophylline and aspirin poisoning, chronic CA toxicity does not appear to cause life-threatening toxicity. A sparse literature describes the clinical course of this cohort.

Several reports describe sudden death in children taking therapeutic doses of CAs.[91,92,111] QT prolongation with resultant torsades de pointes, advanced atrioventricular conduction delays, blood pressure fluctuations, and ventricular tachycardia are postulated mechanisms, although whether any of these effects contributed to the deaths is unknown. Prospective studies using 12-lead ECG, 24-hour ECG recording, and Doppler echocardiography in children receiving therapeutic doses of CAs have failed to find any significant cardiac abnormalities when compared to children not taking CAs.[12,28] However, authors recommend that CAs not be initiated or continued in any child with a resting QT interval greater than 450 ms or with bundle-branch block.[31]

■ UNIQUE TOXICITY FROM "ATYPICAL" CYCLIC ANTIDEPRESSANTS

Although the incidence of serious cardiovascular toxicity is lower in patients with amoxapine overdoses, the incidence of seizures is significantly greater than with the traditional CAs.[54,63] Moreover, seizures may be more frequent or status epilepticus may develop.[78] Similarly, the incidences of seizures, cardiac dysrhythmias, and duration of coma are greater with maprotiline toxicity compared to the CAs.[53]

DIAGNOSTIC TESTING

Diagnostic testing for patients with CA poisoning primarily relies on indirect bedside tests (ECG) and other qualitative laboratory analyses. Quantification of CA concentration provides little help in the acute management of patients with CA overdose, but provides adjunctive information to support the diagnosis.

■ ELECTROCARDIOGRAPHY

The ECG can provide important diagnostic information and may predict clinical toxicity after a CA overdose. CA toxicity results in distinctive and diagnostic electrocardiographic changes that may allow early diagnosis and targeted therapy when the clinical history and physical examination are unreliable.

A T40-ms axis between 120° and 270° is associated with CA toxicity and in one study was a sensitive indicator of drug presence.[21,81,121] A terminal QRS vector of 130°–270° discriminated between 11 patients with positive toxicology screens for CAs and 14 patients with negative toxicology screens.[81] With further analyses, this report concluded that the positive and negative predictive values of this ECG parameter for CA ingestions were 66% and 100%, respectively, in a population of 299 general overdose patients. A retrospective study reported that a CA-poisoned patient was 8.6 times more likely to have a T40-ms axis greater than 120° than was a non–CA-poisoned patient.[121] This parameter was a more sensitive indicator of CA-induced altered mental status, but not necessarily of seizure or dysrhythmia. However, the T40-ms axis is not easily measured in the absence of specialized
FIGURE 73–3. (**A**) Normal QRS complex in lead aVR. (**B**) Abnormal QRS complex in a patient with cyclic antidepressant (CA) poisoning. The R wave in lead aVR is measured as the maximal height in millimeters of the terminal upward deflection in the QRS complex. In this example, the QRS complex duration is prolonged, indicating significant CA poisoning.

computer-assisted analysis, which limits its practical utility. An abnormal terminal rightward axis can be estimated by observing a negative deflection (terminal S wave) in leads I and aVL and a positive deflection (terminal R wave) in lead aVR (Fig. 73–3).

The maximal limb lead QRS complex duration is an easily measured ECG parameter that is a sensitive indicator of toxicity. One investigation reported that 33% of patients with a limb lead QRS interval greater than or equal to 100 ms developed seizures and 14% developed ventricular dysrhythmias.[14] No seizures or dysrhythmias occurred in those patients whose QRS interval remained less than 100 ms. There was a 50% incidence of ventricular dysrhythmias among patients with a QRS duration greater than or equal to 160 ms. No ventricular dysrhythmias occurred in patients with a QRS duration less than 160 ms. Subsequent studies confirmed that a QRS duration greater than 100 ms is associated with an increased incidence of serious toxicity, including coma, need for intubation, hypotension, seizures, and dysrhythmias, making this ECG parameter a useful indicator of toxicity.[21,60]

Evaluation of lead aVR on a routine ECG may also predict toxicity (Figs. 73–2 and 73–3). When prospectively studied, 79 patients with acute CA overdoses demonstrated that the amplitude of the terminal R wave and R/S wave ratio in lead aVR (R_{aVR}, R/S_{aVR}) were significantly greater in patients who developed seizures and ventricular dysrhythmias.[60] The sensitivity of $R_{aVR} = 3$ mm and $R/S_{aVR} = 0.7$ in predicting seizures and dysrhythmias was comparable to the sensitivity of QRS = 100 ms.

The Type 1 Brugada pattern is similar to a right bundle branch block (rSR′), with downsloping ST elevations ("coved") in the right precordial leads (V1-V3).[10,78] This pattern is neither highly sensitive nor specific for CA toxicity, and it is reported in patients with cocaine and phenothiazine toxicity as well as those on Type IA antidysrhythmic therapy. In one series of over 400 pateints with CA overdose, a significant increase in adverse outcomes (ie, seizures, widened QRS interval, and

hypotension) was identified in those patients with a Brugada ECG pattern compared to those who did not have the pattern.[10] However, there were no deaths or dysrhythmias in the nine patients with this pattern.

Serial ECGs should be obtained as the electrocardiographic changes can be dynamic. Electrocardiographic parameters should always be interpreted in conjunction with the patient's clinical presentation, history, and course during the first several hours to assist in decision making regarding interventions and disposition.[61]

■ LABORATORY TESTS

Determination of serum CA concentrations has limited utility in the immediate evaluation and management of patients with acute overdoses. In one study, serum drug concentrations failed to accurately predict the development of seizures or ventricular dysrhythmias.[14] The pharmacologic properties of CAs—namely, large volumes of distributions, prolonged absorption phase, long distribution half-lives, pH-dependent protein binding, and the wide interpatient variability of terminal elimination half-lives, explain the limited value of serum concentrations in this situation. Any concentration above the therapeutic range (50–300 ng/mL, including active metabolites) may be associated with adverse effects, and is an indication to decrease or discontinue the medication.

Although CA concentrations greater than 1000 ng/mL usually are associated with significant clinical toxicity such as coma, seizures, and dysrhythmias, life-threatening toxicity may be observed in patients with serum concentrations less than 1000 ng/mL.[14,56] Serious toxicity at lower concentrations probably results from a number of factors, including the timing of the specimen in relation to the ingestion and the limitations of measuring the concentration in blood and not the affected tissue. Quantitative concentrations usually cannot be readily obtained in most hospital laboratories. However, qualitative screens for CAs using an enzyme-multiplied immunoassay test are available at many hospitals. Unfortunately, false-positive results can occur with many drugs such as carbamazepine, cyclobenzaprine, thioridazine, diphenhydramine, quetiapine, and cyproheptadine (Chap. 6). Thus the presence of a CA on a qualitative assay should not be relied upon to confirm the diagnosis of CA poisoning in the absence of corroborating historical or clinical evidence.

Quantitative concentrations may be helpful in determining the cause of death in suspected overdose patients. CA concentrations reported in lethal overdoses typically range from 1100–21,800 ng/mL. CA concentrations may increase over 5-fold because of postmortem redistribution (Chap. 33).[5] Measurement of liver CA concentration or the parent-to-metabolite drug ratio may be useful in the postmortem setting.

MANAGEMENT

Any person with a suspected or known ingestion of a CA requires immediate evaluation and treatment (Table 73–2). The patient should be attached to a cardiac monitor and intravenous access should be secured. Early intubation is advised for patients with CNS depression and/or hemodynamic instability because of the potential for rapid clinical deterioration. A 12-lead ECG should be obtained for all patients. Laboratory tests including concentrations of glucose and electrolytes should be performed for all patients with altered mental status, as well as blood gas analysis to both assess the degree of acidemia and guide alkalinization therapy. Aggressive interventions for maintenance of blood pressure and peripheral perfusion must be performed early to avoid irreversible damage. Both children and adults receiving cardiopulmonary resuscitation have recovered successfully

TABLE 73–2. Treatment of Cyclic Antidepressant Toxicity

Toxic Effect	Treatment
Sinus rhythm with a QRS >100 ms	Sodium bicarbonate: 1--2 mEq/kg IV boluses at 3 to 5 min intervals to reverse the abnormality or to a target serum pH no greater than 7.55 Controlled ventilation (if clinically indicated for hypoventilation)
Wide-complex tachycardia/ ventricular tachycardia	Sodium bicarbonate: 1--2 mEq/kg IV boluses to reverse the dysrhythmias or to a target serum pH no greater than 7.55 Correct hypoxia, acidosis, hypotension Consider lidocaine: 1 mg/kg slow IV bolus, followed by infusion of 20--50 µg/kg/min Consider hypertonic saline (3% NaCl) Consider magnesium sulfate 25--50 mg/kg (maximum 2 g) IV over 2 min
Torsades de pointes	Magnesium sulfate Overdrive pacing (caution due to rate dependence of CA)
Hypotension	Isotonic saline (0.9% NaCl) boluses (up to 30 mL/kg) Correct hypoxia, acidosis Sodium bicarbonate: 1--2 mEq/kg IV boluses to a target serum pH of no greater than 7.50–7.55 Norepinephrine
Seizures	Benzodiazepines Secure airway with intubation if necessary Correct hypoxia, acidosis Barbiturates Continuous infusion of midazolam or propofol if barbiturates fail Consider neuromuscular paralysis/general anesthesia with EEG monitoring if all other measures fail
Refractory poisoning	Consider intravenous fat emulsion in moribund patients Consider extracorporeal mechanical circulation (extracorporeal membrane oxygenation, cardiopulmonary bypass)

despite periods of asystole exceeding 90 minutes.[23,25,83,105] The options for GI decontamination discussed in the following section should then be considered.

■ GASTROINTESTINAL DECONTAMINATION

Induction of emesis is contraindicated, given the potential for precipitous neurologic and hemodynamic deterioration. Because of the potential lethality of large quantities of CAs, orogastric lavage should be considered in the symptomatic patient with an overdose. Although the benefits of orogastric lavage for CA toxicity are not substantiated by controlled trials, the potential benefits of removing significant quantities of a highly toxic drug must be weighed against the risks of the procedure (Chap. 7).[15] Because the anticholinergic actions of

some CAs may decrease spontaneous gastric emptying, attempts at orogastric lavage up to 12 hours after ingestion may yield unabsorbed drug. Because of the potential for rapid deterioration of mental status and seizures, orogastric lavage should only be performed after endotracheal intubation has assured airway protection. Orogastric lavage in young children with unintentional ingestions of CAs may be associated with more risk and impracticalities, such as the inadequate hole size of pediatric tubes, and less benefit given the amount of drug usually ingested. Activated charcoal should be administered in nearly all cases. Irrespective of age, an additional dose of activated charcoal several hours later is reasonable in a seriously poisoned patient in whom unabsorbed drug may still be present in the GI tract, or in the case of desorption of CAs from activated charcoal. It is important to monitor for the development of an ileus to prevent abdominal complications from additional doses of activated charcoal.[75]

■ WIDE-COMPLEX DYSRHYTHMIAS, CONDUCTION DELAYS, AND HYPOTENSION

The mainstay therapy for treating wide-complex dysrhythmias and for reversing conduction delays and hypotension is the combination of serum alkalinization and sodium loading. Increasing the extracellular concentration of sodium, or sodium loading, may overwhelm the effective blockade of sodium channels presumably through gradient effects (Fig. 73–1). Controlled in vitro and in vivo studies in various animal models demonstrate that hypertonic sodium bicarbonate effectively reduces QRS complex prolongation, increases blood pressure, and reverses or suppresses ventricular dysrhythmias caused by CAs.[85,95–97] These studies showed a clear benefit of hypertonic sodium bicarbonate when compared to hyperventilation, hypertonic sodium chloride, or nonsodium buffer solutions. A systematic review of all animal and human studies published until 2001 revealed that alkalinization therapy was the most beneficial therapy for consequential dysrhythmias and shock[13] (see Antidote in Depth A5: Sodium Bicarbonate).

The optimal dosing and mode of administration of hypertonic sodium bicarbonate and the indications for initiating and terminating this treatment are unsupported by controlled clinical studies. Instead, the information is extrapolated from animal studies, clinical experience, and an understanding of the pathophysiologic mechanisms of CA toxicity. A bolus, or rapid infusion over several minutes, of hypertonic sodium bicarbonate (1–2 mEq/kg) should be administered initially.[69,102] Additional boluses every 3–5 minutes can be administered until the QRS interval narrows and the hypotension improves (Fig. 73–2). Blood pH should be carefully monitored after several bicarbonate boluses, aiming for a target pH of no greater than 7.50–7.55. Because CA may redistribute from the tissues into the blood over several hours, it may be reasonable to begin a continuous sodium bicarbonate infusion to maintain the pH in this range. Differences in outcomes between repetitive boluses versus bicarbonate infusions are not well studied. Although diluting sodium bicarbonate in 5% dextrose in water and infusing it slowly renders it less able to increase the sodium gradient across the cell, the beneficial effects of pH elevation still warrant its use once the patient is stabilized. No evidence supports prophylactic alkalinization in the absence of cardiovascular toxicity.

Hypertonic sodium chloride (3% NaCl) reverses cardiotoxicity in several animal studies,[45,70,85] and numerous reports and extensive clinical experience support its efficacy in humans.[13,46,47,74] However, the dose of hypertonic saline for CA poisoning has never been evaluated in humans for safety or efficacy, and the dose suggested by animal studies (up to 15 mEq/kg) exceeds the amount that most clinicians would consider safe (1–2 mEq/kg). Hypertonic sodium chloride is associated with a hyperchloremic metabolic acidosis, an undesired effect that highlights one benefit of hypertonic sodium bicarbonate. However,

hypertonic saline could be considered in situations in which alkalinization with sodium bicarbonate is not possible.

Hyperventilation of an intubated patient is a more rapid and easily titratable method of serum alkalinization but is not as effective as NaHCO$_3$ in reversing cardiotoxicity.[49,69] Simultaneous hyperventilation and sodium bicarbonate administration may result in profound alkalemia and should be performed only with extreme caution and careful monitoring of pH.[122] Hyperventilation without bicarbonate administration may be indicated in patients with acute lung injury or congestive heart failure in whom administration of large quantities of sodium are contraindicated.

Alkalinization and sodium loading with hypertonic sodium bicarbonate and/or hypertonic saline along with controlled ventilation (if clinically indicated) should be administered to all CA overdose patients presenting with major cardiovascular toxicity and altered mental status. Indications include conduction delays (QRS > 100 ms) and hypotension. It is imperative to initiate treatment until CA toxicity can be excluded because of the risk for rapid and precipitous deterioration. Although commonly assumed, it is unclear whether the failure of the QRS complex to narrow with sodium bicarbonate treatment excludes CA toxicity.

It is unclear whether alkalinization and sodium loading is effective for reversing the Brugada pattern. The sparse available literature is equivocal.[9,78] It would seem prudent to administer sodium bicarbonate in the presence of a presumed TCA-induced Brugada pattern, especially with concomitant signs of other TCA toxicity.

Alkalinization may be continued for at least 12–24 hours after the ECG has normalized because of the redistribution of the drug from the tissue. However, the time observed for resolution or normalization of conduction abnormalities is extremely variable, ranging from several hours to several days, despite continuous bicarbonate infusion.[61] We recommend stopping alkalinization when the patient's mental status improves and there is improvement, but not necessarily normalization, of abnormal ECG findings.

■ ANTIDYSRHYTHMIC THERAPY

Lidocaine is the antidysrhythmic most commonly advocated for treatment of CA-induced dysrhythmias, although no controlled human studies demonstrate its efficacy.[86] Because lidocaine has sodium channel blocking properties, some investigators argue against its use in CA poisoning.[1] These theoretical concerns are not well supported in the literature, and the class IB antidysrhythmic channel binding kinetics may prove favorable. Although limited data also suggest that the IB antidysrhythmic phenytoin prevents or reverses conduction abnormalities,[41,68] these data were poorly controlled for other confounding factors, such as blood pH and sodium bicarbonate administration, they had very small numbers, and, in some, the cardiotoxicity was not severe. Since phenytoin exacerbates ventricular dysrhythmias in animals[20] and fails to protect against seizures,[8] its use is no longer recommended.

The use of class IA (quinidine, procainamide, disopyramide, and moricizine) and class IC (flecainide, propafenone) antidysrhythmics is absolutely contraindicated because they have similar pharmacologic actions to CAs and thus may worsen the sodium channel inhibition and exacerbate cardiotoxicity. Class III antidysrhythmics (amiodarone, bretylium, and sotalol) prolong the QT interval and, although unstudied, may be contraindicated as well (see Chap. 63).

Because magnesium sulfate has antidysrhythmic properties, it may be beneficial in the treatment of ventricular dysrhythmias. Animal studies of the effects of magnesium on CA-induced dysrhythmias yield conflicting results.[50,51] However, successful use of magnesium sulfate in the treatment of refractory ventricular fibrillation after TCA overdose is reported.[23,25,52,94] When dysrhythmias fail to reverse after alkalinization, sodium loading, and a trial of lidocaine, or magnesium sulfate may be warranted.

Slowing the heart rate in the presence of CAs may allow more time during diastole for CA unbinding from sodium channels and result in an improvement in ventricular conduction.[3,96] This may abolish the reentry mechanism for dysrhythmias and was one rationale for the past use of physostigmine and propranolol. Thus, decreasing the sinus rate may itself be effective in abolishing ventricular dysrhythmias by eliminating rate-dependent conduction slowing. Propranolol terminated ventricular tachycardia in an animal model but also caused significant hypotension and death.[97] In one case series, patients developed severe hypotension or had a cardiac arrest shortly after receiving a β-adrenergic antagonist.[33] Other animal studies suggest that preventing or abolishing tachycardia by sinus node destruction, or by using bradycardic agents that impede sinus node automaticity without affecting myocardial repolarization or contractility, may successfully prevent CA-induced ventricular dysrhythmias.[3,4] The combined negative inotropic effects of β-adrenergic antagonists and CAs, along with the significant cardiac and CNS effects reported with physostigmine use, do not support their routine use in the management of CA-induced tachydysrhythmias.

■ HYPOTENSION

Standard initial treatment for hypotension should include volume expansion with isotonic saline or sodium bicarbonate. Hypotension unresponsive to these therapeutic interventions necessitates the use of inotropic or vasopressor support and possibly extracorporeal cardiovascular support.

No controlled human trials are available to guide the use of vasopressor therapy. The pharmacologic properties of CAs complicate the choice of a specific agent. Specifically, CA blockade of neurotransmitter reuptake theoretically could result in depletion of intracellular catecholamines. This could blunt the effect of dopamine, which is dependent on the release of endogenous norepinephrine for its inotropic activity.[18] This suggests that a direct-acting vasopressor such as norepinephrine is more efficacious than an indirect-acting catecholamine such as dopamine.

In fact, limited clinical data suggest that norepinephrine is more efficacious than dopamine.[113] In a retrospective study of 26 adult hypotensive patients receiving nonstandardized therapy, response rates to norepinephrine (5–53 µg/min) were significantly better than response rates to dopamine (5–10 µg/kg/min).[114] Patients who did not respond to dopamine at vasopressor doses (10–50 µg/kg/min) responded to norepinephrine (5–74 µg/min). Animal data comparing various treatments are conflicting, and their direct applicability to clinical human poisoning is limited.[29,115] Both norepinephrine and epinephrine increased the survival rate in CA-poisoned rats. In addition, epinephrine was superior to norepinephrine when used both with and without sodium bicarbonate, and the most effective treatment regimen in this study was epinephrine plus sodium bicarbonate; neither precipitated dysrhythmias. The authors propose that epinephrine is more efficacious because it augments myocardial perfusion more than norepinephrine and improves the recovery of CA sodium channel blockade by hyperpolarization of the membrane potential through its stimulation of increased potassium intracellular transport.

Based on the available data, pharmacologic effects, theoretical concerns, and experience, norepinephrine (0.1–0.2 µg/kg/min) is recommended for hypotension that is unresponsive to volume expansion and hypertonic sodium bicarbonate therapy. Central venous pressure and/or pulmonary artery catheterization may be necessary to guide the choice of additional vasopressor or inotropic agents, especially in the presence of other cardiodepressant drugs.

If these measures fail to correct hypotension, extracorporeal life support measures should be considered. Extracorporeal membrane oxygenation, extracorporeal circulation, and cardiopulmonary bypass are successful adjuncts for refractory hypotension and life support when maximum therapeutic interventions fail.[40,55,105,120] These modalities can provide critical perfusion to the heart and brain and maintain metabolic function while giving the body time to metabolize and eliminate the CA by maintaining hepatorenal blood flow.

■ INVESTIGATIONAL THERAPY

Intravenous fat emulsion is reported to be effective in reversing cardiovascular toxicity due to several lipophilic drugs including clomipramine. Its use is currently reserved for moribund patients, though as more data emerges the indications may be expanded or its use eliminated[43] (see Antidotes in Depth: Intravenous Fat Emulsion).

■ CENTRAL NERVOUS SYSTEM TOXICITY

Seizures caused by CAs usually are brief and may stop before treatment can be initiated. Recurrent seizures, prolonged seizures (>2 minutes), and status epilepticus require prompt treatment to prevent worsening acidosis, hypoxia, and development of hyperthermia and rhabdomyolysis. Benzodiazepines are effective as first-line therapy for seizures. If this therapy fails, barbiturates or propofol should be administered. Propofol controlled refractory seizures resulting from amoxapine toxicity.[76] Failure to respond to barbiturates or propofol should lead to consideration of neuromuscular paralysis and general anesthesia with continuous EEG monitoring. Phenytoin is not recommended for seizures because data not only demonstrate a failure to terminate seizures, but also suggest enhanced cardiovascular toxicity.[8,20]

Use of flumazenil in the patient with known or suspected CA ingestion is contraindicated. Several case reports of patients with CA overdoses describe seizures following administration of flumazenil.[42,58,71] Physostigmine was used in the past to reverse the acute CNS toxicity of CAs (Antidotes in Depth A12: Physostigmine). However, physostigmine is not recommended because it may increase the risk of cardiac toxicity, cause bradycardia and asystole, and precipitate seizures in acutely CA-poisoned patients.[89]

■ ENHANCED ELIMINATION

No specific treatment modalities have demonstrated clinical significant efficacy in enhancing the elimination of CAs. Some investigators propose multiple doses of activated charcoal to enhance CA elimination because of their small enterohepatic and enterogastric circulation.[66] Human volunteer studies and case series of patients with CA overdoses suggest that the half-life of CAs may be decreased by multiple-dose activated charcoal (MDAC).[24,82,111] Activated charcoal reduced the apparent half-life of amitriptyline to 4–40 hours in overdose patients, compared to previously published values of 30 to more than 60 hours.[111] Changes in the severity or duration of clinical toxicity, however, were not reported. Other investigators showed that in human volunteers MDAC reduced the half-life of therapeutic doses of amitriptyline approximately 20% compared with no activated charcoal administration. However, the methodologic flaws and equivocal findings of these studies and the lack of any positive outcome data for this intervention from additional studies do not provide evidence supporting its use in this setting.[22,38] Pharmacokinetic properties of CAs (large volumes of distribution, high plasma-protein binding) weighed against the small increases in clearance and the potential complications of MDAC, such as impaction, intestinal infarction, and perforation, do not warrant its routine use.[22,75] One additional dose of activated charcoal may be given to decrease GI absorption in patients with evidence of significant CNS and cardiovascular toxicity if bowel sounds are present.

Measures to enhance urinary CA excretion have a minimal effect on total clearance. Urinary alkalinization does not enhance, and may reduce, urinary clearance due to passive reabsorption of the unionized CA from an alkaline urine. Hemodialysis is ineffective in enhancing the elimination of CAs because of their large volumes of distribution, high lipid solubility, and extensive protein binding.[44] Hemoperfusion overcomes some of the limitations of hemodialysis, but may not be effective because of the large volumes of distributions of CAs. Although several uncontrolled case reports and a case series described improvement in cardiotoxicity during hemoperfusion, this finding may be coincidental.[11,23,32]

■ HOSPITAL ADMISSION CRITERIA

All patients who present with known or suspected CA ingestion should undergo continuous cardiac monitoring and serial electrocardiography for a minimum of 6 hours. Recommendations in the older literature for 48–72 hours of ICU monitoring even for patients with minor CA ingestions stem from isolated case reports of late-onset dysrhythmias, CNS effects, and sudden deaths.[34,36,88] However, review of these cases shows inadequate gastric decontamination, inadequate therapeutic interventions, and significant ongoing complications of overdose. Several retrospective studies demonstrate that late, unexpected complications in CA overdoses such as seizures, dysrhythmias, and death did not occur in patients who had few or no major signs of toxicity at presentation or a normal level of consciousness and a normal ECG for 24 hours.[19,25,27,90] A disposition algorithm has been proposed based on clinical signs and symptoms.[6,24,112] If the patient is asymptomatic at presentation, undergoes GI decontamination, has normal ECGs, or has sinus tachycardia (with normal QRS complexes) that resolves, and the patient remains asymptomatic in the healthcare facility for a minimum of 6 hours without any treatment interventions, the patient may be medically cleared for psychiatric evaluation (if appropriate) or discharged home as appropriate.

A prospective study of 67 patients used the Antidepressant Overdose Risk Assessment (ADORA) criteria to identify patients who were at high risk for developing serious toxicity and proposed criteria for hospitalization.[30] In this study, the presence of QRS interval greater than 100 ms, cardiac dysrhythmias, altered mental status, seizures, respiratory depression, or hypotension on presentation to the ED (or within 6 hours of ingestion, if the time was known) was 100% sensitive in identifying patients with significant toxicity and subsequent complications. Criteria specific for ICU admission (other than patients requiring ventilatory and/or blood pressure support), versus an inpatient bed with continuous cardiac monitoring, are less clear and probably are institution dependent.[107]

The disposition of patients with persistent isolated sinus tachycardia, or prolonged QT interval with no concomitant altered mental status, or blood pressure changes, is not clearly defined. Previous studies demonstrate that these two parameters alone are not predictive of subsequent clinical toxicity or complications.[30,31] In addition, the sinus tachycardia may persist for up to 1 week following ingestion.[80,100] However, a study of isolated CA overdose patients reported that a heart rate greater than 120 beats/min and QT interval greater than 480 ms were associated with an increased likelihood of major toxicity.[21] These patients are candidates for observation units with continuous ECG monitoring and serial ECGs for 24 hours.

■ INPATIENT CARDIAC MONITORING

The duration of cardiac monitoring in any patient initially exhibiting signs of major clinical toxicity depends on many factors. Certainly the duration of CA cardiotoxicity and neurotoxicity may be prolonged, and using normalization of ECG abnormalities as an end point for therapy and discharge, is problematic. Some studies document the variable resolution and normalization of QRS prolongation and T40-ms axis rotation.[84,103] Based on the available literature, it is reasonable to recommend that after the mental status and blood pressure normalize, and the electrocardiogram improves, patients who exhibited significant poisoning should be monitored for another 24 hours off of all of therapy, including alkalinization, antidysrhythmics, and inotropics/vasopressors.

SUMMARY

Cyclic antidepressant poisoning continues to be a cause of serious morbidity and mortality worldwide. The distinctive characteristics of these drugs can cause significant CNS and cardiovascular toxicity, the latter being responsible for mortality as a result of overdose of these drugs. Cardiovascular toxicity ranges from mild conduction abnormalities and sinus tachycardia to wide-complex tachycardia, hypotension, and asystole. CNS toxicity includes delirium, lethargy, seizures, and coma. The ECG is a simple, readily available diagnostic test that can predict the development of significant toxicity, particularly seizures and/or dysrhythmias. Management strategies are based primarily on the pathophysiology of these drugs, namely, sodium channel blockade in the myocardium. Alkalinization and sodium loading with hypertonic sodium bicarbonate and isotonic saline are the principal modes of specific therapy for cardiovascular toxicity. Guidelines for observing or admitting patients to the hospital may be based on initial clinical presentation or development of clinical symptomatology and ECG changes.

CHAPTER 74
SEDATIVE-HYPNOTICS

David C. Lee and Kathy Lynn Ferguson

Sedative-hypnotics are xenobiotics that limit excitability (sedation), and/or induce drowsiness and sleep (hypnosis). *Anxiolytics* (formerly known as *tranquilizers*) are medications prescribed for their sedative-hypnotic properties. There are many different types of medications used to induce anxiolysis or sleep. This chapter focuses primarily on pharmaceuticals prescribed for their sedative-hypnotic effects, many of which interact with the γ-aminobutyric acid-A ($GABA_A$) receptor (Table 74–1). Specific sedative-hypnotics such as ethanol and γ-hydroxybutyric acid are discussed in more depth in their respective chapters (Chaps. 77 and 80).

HISTORY AND EPIDEMIOLOGY

Mythology of ancient cultures is replete with stories of xenobiotics that cause sleep or unconsciousness (Chap. 1). Symptomatic overdoses of sedative-hypnotics were described in the medical literature soon after the commercial introduction of bromide preparations in 1853. Other commercial xenobiotics that subsequently were developed include chloral hydrate, paraldehyde, sulfonyl, and urethane.

The barbiturates were introduced in 1903 and quickly supplanted the older xenobiotics. This class of medications dominated the sedative-hypnotic market for the first half of the 20th century. Unfortunately, because they have a narrow therapeutic-to-toxic ratio and substantial potential for abuse, they quickly became a major health problem. By the 1950s, barbiturates were frequently implicated in overdoses and were responsible for the majority of drug-related suicides. As fatalities from barbiturates increased, attention shifted toward preventing their abuse and finding less toxic alternatives.[19] The "safer" drugs of that era included methyprylon, glutethimide, ethchlorvynol, bromides, and methaqualone. Unfortunately, many of these sedative hypnotics also had significant undesirable effects. After the introduction of benzodiazepines in the early 1960s, barbiturates and the other alternatives were quickly replaced as commonly used sedatives in the United States.

Intentional and unintentional overdoses with sedative-hypnotics occur frequently. According to the American Association of Poison Control Centers, sedative-hypnotics is consistently one of the top five classes of xenobiotics associated with overdose fatalities (see Chap. 135). With the ubiquitous worldwide use of sedative-hypnotics, they may be associated with a substantially higher number of overdoses and deaths than are officially reported. For example, a recent report described benzodiazepines as being increasingly used in drug-facilitated thefts outside the United States.[75]

Chlordiazepoxide, the first commercially available benzodiazepine, initially was marketed in 1960. Since then, more than 50 benzodiazepines have been marketed, and more are being developed. Compared with barbiturate overdoses, overdoses of benzodiazepines alone account for relatively few deaths.[37] Most deaths associated with benzodiazepines result from mixed overdoses with other centrally acting respiratory depressants.[46]

Benzodiazepines remain the most popular prescribed anxiolytics. However, the recently introduced hypnotics zolpidem, zaleplon, zopiclone, and eszopiclone have replaced benzodiazepines as the most commonly prescribed pharmaceutical sleep aids. Melatonin and ramelteon are emerging as popular sleep aids whose effects are mediated through melatonin receptor subtypes MT-1 and MT-2 specifically.[107,112,127] Dexmedetomidine, a central α_2-adrenergic agonist, is now increasingly used in the hospital setting for short-term sedation.[5,111]

PHARMACODYNAMICS/TOXICODYNAMICS

All sedative-hypnotics induce central nervous system (CNS) depression. Most clinically effective sedative-hypnotics produce their physiologic effects by enhancing the function of GABA-mediated chloride channels via agonism at the $GABA_A$ receptor. These receptors are the primary mediators of inhibitory neurotransmission in the brain (see Chap. 13). The $GABA_A$ receptor is a pentameric structure composed of varying polypeptide subunits associated with a chloride channel on the postsynaptic membrane. These subunits are classified into families (α, β, γ, etc.). Variations in the five subunits of the GABA receptor confer the potency of its sedative, anxiolytic, hypnotic, amnestic, and muscle relaxing properties. The most common $GABA_A$ receptor in the brain is composed of $\alpha_1\beta_2\gamma_2$ subunits. Almost all sedative-hypnotics bind to $GABA_A$ receptors containing the α_1 subunit. One exception may be etomidate, which has been shown to produce sedation at the β_2 unit and anesthesia at the β_3 subunit.[24,91,104,150] Low doses of benzodiazepines will be effective only at $GABA_A$ receptors with the γ_2 subunit. Even within classes of sedative-hypnotics, there will be varying affinities for differing subunits of the GABA receptor.[30,79]

Many sedative-hypnotics also act at receptors other than the $GABA_A$ receptor. Trichloroethanol and propofol, also inhibit glutamate-mediated *N*-methyl-D-aspartate (NMDA) receptors, thereby inhibiting excitatory neurotransmission.[26,99,116] Some benzodiazepines may also inhibit adenosine metabolism and reuptake, thereby potentiating both A_1-adenosine (negative dromotropy) and A_2-adenosine (coronary vasodilation) receptor-mediated effects.[87,124] Benzodiazepines also interact with specific benzodiazepine receptors that are not associated with the GABA receptor. These receptors have been labeled ω receptors. Benzodiazepines can also interact with serotonergic pathways. For example, diazepam modulates morphine analgesia via interactions with serotonin receptors. In addition, the anxiolytic effects of clonazepam can be partially explained by upregulation of serotonergic receptors, specifically 5-HT$_1$ and 5-HT$_2$.[8,88,157] Newer sleep aids, such as melatonin and ramelteon, do not appear to act at the $GABA_A$ receptor. Instead, they are agonists at melatonin receptor subtypes MT-1 and MT-2 in the suprachiasmatic nucleus of the brain.[127] Dexmedetomidine, a central α_2-adrenergic agonist similar to clonidine, induces a state of "cooperative sedation."[136]

PHARMACOKINETICS/TOXICOKINETICS

Most sedative-hypnotics are rapidly absorbed via the gastrointestinal (GI) tract, with the rate-limiting step consisting of dissolution and dispersion of the xenobiotic. Barbiturates and benzodiazepines are primarily absorbed in the small intestine. Clinical effects are determined by their relative ability to penetrate the blood–brain barrier. Drugs that are highly lipophilic penetrate most rapidly. The ultrashort-acting barbiturates are clinically active in the most vascular parts of the brain (gray matter first), with sleep occurring within 30 seconds of administration. Table 74–1 lists individual sedative-hypnotics and some of their pharmacokinetic properties.

TABLE 74–1. Pharmacology of Sedative-Hypnotics

	Equipotent Dosing Oral Dose (mg)[a]	$t_{1/2}$ (min.)	Protein Binding (%)	V_d (L/kg)	Active Metabolite Important
Benzodiazepines					
Agents with full agonist activity at the benzodiazepine site					
Alprazolam (Xanax)	1.0	10–14	80	0.8	No
Chlordiazepoxide (Librium)	50	5–15	96	0.3	Yes
Clorazepate (Tranxene)	15		97	0.9	Yes
Clonazepam (Klonopin)	0.5	18–50	85.4	Unclear	Yes
Diazepam (Valium)	10	20–70	98.7	1.1	Yes
Estazolam (ProSom)	2.0	8–31	93	0.5	No
Flunitrazepam[b] (Rohypnol)	1.0	16–35	80	1.0–1.4	Yes
Flurazepam (Dalmane)	30	2.3	97.2	3.4	Yes
Lorazepam (Ativan)	2.0	9–19	90	1–1.3	None
Midazolam (Versed)	–	3–8	95	0.8–2	Yes
Oxazepam (Serax)	30	5–15	Unclear	Unclear	No
Temazepam (Restoril)	30	10–16	97	0.75–1.37	No
Triazolam (Halcion)	0.25	1.5–5.5	90	0.7–1.5	Yes
Nonbenzodiazepines active mainly at the type I (ω_1) benzodiazepine site					
Eszopicone (Lunesta)	?	6	55	1.3	No
Zaleplon (Sonata)	20	1.0	92	0.54	No
Zolpidem (Ambien)	20	1.7	92	0.5	No
Barbiturates					
Amobarbital (Amytal)	–	8–42	Unclear	Unclear	Unclear
Aprobarbital[b] (Alurate)	–	14–34	Unclear	Unclear	Unclear
Butabarbital (Butisol)	–	34–42	Unclear	Unclear	Unclear
Barbital[b]	–	6–12	25	Unclear	Unclear
Mephobarbital (Mebaral)	–	5–6	40–60	Unclear	Yes
Methohexital (Brevital)	–	3–6	73	2.2	Unclear
Pentobarbital (Nembutal)	100	15–48	45–70	0.5–1.0	Unclear
Phenobarbital (Luminal)	30	80–120	50	0.5–0.6	No
Primidone (Mysoline)	–	3.3–22.4	19	Unclear	Yes
Secobarbital (Seconal)	–	15–40	52–57	Unclear	Unclear
Thiopental (Pentothal)	–	6–46	72–86	1.4–6.7	Unclear
Other					
Chloral hydrate (Aquachloral)	NA	4.0–9.5	35–40	0.6–1.6	Yes
Ethchlorvynol[b] (Placidyl)	NA	10–25	30–40	4	Unclear
Etomidate (Amidate)	NA	2.9–5.3	98	2.5–4.5	Unclear
Glutethimide[b] (Doriden)	NA	5–22	47–59	2.7	Unclear
Methyprylon[b] (Nodular)	NA	3–6	60	0.97	Unclear
Meprobamate[b] (Miltown)	NA	6–17	20	0.75	Unclear
Methaqualone[b] (Quaalude)	NA	19	80–90	5.8–6.0	Yes
Paraldehyde[b] (Paral)	NA	7	Unclear	0.9	Unclear
Propofol (Diprivan)	NA	4–23	98	2–10	No
Ramelteon (Rozerem)	NA	1–2.6	82	High	Yes
Dexmedetomidine (Precedex)	NA	2	94	1.5	No

NA = not applicable comparison.

[a]This table is an approximation of equipotent doses of xenobiotics affecting the benzodiazepine receptor and several barbiturates. All of the full agonist benzodiazepines have similar amnestic, anxiolytic, sedative, and hypnotic effects. These effects are a reflection of dose and serum concentration. There can be significant variation of these effects according to age and gender.

[b]Not presently available in the United States.

After initial distribution, many of the sedative-hypnotics undergo a redistribution phase as they are dispersed to other body tissues, specifically fat. Xenobiotics that are redistributed, such as the lipophilic (ultrashort-acting) barbiturates and some of the benzodiazepines (diazepam, midazolam), may have a brief clinical effect as the early peak concentrations in the brain rapidly decline. The clinical activity of many of them after single doses is determined by their rapid distribution and redistribution (alpha phase) and not by their elimination (beta phase) (see Chap. 8).

Many of the sedative-hypnotics are metabolized to pharmacologically active intermediates. This is particularly true for chloral hydrate and some of the benzodiazepines. Benzodiazepines can be demethylated, hydroxylated, or conjugated with glucuronide in the liver. Glucuronidation results in the production of inactive metabolites. Benzodiazepines, such as diazepam, are demethylated which produces active intermediates with a more prolonged therapeutic half-life than the parent compound. Because of the individual pharmacokinetics of sedative-hypnotics and the production of active metabolites, there is often little correlation between the therapeutic and biologic half-lives.

The majority of sedative-hypnotics, such as the highly lipid-soluble barbiturates and the benzodiazepines, are highly protein bound. These drugs are poorly filtered by the kidneys. Elimination occurs principally by hepatic metabolism. Chloral hydrate and meprobamate are notable exceptions. Xenobiotics with a low lipid-to-water partition coefficient, such as meprobamate and the longer-acting barbiturates, are poorly protein bound and more subject to renal excretion. Phenobarbital is a classic example of a drug whose elimination can be enhanced through alkalinization. Most other sedative-hypnotics are not amenable to urinary pH manipulation.

Overdoses of combinations of sedative-hypnotics enhance toxicity through synergistic effects. For example, both barbiturates and benzodiazepines act on the $GABA_A$ receptor, but barbiturates prolong the opening of the chloride ionophore, whereas benzodiazepines increase the frequency of ionophore opening.[128] Various sedative-hypnotics may increase the affinity of another xenobiotic at its respective binding site. For example, pentobarbital increases the affinity of γ-hydroxybutyrate (GHB) for its non-GABA binding site.[130] Propofol potentiates the effect of pentobarbital on chloride influx at the GABA receptor.[142] Propofol also increases the affinity and decreases the rate of dissociation of benzodiazepines from their site on the GABA receptor.[18,106] These actions increase the clinical effect of each xenobiotic and may lead to deeper CNS and respiratory depression.

Another mechanism of synergistic toxicity occurs via alteration of metabolism. The combination of ethanol and chloral hydrate, historically known as a "Mickey Finn," has additive CNS depressant effects. Chloral hydrate competes for alcohol and aldehyde dehydrogenases, thereby prolonging the half-life of ethanol. The metabolism of ethanol generates the reduced form of nicotinamide adenine dinucleotide (NADH), which is a cofactor for the metabolism of choral hydrate to trichloroethanol, an active metabolite. Finally, ethanol inhibits the conjugation of trichloroethanol, which in turn inhibits the oxidation of ethanol (Fig. 74–1).[16,80,121,122] The end result of these synergistic pharmacokinetic interactions is enhanced CNS depression.

Multiple drug–drug interactions can occur that may prolong the half-life of many sedative-hypnotics and significantly increase their potency or duration of action. The half-life of midazolam, which undergoes hepatic metabolism via cytochrome CYP3A4, can change dramatically in the presence of certain drugs that compete for its metabolism, or that induce or inhibit CYP3A4.[94,145] For example, the half-life of midazolam rises 400-fold when coadministered with itraconazole.[7] Various receptor and metabolic enzyme alterations resulting in upregulation or downregulation may occur in the setting of acute or chronic exposure to certain sedative-hypnotics.
FIGURE 74–1. Metabolism of chloral hydrate and ethanol, demonstrating the interactions between chloral hydrate and ethanol metabolism. Note the inhibitory effects (dotted lines) of ethanol on trichloroethanol metabolism and the converse.

TOLERANCE/WITHDRAWAL

Ingestions of relatively large doses of sedative-hypnotics may not have predictable effects in patients who chronically use them. This is due to *tolerance*, defined as the progressive diminution of effect of a particular drug with repeated administrations that results in a need for greater doses to achieve the same effect. Tolerance occurs when adaptive neural and receptor changes (plasticity) occur after repeated exposures. These changes include a decrease in the number of receptors (downregulation), reduction of firing of receptors (receptor desensitization), structural changes in receptors (receptor shift), or reduction of coupling of sedative-hypnotics and their respective $GABA_A$ related receptor site (see Chap. 14). Tolerance can also be secondary to pharmacokinetic factors. However, in the majority of cases, tolerance to sedative-hypnotics is caused by pharmacodynamic changes such as receptor downregulation.[129]

Cross-tolerance readily exists among the sedative-hypnotics. For example, chronic use of benzodiazepines not only decreases the activity of the benzodiazepine site on the GABA receptor but also decreases the binding affinity of the barbiturate sites.[3,55] Many sedative-hypnotics are also associated with drug dependence after chronic exposure. Some of these, classically the barbiturates, benzodiazepines, and ethanol, are associated with characteristic potentially life-threatening withdrawal syndromes.

CLINICAL MANIFESTATIONS

Patients with sedative-hypnotic overdoses may exhibit slurred speech, ataxia, and incoordination. Larger doses result in stupor or coma. In most instances, respiratory depression parallels CNS depression. However, not all sedative-hypnotics cause significant hypoventilation. Oral overdoses of benzodiazepines alone may lead to sedation and hypnosis, but rarely life-threatening hypoventilation. Typically, the patient may appear comatose but have relatively normal vital signs. In contrast, large intravenous doses of benzodiazepines may lead to potentially life-threatening respiratory depression. Single overdoses of zolpidem and its congeners have not been shown to cause life-threatening respiratory depression in adults.[40]

Although the physical examination is rarely specific for a particular sedative-hypnotic, it can sometimes offer clues of exposure based on certain physical and clinical findings (Table 74–2). Hypothermia has been described with most of the sedative-hypnotics but may be more pronounced with barbiturates.[56,113] Barbiturates may cause fixed drug eruptions that often are bullous and appear over pressure-point areas. Although classically referred to as "barbiturate blisters," this phenomenon is not specific to barbiturates and has been documented with other CNS depressants, including carbon monoxide, methadone, imipramine, glutethimide, and benzodiazepines. Methaqualone can cause muscular rigidity and clonus.[1] Glutethimide can result in anticholinergic signs and symptoms.[47] Chloral hydrate use may result in vomiting, gastritis, and cardiac dysrhythmias.[45,71,92,149] Meprobamate overdoses may present with significant hypotension due to myocardial depression.[21]

Large or prolonged intravenous doses of sedative-hypnotics may also be associated with toxicities due to their diluents. Propylene glycol is a classic example of a diluent that may accumulate with prolonged infusions of certain medications such as lorazepam. Rapid infusions of propylene glycol may induce hypotension. Accumulated amounts of propylene glycol may lead to metabolic acidosis and a hyperosmolar state with elevated serum lactate concentrations.[68,72,78,105,146] In one study, two-thirds of critical care patients given high doses of lorazepam (0.16 mg/kg/h) for more than 48 hours had significant accumulations of propylene glycol as manifested by hyperosmolar anion gap metabolic acidosis[6] (see Chap. 55).

TABLE 74–2. Clinical Findings of Sedative-Hypnotic Overdose

Clinical Signs	Sedative-Hypnotics
Hypothermia	Barbiturates, bromides, ethchlorvynol
Unique odors	Chloral hydrate (*pear*), ethchlorvynol (*new vinyl shower curtain*)
Cardiotoxicity	
Myocardial depression	Meprobamate
Dysrhythmias	Chloral hydrate
Muscular twitching	GHB, methaqualone, propofol, etomidate
Acneiform rash	Bromides
Fluctuating coma	Glutethimide, meprobamate
GI hemorrhage	Chloral hydrate, methaqualone
Discolored urine	Propofol (green/pink)
Anticholinergic signs	Glutethimide

DIAGNOSTIC TESTING

When overdose is a primary concern in the undifferentiated comatose patient without a clear history laboratory testing, including electrolytes, liver enzymes, thyroid function tests, blood urea nitrogen (BUN), creatinine, glucose, venous or arterial blood gas analysis, and cerebrospinal fluid analysis, may be useful to exclude metabolic abnormalities. With any suspected intentional overdose, a serum acetaminophen concentration should be obtained. Diagnostic imaging studies, such as head CT scans, may be warranted on a case-by-case basis.

Routine laboratory screening for "drugs of abuse" generally is not helpful in the management of undifferentiated comatose adult patients, although screening may be useful for epidemiologic purposes in a particular community. These tests vary in type, sensitivity, and specificity. Furthermore, many sedative-hypnotics are not included on standard screening tests for drugs of abuse. For example, a typical benzodiazepine urine screen identifies metabolites of 1,4-benzodiazepines, such as oxazepam or desmethyldiazepam. Many benzodiazepines that are metabolized to alternative compounds remain undetected and thus may exhibit a false-negative result on the benzodiazepine screening assay. Benzodiazepines that are 7-amino analogs, such as clonazepam and flunitrazepam, may not be detected because they do not have a metabolite with a 1,4-benzodiazepine structure. Alprazolam and triazolam are not detected because they undergo minimal metabolism.[33]

Specific concentrations of xenobiotics such as ethanol or phenobarbital may be helpful to confirm or disprove exposure. However, specific concentrations of most other sedative-hypnotics are not routinely performed in hospital laboratories. Abdominal radiographs may detect chloral hydrate in the gastrointestinal tract because of its potential radiopacity (see Chap. 5). Although immediate identification of a particular sedative-hypnotic may be helpful in predicting the length of toxicity, it rarely affects the acute management of the patient. One exception is phenobarbital, for which urinary alkalinization and MDAC may enhance elimination.[39,102]

MANAGEMENT

Death secondary to sedative-hypnotic overdose usually results from cardiorespiratory collapse. Careful attention should focus on monitoring and maintaining adequate airway, oxygenation, and hemodynamic support. Supplemental oxygen, respiratory support, and prevention of aspiration are the cornerstones of treatment. Hemodynamic instability, although often a secondary or a delayed manifestation of sedative-hypnotic poisoning, should be treated initially with volume expansion. Historically, analeptics and other nonspecific arousal xenobiotics (see Chap. 1) were used, but their use is no longer recommended. With good supportive care and adequate early airway/respiratory support as needed, patients with sedative-hypnotic overdoses should eventually recover. Patients with meprobamate and chloral hydrate overdoses, however, may present with both respiratory depression and cardiac toxicity. Meprobamate toxicity may be associated with myocardial depression and significant hypotension, often resistant to standard intravenous fluid resuscitation.[21] Chloral hydrate cardiotoxic effects include lethal ventricular dysrhythmias, resulting from its active halogenated metabolite trichloroethanol. In the setting of cardiac dysrhythmias from chloral hydrate, judicious use of β-adrenergic antagonists is recommended.[15,45,158]

The use of gastrointestinal decontamination should be decided on a case-by-case basis. The benefits of activated charcoal (AC) must be balanced with the risks of its aspiration and subsequent potential for pulmonary toxicity. The use of AC should be determined judiciously

based upon a patient's current mental status, potential for further deterioration, the xenobiotic(s) ingested if known, and the expected clinical course. Phenobarbital overdose is one particular scenario in which multiple-dose AC (MDAC) may be considered. MDAC increases phenobarbital elimination by 50%–80%.[9,10,14] However, in the only controlled study, no difference could be demonstrated in outcome measures (time to extubation and length of hospitalization) in intubated, phenobarbital-poisoned patients who were randomized to single-dose activated charcoal versus MDAC.[101] Although inconclusive, after ensuring an adequately protected airway, activated charcoal may have potential benefits in certain situations (Antidotes in Depth A2: Activated Charcoal).

Although the efficacy of delayed orogastric lavage is controversial, orogastric lavage may be considered in overdoses with xenobiotics that slow GI motility or that are known to develop concretions, specifically phenobarbital and meprobamate,[21,59,119] Orogastric lavage in the setting of oral benzodiazepine overdoses alone is not recommended, as the benefits of lavage are minimal compared to the significant risks of aspiration. The use of orogastric lavage in sedative-hypnotic overdose should always be done cautiously as outlined in Chap. 7. No antidote counteracts all sedative-hypnotic overdoses. Flumazenil, a competitive benzodiazepine antagonist, rapidly reverses the sedative effects of benzodiazepines as well as zolpidem and its congeners.[30,73,156] However, flumazenil has been documented to precipitate life-threatening benzodiazepine withdrawal in benzodiazepine-dependent patients and precipitate seizures, especially in patients who have overdosed on tricyclic antidepressants[41,132,133] (see Antidotes in Depth A23: Flumazenil).

Patients with sedative-hypnotic overdoses rarely require invasive therapy other than respiratory support. Hemodialysis may be considered in patients with chloral hydrate overdoses who develop life-threatening cardiac manifestations or in patients who ingest extremely large quantities of phenobarbital and meprobamate who might require prolonged intubation.

Because the lethality of sedative-hypnotics is associated with their ability to cause respiratory depression, asymptomatic patients can be downgraded to a lower level of care after a period of observation with no signs of respiratory depression. Patients with symptomatic overdoses of long-acting sedative hypnotics, such as meprobamate and clonazepam, or drugs that can have significant enterohepatic circulation, such as glutethimide, may require 24 hours of observation (see Chap. 10). Patients with mixed overdoses of various sedative-hypnotics and CNS depressants also warrant closer observation for respiratory depression due to synergistic respiratory depressant effects.

SPECIFIC SEDATIVE-HYPNOTICS
■ BARBITURATES

Barbital became the first commercially available barbiturate in 1903. Although many other barbiturates were subsequently developed, their popularity has greatly waned since the introduction of benzodiazepines. Barbiturates are derivatives of barbituric acid (2,4,6-trioxo-hexahydropyrimidine), which itself has no CNS depressant properties. The addition of various side chains influence pharmacologic properties.

Barbiturates with long side chains tend to have increased lipophilicity, potency, and slower rates of elimination. However, the observed clinical effects also depend on absorption, redistribution, and the presence of active metabolites. For this reason, the duration of action of barbiturates (like those of benzodiazepines) does not correlate well with their biologic half-lives.

Oral barbiturates are preferentially absorbed in the small intestine and are eliminated by both hepatic and renal mechanisms. Longer-acting barbiturates tend to be more lipid soluble, more protein bound, have a high pK_a, and are metabolized almost completely by the liver. Renal excretion of unchanged drug is significant for phenobarbital, a long-acting barbiturate with a relatively low pK_a (7.24). Alkalinizing the urine with sodium bicarbonate to a urinary pH of 7.5–8.0 can increase the amount of phenobarbital excreted by 5- to 10-fold. This procedure is not effective for the short-acting barbiturates because they have higher pK_a values, are more protein bound, and are primarily metabolized by the liver with very little unchanged drug excreted by the kidneys (see Chap. 9).

Barbiturates (especially the shorter-acting barbiturates) can accelerate their own hepatic metabolism by cytochrome P450 enzyme autoinduction. Phenobarbital is a nonselective inducer of hepatic cytochromes, the greatest effects being on CYP2B1, CYP2B2, and CYP2B10, although CYP3A4 is also affected.[65,93,115,126,143] Not surprisingly, a variety of interactions are reported following the use of barbiturates. Clinically significant interactions as a result of enzyme induction lead to increased metabolism of β-adrenergic antagonists, corticosteroids, doxycycline, estrogens, phenothiazines, quinidine, theophylline, and many other xenobiotics.

Similar to other sedative-hypnotics, patients with significant barbiturate overdoses present with CNS and respiratory depression. Hypothermia and cutaneous bullae ("barb blisters") are often present. These two signs are also described for other patients with sedative-hypnotic overdoses, but they may be more pronounced with barbiturates.[11,32] Early deaths caused by barbiturate ingestions result from respiratory arrest and cardiovascular collapse. Delayed deaths result from acute renal failure, pneumonia, acute lung injury, cerebral edema, and multiorgan system failure as a result of prolonged cardiorespiratory depression.[2,48]

■ BENZODIAZEPINES
The commercial use of benzodiazepines began with the introduction of chlordiazepoxide for anxiety in 1961 and diazepam for seizures in 1963. Benzodiazepines are used principally as sedatives and anxiolytics. Clonazepam is the only benzodiazepine approved for use as a chronic anticonvulsant. Benzodiazepines may rarely cause paradoxical psychological effects, including nightmares, delirium, psychosis, and transient global amnesia.[12,13,34,86] The incidence and intensity of CNS adverse events increases with age.[81]

Similar to barbiturates, various benzodiazepine side chains influence potency, duration of action, metabolites, and rate of elimination. Most benzodiazepines are highly protein bound and lipophilic. They

passively diffuse into the CNS, their main site of action. Because of their lipophilicity, benzodiazepines are extensively metabolized via oxidation and conjugation in the liver prior to their renal elimination.

Benzodiazepines bind nonselectively to "central" benzodiazepine receptors within the brain, termed ω_1 and ω_2. ω_1 receptors are located throughout the brain and contain the $GABA_A$ α_1 subunit.[30] They are hypothesized to affect anxiety, sleep, and amnesia. ω_2 receptors are concentrated predominantly in the hippocampus, striatum, and the spinal cord. They are hypothesized to affect muscle relaxation, cognition, memory, and dependence. Peripheral benzodiazepine receptors ω_3 are found throughout the body, with the greatest concentrations in steroid-producing cells in the adrenal gland, anterior pituitary gland, and reproductive organs (Antidote in Depth A24: Benzodiazepines).

One unique property of the benzodiazepines is their relative safety even after substantial ingestion, which probably results from their GABA receptor properties.[30,95] Unlike many other sedative-hypnotics, benzodiazepines do not open GABA channels independently at high concentrations. Benzodiazepines are not known to cause any specific systemic injury, and their long-term use is not associated with specific organ toxicity. Deaths resulting from benzodiazepine ingestions alone are extremely rare. Most often deaths are secondary to a combination of alcohol or other sedative-hypnotics.[46,123] Supportive care is the mainstay of treatment.

Tolerance to the sedative effects of benzodiazepines occurs more rapidly than does tolerance to the antianxiety effects.[74,110] Abrupt discontinuation following long-term use of benzodiazepines may precipitate benzodiazepine withdrawal, which is characterized by autonomic instability, changes in perception, paresthesias, headaches, tremors, and seizures. Withdrawal from benzodiazepines is common, manifested by almost one-third of long-term users.[66] Alprazolam and lorazepam are associated with more severe withdrawal syndromes compared with chlordiazepoxide and diazepam.[66,67] This is likely due to the fact that both chlordiazepoxide and diazepam have active metabolites. Withdrawal may also occur when a chronic user of a particular benzodiazepine is switched to another benzodiazepine with different receptor activity.[76]

CHLORAL HYDRATE

$$Cl-\overset{\overset{\displaystyle Cl}{|}}{\underset{\underset{\displaystyle Cl}{|}}{C}}-\overset{\overset{\displaystyle OH}{|}}{\underset{\underset{\displaystyle H}{|}}{C}}-OH$$
Chloral hydrate, first introduced in 1832, belongs to one of the oldest classes of pharmaceutical hypnotics, the chloral derivatives. Although still used fairly commonly in children, its use has substantially decreased. Chloral hydrate is well absorbed but is irritating to the GI tract. It has a wide tissue distribution, rapid onset of action, and rapid hepatic metabolism by alcohol and aldehyde dehydrogenases. Trichloroethanol is a lipid soluble, active metabolite that is responsible for the hypnotic effects of chloral hydrate. It has a plasma half-life of 4–12 hours and is metabolized to inactive trichloroacetic acid by alcohol dehydrogenases. It is also conjugated with glucuronide and excreted by the kidney as urochloralic acid. Less than 10% of trichloroethanol is excreted unchanged.

Metabolic rates in children vary widely because of variable development and function of hepatic enzymes, in particular glucuronidation.[16,80] The elimination half-life of chloral hydrate and triculoroethanol is markedly increased in children younger than 2 years. This may be especially of concern in neonates and in infants exposed to repetitive doses.

Acute chloral hydrate poisoning is unique compared with that of other sedative-hypnotics. Cardiac dysrhythmias are believed to be the major cause of death.[45] Chloral hydrate and its metabolites reduce myocardial contractility, shorten the refractory period, and increase myocardial sensitivity to catecholamines.[17,18,26,158] Persistent cardiac dysrhythmias (ventricular fibrillation, ventricular tachycardia, torsades de pointes) are common terminal events.[45] Standard antidysrhythmics often are ineffective, and β-adrenergic antagonists are considered the treatment of choice.[15,17,70,163] In addition to cardiotoxicity, chloral hydrate toxicity may cause vomiting, hemorrhagic gastritis, and rarely gastric and intestinal necrosis, leading to perforation and esophagitis with stricture formation.[71,92] Chloral hydrate is radiopaque and may be detected on radiographs; however, a negative radiograph should not be used to exclude chloral hydrate ingestion. Few hospital-based laboratories have the ability to rapidly detect chloral hydrate or its metabolites.

MEPROBAMATE/CARISOPRODOL

$$NH_2-\overset{\overset{\displaystyle O}{||}}{C}-O-CH_2-\overset{\overset{\displaystyle CH_2}{|}}{\underset{\underset{\displaystyle CH_2CH_2CH_3}{|}}{C}}-CH_2-O-\overset{\overset{\displaystyle O}{||}}{C}-NH_2$$
Meprobamate
Meprobamate was introduced in 1950 and was used for its muscle-relaxant and anxiolytic characteristics. Carisoprodol, which was introduced in 1955, is metabolized to meprobamate. Both drugs have pharmacologic effects on the $GABA_A$ receptor similar to those of the barbiturates. Like barbiturates, meprobamate can directly open the GABA-mediated chloride channel and may inhibit NMDA receptor currents.[108] Both are rapidly absorbed from the GI tract. Meprobamate is metabolized in the liver to inactive hydroxylated and glucuronidated metabolites that are excreted almost exclusively by the kidney. Of all the nonbarbiturate tranquilizers, meprobamate most likely will produce euphoria.[57,58] Unlike most sedative-hypnotics, meprobamate has been reported to cause profound hypotension from myocardial depression.[21] Large masses or bezoars of pills have been noted in the stomach at autopsy after large meprobamate ingestions.[119] Orogastric lavage with a large-bore tube and MDAC may be indicated for significant meprobamate ingestion; however, the potential benefits of orogastric lavage must be weighed against the risks of aspiration. Whole-bowel irrigation may be helpful if multiple pills or small concretions are noted. It is important to note that patients can experience recurrent toxic manifestations as a result of concretion formation with delayed drug release and absorption. Careful monitoring of the clinical course is essential even after the patient shows initial improvement because recurrent and cyclical CNS depression may occur.[119]

BROMIDES

Bromides have been used in the past as "nerve tonics," headache remedies, and anticonvulsants. Although medicinal bromides have largely disappeared from the US pharmaceutical market, bromide toxicity still occurs through the availability of bromide salts of common drugs, such as dextromethorphan.[89] Poisoning also may occur in immigrants and travelers from other countries where bromides are still therapeutically used.[38] An epidemic of more than 400 cases of mass bromide poisoning occurred in the Cacuaco municipality of Luanda Province, Angola in 2007. According to a World Health Organization report, the etiology of the bromide exposure in these cases was believed to be table salt contaminated with sodium bromide. Although the majority of persons affected were children, no actual deaths were attributed to bromide poisoning in this epidemic.[159]

Bromides tend to have long half-lives and toxicity typically occurs over time as concentrations accumulate in tissue. Bromide and chloride ions have a similar distribution pattern in the extracellular fluid. It is postulated that because the bromide ion moves across membranes slightly more rapidly than the chloride ion, it is more quickly reabsorbed in the tubules from the glomerular filtrate than the chloride ion. Although osmolar equilibrium persists, CNS function is progressively impaired by a poorly understood mechanism, with resulting inappropriateness of behavior, headache, apathy, irritability, confusion, muscle weakness, anorexia, weight loss, thickened speech, psychotic behavior, tremulousness, ataxia, and eventually coma.[20,164] Delusions and hallucinations can occur. Bromide can lead to hypertension, increased intracranial pressure, and papilledema. Chronic use of bromides can also lead to dermatologic changes, with the hallmark characteristic of a facial acneiform rash.[53,141] Toxicity with bromides during pregnancy may lead to accumulation of bromide in the fetus.[100] A spurious laboratory result of hyperchloremia with decreased anion gap may result from bromide's interference with the chloride assay on older analyzers[161] (Chap. 16). Thus an isolated elevated serum chloride concentration with neurologic symptoms should raise suspicion of possible bromide poisoning.

◼ ZOLPIDEM/ZALEPLON/ZOPICLONE/ESZOPICLONE
These oral xenobiotics have supplanted benzodiazepines as the most commonly prescribed sleep aid medications.[35] Although they are structurally unrelated to the benzodiazepines, they bind preferentially to the ω_1 benzodiazepine receptor subtype in the brain, specifically the $GABA_A$ α_1 subunit.[30] They have a lower affinity for ω_2 receptors than benzodiazepines, therefore they have potent hypnotic effects with less potential for dependence.[30,52] Each of these xenobiotics has a relatively short half-life (≤ 6 hours), with zaleplon exhibiting the shortest half-life (1 hour). Unlike benzodiazepines that prolong the first two stages of sleep and shorten stages 3 and 4 of rapid eye movement (REM) sleep, zolpidem and its congeners all decrease sleep latency with little effect on sleep architecture. Because of their receptor selectivity, they appear to have minimal effect at other sites on the GABA receptor that mediate anxiolytic, anticonvulsant, or muscle-relaxant effects.[69,151]

They are hepatically metabolized by various CYP450 enzymes. Zolpidem is mainly metabolized by CYP3A4. Zaleplon is primarily metabolized by aldehyde oxidase, but CYP3A4 is also involved in parent compound oxidation. Zopiclone is primarily metabolized by CYP3A4 and CYP2C8, whereas eszopiclone is metabolized mainly by CYP3A4 and CYP2E1. Various pharmacokinetic interactions with inhibitors or inducers of CYP450 enzymes and these medications have been reported.[51]

In isolated overdoses, drowsiness and CNS depression are common. However, prolonged coma with respiratory depression is exceptionally rare. Isolated overdoses usually manifest with depressed level of consciousness without respiratory depression. For example, even at

40 times the therapeutic dose of zolpidem, no biologic or electrocardiographic abnormalities were reported.[40] Tolerance to zolpidem and its congeners has also been described. Withdrawal has been reported after abrupt discontinuation following chronic use but typically is mild.[50,155] Flumazenil may reverse the hypnotic or cognitive effects of these agents.[73,156] Deaths have resulted when zolpidem was taken in large amounts with other CNS depressants (Antidote in Depth A23 Flumazenil).[40]

◼ PROPOFOL
Propofol is a rapidly acting intravenous sedative-hypnotic that is a postsynaptic $GABA_A$ agonist and also induces presynaptic release of GABA.[117] Propofol is also an antagonist at NMDA receptors.[63,64,131] In addition, propofol also interacts with dopamine, promotes nigral dopamine release possibly via $GABA_B$ receptors,[96,120] and has partial agonist properties at dopamine (D_2) receptors.[118] Propofol is used for procedural sedation and either induction or maintenance of general anesthesia. It is highly lipid soluble, so it crosses the blood–brain barrier rapidly. The onset of anesthesia usually occurs in less than 1 minute. The duration of action after short-term dosing is usually less than 8 minutes due to its rapid redistribution from the CNS.

Propofol use is associated with various adverse effects. Acutely, propofol causes dose-related respiratory depression. Propofol may decrease systemic arterial pressure and cause myocardial depression. Although short-term use of propofol does not typically cause dysrhythmias or myocardial ischemia, atropine-sensitive bradydysrhythmias have been noted, specifically sinus bradycardia and Mobitz type I atrioventricular block.[140,154,162] Short-term use of propofol in the perioperative setting is associated with a myoclonic syndrome manifesting as opisthotonus, myoclonus, and sometimes myoclonic seizure like activity.[82,90]

Prolonged propofol infusions for more than 48 hours at rates of 4–5 mg/kg/h or greater are associated with a life-threatening *propofol-infusion syndrome* (PIS) involving metabolic acidosis, cardiac dysrhythmias, and skeletal muscle injury.[61] The clinical signs of PIS often begin with the development of a new right bundle branch block and ST segment convex elevations in the electrocardiogram precordial leads.[60] Predisposing factors to the development of PIS include young age, severe brain injury (especially in the setting of trauma), respiratory compromise, concurrent exogenous administration of catecholamines or glucocorticoids, inadequate carbohydrate intake, and undiagnosed mitochondrial myopathy. Some authors propose a "priming" and "triggering" mechanism for PIS with endogenous glucocorticoids, catecholamines, and possibly cytokines as "priming" agents, and exogenous catecholamines and glucocorticoids in the setting of high-dose propofol infusion as "triggering" stimuli.[147] Propofol is suggested to induce disruption of mitochondrial free fatty acid utilization and metabolism, causing a syndrome of energy imbalance and myonecrosis similar to other mitochondrial myopathies.[22,125,148] Case reports associate propofol with metabolic acidosis with elevated lactate concentration and fatal myocardial failure in children and young adults; however, it has been reported in older adults as well.[98] Cases of metabolic acidosis may be associated with an inborn disorder of acylcarnitine metabolism.[160] Caution is advised when prolonged propofol infusions are used in any patient, especially children, as they may have a previously undiagnosed myopathy that would cause them to be at increased risk for PIS. Despite

the increasing number of reports of PIS in the literature, a direct cause-and-effect relationship remains to be fully elucidated.

The unique nature of propofol's carrier base, a milky soybean emulsion formulation, is associated with multiple adverse events. It is a fertile medium for many organisms, such as enterococcal, pseudomonal, staphylococcal, streptococcal, and candidal strains. In 1990, the Centers for Disease Control and Prevention (CDC) reported an outbreak of *Staphylococcus aureus* associated with contaminated propofol. This carrier base also impairs macrophage function,[22] causes hypertriglyceridemia[33,55,67,76] and histamine-mediated anaphylactoid reactions,[31,62,148] and impairs platelet and coagulation function.[4,29]

■ ETOMIDATE
Etomidate is an intravenous nonbarbiturate, hypnotic primarily used as an anesthesia induction agent. It is active at the $GABA_A$ receptor, specifically the β_2 and β_3 subunits.[91,104] Only the intravenous formulation is available in the United States. The onset of action is less than 1 minute and its duration of action is less than 5 minutes.

Etomidate is commercially available as a 2 mg/mL solution in a 35% propylene glycol solution. Propylene glycol toxicity from prolonged etomidate infusions is implicated in the development of hyperosmolar metabolic acidosis.[78,144,146] Etomidate has minimal effect on cardiac function, but rare cases of hypotension are reported.[42–44,135] Etomidate has both proconvulsant and anticonvulsant properties.[25,103] Involuntary muscle movements are common during induction, and may be caused by etomidate interaction with glycine receptors at the spinal cord level.[27,84,85]

Etomidate depresses adrenal production of cortisol and aldosterone and has thus been associated with adrenocortical suppression, usually after prolonged infusions.[117,152,153] One prospective randomized trial demonstrated chemical adrenal suppression with decreased serum cortisol levels and decreased responses to ACTH stimulation in trauma patients even after receiving single-dose etomidate.[54] The authors postulate that this may have been associated with prolonged duration of hospital and ICU stays, as well as prolonged ventilator requirements. Other authors question the clinical significance of adrenal suppression from single-dose etomidate administration.[137]

■ DEXMEDETOMIDINE

Dexmedetomidine is a central α_2 adrenergic agonist that decreases central presynaptic catecholamine release, primarily in the locus coeruleus. It was approved by the FDA in 1999 for short-term use in the critical care setting. It has a terminal half-life of 1.8 hours and its volume of distribution is less than 1 L/kg. When dexmedetomidine is used to help wean patients from ventilators, a better level of desired sedation is achieved with less associated delirium.[97,136] It is also used for procedural sedation in certain settings such as interventional radiology procedures and awake fiberoptic intubations. In addition, other authors have described lesser opioid requirements in postoperative patients sedated with dexmedetomidine, compared with propofol. Individual case reports also document the use of dexmedetomidine in benzodiazepine, opioid, or ethanol withdrawal.[28,36,114,138,139]

Dexmedetomidine has no effect at the GABA receptor, and unlike other sedative-hypnotics, it is not associated with significant respiratory depression. Although mechanistically similar to clonidine, dexmedetomidine does not appear to cause as much respiratory depression as clonidine. Dexmedetomidine is said to induce a state of "cooperative sedation," in which a patient is sedated but yet able to interact with health-care providers. Dexmedetomidine may also have analgesic effects.[23]

Dexmedetomidine is currently approved for use only for less than 24 hours, as safety trials have not yet explored its use beyond 24 hours. Unlike clonidine, rebound hypertension and tachycardia have not been described upon cessation of dexmedetomidine. Because dexmedetomidine decreases central sympathetic outflow, its use should probably be avoided in patients whose clinical stability is dependent on high resting sympathetic tone. The most common adverse effects from its use are nausea, dry mouth, bradycardia, and varying effects on blood pressure (usually hypertension followed by hypotension). Slowing of the continuous infusion may help to prevent or lessen the hypotensive effects.[23]

RAMELTEON/MELATONIN

Ramelteon is a synthetic melatonin-analog that is FDA approved for the treatment of chronic insomnia. Ramelteon has been proposed to decrease both latency to sleep induction and length of persistent sleep.[127] Melatonin (*N*-acetyl-5-methoxytryptamine) and melatonin-containing products are sold as dietary supplements. Melatonin is naturally synthesized from tryptophan by the enzyme 5-hydroxyindole-*O*-methyltransferase, primarily within the pineal gland in humans. Melatonin and ramelteon both act as agonists at MT-1 and MT-2 receptors, which are G protein–coupled receptors mainly located in the suprachiasmatic nucleus of the brain.[127] Ramelteon is specific for MT-1 and MT-2 receptors, whereas melatonin is active at other melatonin receptors that are likely not involved in sleep. MT-1 receptors appear to be involved in sleep induction, whereas MT-2 receptors are involved in regulation of the circadian sleep-wake cycle in humans.[134]

Ramelteon is administered as an oral medication that is rapidly absorbed but undergoes significant first-pass metabolism. Ramelteon is metabolized primarily by CYP1A2 hepatic isoenzyme. The half-life of ramelteon with therapeutic use is roughly 1.5 hours.

Adverse effects of ramelteon are often mild, and usually include dizziness, fatigue, headache. The endocrine effects of long-term exposure to ramelteon seem to be limited to subclinical increases in serum prolactin concentration in women, and do not appear to affect adrenal or thyroid function.[109] In addition, ramelteon has a low abuse potential and does not appear to be associated with a withdrawal syndrome or with rebound insomnia.[49,77,83] As of yet, there are no reported cases of significant toxicity from ramelteon overdose.

SUMMARY

Sedative-hypnotics encompass a wide range of xenobiotics with varying mechanisms of action. Patients with sedative-hypnotic overdoses often present with the primary manifestation of CNS depression; however, death typically results from respiratory depression and subsequent cardiovascular collapse in the setting of concurrent co-ingestion of other CNS depressants. Careful monitoring, airway protection, and good supportive care are the cornerstones of treatment. Specific antidotes such as flumazenil and treatments such as hemodialysis are rarely indicated.

FLUMAZENIL

Mary Ann Howland
Flumazenil is a competitive benzodiazepine receptor antagonist. Its role in patients with unknown overdose is limited because seizures and dysrhythmias may develop when the effects of a benzodiazepine are reversed in a mixed overdose. Flumazenil also has the potential to induce benzodiazepine withdrawal symptoms, including seizures in patients who are benzodiazepine dependent. Flumazenil does not reliably reverse the respiratory depression induced by intravenous benzodiazepines.[57] Flumazenil is the ideal antidote for the relatively few patients who are both naïve to benzodiazepines and who overdose solely on a benzodiazepine as well as benzodiazepine-naïve patients whose benzodiazepine component must be reversed after procedural sedation. Because the duration of effect of flumazenil is shorter than that of most benzodiazepines, repeat doses may be necessary and vigilance is warranted. Flumazenil has no role in the management of ethanol intoxication but may be considered for patients with hepatic encephalopathy. However, further study is needed before its routine use can be recommended.[4] Case reports raise the possibility of a role for flumazenil in patients with paradoxical reactions to therapeutic doses of benzodiazepines.[75] Flumazenil is not expected to be effective in sedating overdoses such as baclofen in which a benzodiazepine receptor is not involved.[14] Flumazenil is effective for overdoses of zolpidem and zaleplon, nonbenzodiazepines that interact with ω_1 receptors, a subclass of central benzodiazepine receptors.[41,51,54]

HISTORY

Haefely and Hunkeler's initial work on chlordiazepoxide synthesis[69] led to an attempt to develop benzodiazepine derivatives that would act as antagonists.[32] This endeavor was initially unsuccessful but led to the promising γ-aminobutyric acid (GABA) hypothesis of benzodiazepine mechanism of action. In 1977, the then-new technique of radioligand binding identified specific high-affinity benzodiazepine binding sites. Other investigators simultaneously isolated a product produced by a *Streptomyces* species that had the basic 1,4-benzodiazepine structure. Synthetic compounds subsequently were derived from this molecule to act as potential tranquilizers. Further research attempted to produce benzodiazepines with potent anxiolytic and anticonvulsant activity and diminished sedative and muscle-relaxing properties. Testing revealed these derivatives had high in vitro binding affinities but lacked in vivo activity. An inability to enter the CNS was considered an explanation for the discordance. During an experiment that attempted to demonstrate CNS penetration of these derivatives, diazepam given to incapacitate the animals had a surprisingly weak effect. This lack of potency led to the discovery of a benzodiazepine antagonist. Further modifications led to the synthesis of flumazenil (Ro 15-1788).[20,55]

PHARMACOLOGY

The benzodiazepine receptor modulates the effect of GABA on the $GABA_A$ receptor by increasing the frequency of Cl^- channel opening, leading to hyperpolarization. Agonists such as diazepam stimulate the benzodiazepine receptor to produce anxiolytic, anticonvulsant, sedative, amnestic, and muscle relaxant effects at low doses, and hypnosis at high doses.[33] Flumazenil is a water-soluble benzodiazepine analog with a molecular weight of 303 Daltons. It is a competitive antagonist at the benzodiazepine receptor, with very weak agonist properties both in animal models and in humans.[50] Inverse agonists bind the benzodiazepine receptor and result in the opposite effects of anxiety, agitation, and seizures. Antagonists, such as flumazenil, competitively occupy the benzodiazepine receptor without causing any functional change and without allowing an agonist or inverse agonist access to the receptor. The zero set point of intrinsic activity may be influenced by the activity of the GABA system or by chronic treatment with benzodiazepines.[22] Positron emission tomography investigations reveal that 1.5 mg flumazenil leads to an initial receptor occupancy of 55%, whereas 15 mg causes almost total blockade of benzodiazepine receptor sites.[60]

The structures of flumazenil, diazepam, and midazolam are shown above. Table A23–1 summarizes the physiochemical and pharmacologic properties of flumazenil.[37]

VOLUNTEER STUDIES

Volunteer studies demonstrate that the ability of flumazenil to reverse the effects of sedating doses of intravenous (IV) benzodiazepines (such as 30 mg diazepam, 3 mg lorazepam, 10 mg midazolam) is dose dependent and begins within minutes.[18] Peak effects occur within 6 to 10 minutes.[57] Most individuals achieve complete reversal of benzodiazepine effect with

TABLE A23–1. Physicochemical and Pharmacologic Properties of Flumazenil

pK$_a$	Weak base
Partition coefficient at pH 7.4	14 (octanol/aqueous PO$_4$ buffer)
Volume of distribution	1.06 L/kg
Distribution half-life (t$_{1/2}\alpha$)	≤5 minutes
Metabolism	Hepatic: three inactive metabolites
	High clearance
Elimination	First order
Protein binding	54%–64%
Elimination half-life (t$_{1/2}\beta$)	53 minutes
Onset of action	1–2 minutes
Duration of action	Dependent on dose and elimination of benzodiazepine, time interval, dose of flumazenil, and hepatic function

a total IV dose of 1 mg, titrated in 0.2-mg aliquots.[5,13] A 3-mg IV dose produces similar effects that last approximately twice as long as the 1-mg dose.

CONSCIOUS SEDATION

A number of studies evaluated patients who received diazepam or midazolam as conscious sedation for endoscopy or cardioversion.[6,12,13,17,39,40] When a benzodiazepine is given for conscious sedation during a procedure, flumazenil appears safe and effective for reversal of sedation and partial reversal of amnesia and cognitive impairment.[25] Most patients respond to total doses of 0.4 to 1 mg. Administering flumazenil slowly at a rate of 0.1 mg/min minimizes the disconcerting symptoms associated with rapid arousal, such as confusion, agitation, and emotional lability. Residual sedation becomes evident within 20 to 120 minutes, depending on the dose and pharmacokinetics of the specific benzodiazepine and the dose of flumazenil.[25] For this reason, patients must be carefully monitored and subsequent doses of flumazenil titrated to clinical response. Because the amnestic effect of benzodiazepines and the cognitive and psychomotor effects are not fully reversed, posttreatment instructions should be reinforced in writing and given to a responsible caregiver accompanying the patient.[18,25] Because of the risk of resedation, many practitioners elect not to use flumazenil routinely.

Two patients undergoing endoscopy who developed seizures following benzodiazepine reversal are reported.[64] One patient had a history of seizures, and the other had no obvious etiology. Both patients recovered uneventfully.

USE FOR PARADOXICAL REACTION TO MIDAZOLAM AND OTHER BENZODIAZEPINES

Paradoxical reactions to benzodiazepines are unpredictable and documented in as many as 10% of adults and in 3.4% of children.[28,46] Common features include worsening restlessness, agitation, disorientation, flailing, and dysphoria.[24,26,52,75] The mechanism is unclear and has been attributed to a disinhibition reaction.[21] These reactions are reported to occur anywhere from several minutes to 210 minutes after sedation is begun.[26,75] Management strategies include administering higher doses of the benzodiazepines, adding other drugs such as opioids or droperidol, stopping the procedure, and using flumazenil.[24,36,52,56,65,66,75] Intravenous flumazenil was administered to six adults with paradoxical reactions to midazolam in 0.1-mg aliquots. Doses of 0.2 to 0.5 mg were effective in all the patients with a response occurring within 30 seconds.[75] Attention to other causes of unexpected behavior such as hypoxia or hypoglycemia must be addressed and corrected.

EFFECTS ON BENZODIAZEPINE-INDUCED RESPIRATORY DEPRESSION

Flumazenil has not consistently reversed benzodiazepine-induced respiratory depression and is not suggested as the initial intervention should respiratory depression occur.[15,29,44,48,57,62,70,73] It is likely that following oral overdose, benzodiazepine-induced respiratory insufficiency is related to smooth muscle relaxation resulting in a mechanical effect with an increase in upper airway resistance and obstructive apnea rather than a central effect.[31] Although flumazenil might improve the situation,[31,53] other standard procedures such as airway repositioning, supplemental oxygen, bag-valve-mask ventilation, and endotracheal intubation, if indicated, should be used either prior to or during reversal.

USE IN THE OVERDOSE SETTING

The role of flumazenil in the overdose setting is controversial.[71] The first argument against flumazenil use is the rare morbidity and mortality associated with benzodiazepine use. An analysis of 702 patients who had taken benzodiazepines alone or in combination with ethanol or other drugs and were subsequently admitted to a medical intensive care unit (ICU) over a 14-year period revealed a 0.7% fatality rate (five deaths) and 9.8% complication rate (69 patients).[35] In comparison, the fatality rate for patients with nonbenzodiazepine-related overdoses was 1.6% (55 of 3430 patients). In the pure benzodiazepine group, two patients died and 18 (12.5%) of 144 patients had complications, mostly aspiration pneumonitis and decubitus ulcers. Proponents of flumazenil therapy suggest that some of the 29 diagnostic procedures used in the patients were unnecessary, and some of the complications could have been prevented. Opponents of flumazenil therapy suggest that many of the cases of aspiration pneumonitis occurred prior to hospital admission and that the patients also suffered from trauma and infectious disease, making most diagnostic procedures necessary.

In an effort to develop indications for safe and effective use of flumazenil, overdosed comatose patients were retrospectively assigned to either a low-risk or non–low-risk group.[30] Low-risk patients had CNS depression with normal vital signs, no other neurologic findings, no evidence of ingestion of a tricyclic antidepressant by history or electrocardiogram (ECG), no seizure history, and absence of an available history of chronic benzodiazepine use. All other patients fell into the non–low-risk category. Of 35 consecutive comatose patients, four patients were assigned to the low-risk group. Flumazenil caused complete awakening in three patients and partial awakening in the fourth patient in the low-risk group, with no adverse effects. In the non–low-risk group of 31 patients, flumazenil caused complete awakening in four patients and partial awakening in five patients. Seizures occurred in five patients, of whom only one had a history of seizures, five were long-term benzodiazepine users, four had abnormal vital signs prior to reversal, and three had evidence of hyperreflexia or myoclonus. Therefore, although flumazenil use probably was safe and effective in the low-risk group, few patients met the criteria for inclusion in that risk group. The risk of seizures appears substantial in non–low-risk patients.

TABLE A23–2. Indications for Flumazenil Use in the Overdose Setting

Pure benzodiazepine overdose in a nontolerant individual who has
- CNS depression
- Normal vital signs, including SaO$_2$
- Normal ECG
- Otherwise normal neurologic examination

CNS, central nervous system; ECG, electrocardiogram.

In conclusion, the risks of flumazenil usually outweigh the benefits in overdose patients.[61] When non–benzodiazepine-dependent patients ingest benzodiazepines alone in overdose, as rarely occurs in adults but might be expected in children, the risks associated with flumazenil use may be limited.[77] Table A23–2 summarizes the indications for flumazenil use in the overdose setting.

ADVERSE EFFECTS AND SAFETY ISSUES

Flumazenil has been studied in more than 3500 patients worldwide, including healthy volunteers and overdosed patients, or patients who had undergone conscious sedation. The safety of flumazenil in healthy volunteers is well established, with no discernible objective or subjective effects. However, precipitation of seizures in benzodiazepine-dependent patients, unmasking of dysrhythmias in patients who coingest a benzodiazepine with a prodysrhythmic drug, and resedation within 20 to 120 minutes in patients receiving benzodiazepines for conscious sedation are recognized adverse effects associated with flumazenil administration.

The ability of flumazenil to precipitate acute benzodiazepine withdrawal seizures in a more controlled environment than the overdose setting was demonstrated by reversal of long-term benzodiazepine sedation in the ICU. A study of 1700 patients revealed that 14 patients developed adverse drug reactions, probably half related to abrupt arousal.[6] Two patients with a history of epilepsy developed tonic–clonic seizures, and one patient developed myoclonic seizures.[6] Dose-dependent induction of withdrawal reactions is therefore suggested. Small total doses (less than 1 mg) of titrated flumazenil may allow sufficient occupation of the benzodiazepine receptor sites by benzodiazepines so that abrupt withdrawal seizures are uncommon.

In a study of 12 patients receiving midazolam sedation for 4 ± 3 days, 0.5 mg flumazenil was administered as a rapid bolus. Serum norepinephrine and epinephrine concentrations rose within 10 minutes, returned to baseline within 30 minutes, and correlated with increased heart rate, blood pressure, and myocardial oxygen consumption.[38]

Flumazenil causes a significant overshoot in cerebral blood flow and may cause a large increase in intracranial pressure in patients who receive midazolam for severe head injury.[79]

In one review, 30 published case studies involving 758 patients with drug overdoses were reviewed.[23] In total, 387 patients participated in double-blind study protocols and 371 patients in open-label studies.[23] Fifty percent of cases were mixed overdoses. The doses of flumazenil ranged from 0.2 to 5 mg. Five cases of seizures were temporally related to flumazenil administration, all after large bolus doses. In three of the five patients, high concentrations of tricyclic antidepressants were present in the blood. The seizures resolved either without treatment or following administration of a small dose of a benzodiazepine.

Dysrhythmias developed in two patients given small doses of flumazenil, both presumably associated with the presence of a tricyclic antidepressant. Of 497 patients enrolled in two clinical US studies sponsored by the manufacturer,[23] six patients developed seizures (five had coingested tricyclic antidepressants) and one patient who had taken a tricyclic antidepressant and carbamazepine had a junctional tachycardia, which normalized after several minutes. Thus, in reviewing 1255 patients, 11 patients had seizures and three developed dysrhythmias, for an incidence of approximately 0.9%. The consensus report was that (1) flumazenil is not a substitute for primary emergency care; (2) hypoxia and hypotension should be corrected before flumazenil is used; (3) when used small titrated doses of flumazenil should be used; (4) flumazenil should not be used in patients with a history of seizures, evidence of seizures or jerking movements, or evidence of a tricyclic antidepressant overdose; and (5) flumazenil should not be used by inexperienced clinicians.

An analysis of all seizures associated with flumazenil gathered from previously published cases or reports to the manufacturer was published.[64] Forty-three patients had seizures and 6 patients died, but the author believed that none of the deaths were attributable to flumazenil.[64] Four patients developed status epilepticus; two were presumed to be caused by concomitant tricyclic antidepressant exposure, and the other two patients had received benzodiazepines to treat status epilepticus prior to flumazenil therapy. In six of 43 seizure episodes, the relationship to flumazenil use was believed to be inadequately defined. The remaining 37 patients were stratified into five categories. In category 1, seven patients were given flumazenil after they had received a benzodiazepine for treatment of a seizure disorder. Six of these seven patients received greater than 1 mg flumazenil. In category 2, 20 patients received flumazenil for reversal of a benzodiazepine in a mixed-drug overdose. Many of these patients had coingested tricyclic antidepressants. Thirteen of these patients received greater than 1 mg flumazenil. Two of the patients in this group developed status epilepticus and died, possibly secondary to a severe tricyclic antidepressant overdose. Category 3 included five patients who received benzodiazepines for suppression of non–drug-induced seizures. Two of these five patients received greater than 1 mg flumazenil. Category 4 included three patients with acute benzodiazepine overdoses in the presence of chronic benzodiazepine dependence. Category 5 included two patients who received a benzodiazepine for conscious sedation. Therefore, flumazenil use may place the patient at risk for seizures by unmasking a toxic effect in mixed overdose, by removing the protective anticonvulsant effect in a patient with non–drug-induced seizures, or by precipitating acute benzodiazepine withdrawal. Table A23–3 summarizes the contraindications to flumazenil use.

TABLE A23–3. Contraindications to Flumazenil Use

History	Clinical
Seizure history or current treatment of seizures	Potential ECG evidence of cyclic antidepressant use: terminal rightward 40 ms axis, QRS or QT prolongation
Ingestion of a xenobiotic capable of provoking seizures or cardiac dysrhythmias	
	Hypoxia
Long-term use of benzodiazepines	Hypotension.

DOSING

Slow IV titration (0.1 mg/min) to a total dose less than or equal to 1 mg seems most reasonable. Resedation may occur at 20 to 120 minutes, and readministration of flumazenil may be necessary. Although not approved by the US Food and Drug Administration (FDA), continuous IV infusion of flumazenil 0.1 to 1.0 mg/h in 0.9% sodium chloride solution or 5% dextrose in water has been used following the loading dose.[41,76,78]

AVAILABILITY

Flumazenil is available as Romazicon and as a generic formulation by many manufacturers in a concentration of 0.1 mg/mL with parabens in 5-mL and 10-mL vials.

ROLE IN NONBENZODIAZEPINE TOXICITY

▪ HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy is considered a reversible metabolic encephalopathy characterized by a spectrum of CNS effects. Symptoms may progress from confusion and somnolence to coma. One current hypothesis implicates an increase in GABAergic tone in the development of encephalopathy.[7,63]

Animal studies of hepatic encephalopathy secondary to galactosamine or thioacetamide (hepatotoxins) demonstrate an increase in GABA effect, which is antagonized by flumazenil, bicuculline (a GABA-receptor antagonist), and isopropylbiclophosphate chloride (a calcium channel blocker).[7] Cerebrospinal fluid (CSF) from these animals contained a benzodiazepine receptor ligand with agonist activity. Rat studies involving hepatic encephalopathy resulting from acute liver ischemia showed only a slight response to flumazenil, but significant improvement after administration of a partial inverse agonist.[11,72]

Human studies have detected benzodiazepine-binding activity in the CSF, (but not in serum), of patients with hepatic encephalopathy. One group identified four to 19 peaks representing benzodiazepine-binding ligands from the frontal cortex of 11 patients who died of hepatic encephalopathy.[10] Two of the peaks were further characterized as diazepam and N-desmethyldiazepam. Brain concentrations of these substances were two to 10 times higher than normal in six of the patients and were normal in five patients. Patients with idiopathic recurring stupor who have measurable "endozepines" (endogenous benzodiazepine ligands) in serum and CSF are reported.[58,68]

Flumazenil improves the clinical and electrophysiologic responses of patients with hepatic encephalopathy and idiopathic recurring stupor.[4,8,19,58,68] Some patients with encephalopathy have improved from stage IV to stage II encephalopathy after intravenous flumazenil. Maximal improvement after flumazenil lasts approximately 1 to 2 hours and gradually dissipates within 6 hours. The response rate in a meta-analysis averaged approximately 30%.[27] The proposed explanations for the unresponsiveness include cerebral edema, hypoxia, other systemic diseases or complications, and irreversible CNS damage.

Animal and human data convincingly support the concept that increased GABAergic tone is responsible for hepatic encephalopathy. Evidence for endogenous benzodiazepine ligands that enhance GABA action also are demonstrated but controversial.[1,3] The source of these benzodiazepine receptor agonists is unclear, but diet and/or production by gut bacteria is postulated.[7] Most authorities believe endogenous de novo synthesis is unlikely and propose prior benzodiazepine exposure and persistence as an explanation. Neurosteroids and hemoglobin metabolites are also implicated in the pathophysiology of hepatic encephalopathy.[3,59]

Flumazenil can lead to short-term improvement of the clinical condition of a subgroup of patients with hepatic encephalopathy and may prove useful as an addition to conventional therapy.[2,4,9] Additional research is necessary to prospectively identify responders, provide dosing considerations, and evaluate adverse effects. There is no survival benefit.

▪ ETHANOL INTOXICATION

Animal studies indicate that many of the actions of ethanol are mediated through GABA neurotransmission.[67] Acute ethanol administration appears to enhance GABA transmission and inhibit N-methyl-d-aspartate (NMDA) excitation. Chronic ethanol administration leads to downregulation of the GABA system. Ethanol enhances $GABA_A$-induced chloride influx in a dose-dependent fashion without a direct effect on chloride. Flumazenil does not influence this action of GABA. Chronic ethanol use selectively increases the sensitivity to inverse benzodiazepine agonists, invoking a change in coupling or conformation of the receptor. These changes may explain the development of tolerance and the kindling and production of seizures that occur on ethanol withdrawal.

Two double-blind studies in patients with benzodiazepine or ethanol overdose evaluated the response to flumazenil. In one study of 13 patients with suspected ethanol intoxication, six had no response to placebo when it was given first, whereas all 13 patients responded to 5 mg flumazenil.[47] Improved consciousness occurred after 15 minutes, and respiratory rates increased from 14 to 16 breaths/min. Heart rate and blood pressure were not affected. The 5-mg dose of flumazenil was selected because no improvement in mental status or vital signs was observed when 1 mg flumazenil was administered to four patients.

Another comparable study demonstrated similar results.[42] Flumazenil (1 mg) administered to nine ethanol-intoxicated patients produced the same effects as placebo. Subsequent administration of 2 to 5 mg flumazenil in the open part of the study produced a clear improvement in the modified Glasgow Coma Score scale in five of 11 patients. However, a closer inspection of phase 1 of the study reveals that an arousal reaction occurred in seven of nine patients after the flumazenil dose and in five of nine patients following placebo administration. It is conceivable that the improvement in phase 2 was a continuation of the arousal reaction.

One case report indicates that ethanol-induced respiratory depression was reversed by flumazenil,[45] but whether the actual data support the authors' conclusions is unclear.

A randomized, double-blind, crossover study of eight male volunteers given IV ethanol to achieve a constant serum ethanol concentration of 160 mg/dL was conducted.[16] Once stabilized, the volunteers were given either placebo or 5 mg flumazenil. Subjective and objective psychomotor tests were conducted, with no differences noted between volunteers given flumazenil and volunteers given placebo. Thus the probability of ethanol reversal at the suggested doses appears unlikely.

Based on this information, flumazenil likely does not have a significant effect on ethanol intoxication, and low doses of flumazenil (less than 1 mg) have no effect. The 5-mg doses reportedly produce favorable changes in sensorium, but these findings may be the result of confounding factors. Because we would not administer 5 mg flumazenil in the overdose setting to avoid the increased risk of adverse effects at this dose, flumazenil cannot be recommended for reversal of ethanol intoxication.

SUMMARY

The risks of flumazenil appear to greatly outweigh the potential benefits of reversal when benzodiazepines are used chronically or acutely to treat a seizure disorder. Flumazenil is best avoided in the overdose setting when evidence indicates coingestion of a drug capable of causing

seizures or dysrhythmias. For example, any indication that theophylline, carbamazepine, chloral hydrate, chloroquine, and/or chlorinated hydrocarbons was ingested is a contraindication to flumazenil use.[74] Flumazenil should also not be used when involvement of a tricyclic antidepressant is strongly suggested based on history, clinical findings, or ECG findings (prolonged QRS complex).[34,43,49,74] In the event of flumazenil-induced seizure, a therapeutic dose of a benzodiazepine such as diazepam should be effective. Flumazenil is a competitive antagonist; higher doses of benzodiazepines will reverse higher doses of flumazenil.

SUBSTANCES OF ABUSE

CHAPTER 75
AMPHETAMINES

William K. Chiang
Phenylethylamine
Methylenedioxymethamphetamine
Methamphetamine

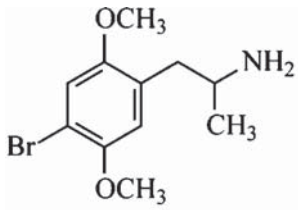
Epinephrine

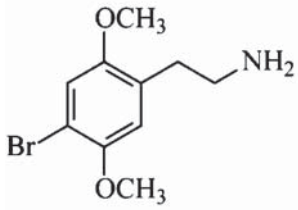
Amphetamine is the trivial name and acronym for racemic β-phenyliso-propylamine or α-methylphenylethylamine. Numerous substitutions of the phenylethylamine structure are possible, resulting in different amphetamine like compounds. Commonly, these compounds are referred to as amphetamines or amphetamine analogs, although phenylethylamine is the more precise term. For the purposes of this chapter, the term *amphetamines* refers to amphetamine analogs, and *amphetamine* specifically refers to β-phenylisopropylamine.

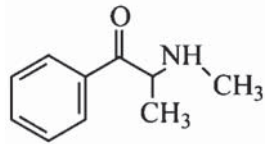
Since the initial marketing of amphetamines, continued abuse and misuse have been substantial.[18,103,184] Over the years amphetamines have been advocated by the medical communities for the treatment of depression, obesity, enuresis, postencephalitic parkinsonism, coma, ADHD, and even alcoholism.[103,139]

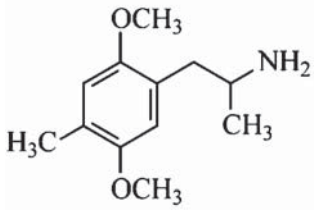
Currently, there are very few medical indications for amphetamines, which include narcolepsy, attention deficit hyperactivity disorder, and short-term weight reduction.[124] The prescriptive amphetamines include methylphenidate, pemoline, phentermine, phendimetrazine, amphetamine, dextroamphetamine, and methamphetamine. Due to their structural differences, some amphetamines can technically be marketed as nonamphetamine products. There continues to be a resurgence of amphetamine abuse, particularly with methamphetamine and methylenedioxymethamphetamine (MDMA).[49,101,208,210,268,275]

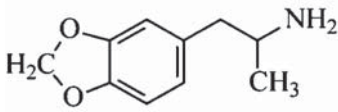
HISTORY AND EPIDEMIOLOGY

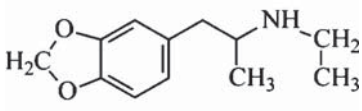
Edeleano first synthesized amphetamine (racemic β-phenylisopro-pylamine) in 1887.[103] However, it was not rediscovered until the 1920s,


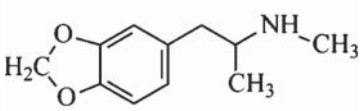


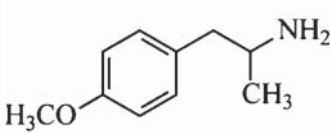


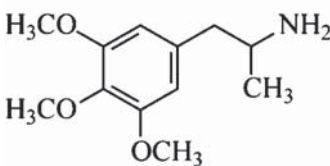












when there was significant concern about the supply of ephedrine for asthma therapy. In the search for the synthesis for ephedrine, Alles from UCLA rediscovered dextroamphetamine, and Ogata from Japan discovered methamphetamine (*d*-phenylisopropylmethylam-ine hydrochloride).[103] Amphetamine was marketed as Benzedrine inhaler, a nasal decongestant, by Smith, Kline, and French in 1932.[18] Amphetamine tablets were available in 1935 for the treatment of nar-colepsy, and were advocated as anorexiants in 1938. The stimulant and euphoric effects of amphetamines were widely recognized, resulting in diverse forms of abuse and misuse. Amphetamine abuse was reported as early as 1936.[139] Benzedrine inhalers, each containing 250 mg of amphetamine, were widely abused, leading to a ban by the FDA in 1959. Propylhexedrine found in Benzedrex inhalers, a less-potent amphetamine like xenobiotic marketed in 1949, supplanted Benzedrine inhalers.[7] Propylhexedrine was also significantly misused.[7]

Both amphetamine and methamphetamine were supplied as stimu-lants for soldiers and prisoners of war in World War II.[18,185] Widespread methamphetamine abuse in Japan persisted for more than a decade after the war. From 1950 to the 1970s, there were sporadic periods of widespread amphetamine use and abuse in the United States. In the 1960s, various amphetamine derivatives such as methylenedioxyam-phetamine (MDA) and *para*-methoxyamphetamine (PMA) were pop-ularized as hallucinogens.[47] Until 1971, only a small proportion of the amphetamines produced by pharmaceutical companies was used for legitimate medical problems.[103,187] The Controlled Substance Act of 1970 placed amphetamines in Schedule II to prevent the diversion of pharmaceutical amphetamines for nonmedicinal uses.[54] Amphetamine abuse subsequently declined in the 1970s.[39,149,183,187]

In the 1980s, the so-called designer amphetamines (Table 75–1), mostly methylenedioxy derivatives of amphetamine and metham-phetamine, came into vogue, as a mechanism of circumventing exist-ing regulations. The most well-known xenobiotics were MDMA and 3,4-methylenedioxyethamphetamine (MDEA), but more than 200 different derivatives are known.[64,249] Before 1986, the Controlled Substances Act classified drugs as illegal only after they were syn-thesized and formally recognized by their structure, effects, or illegal usage. During this period, any analogs, such as these "designer drugs" not yet formally classified could be sold legally. In 1986, the standard became prospective for any xenobiotic that was used as a stimulant, hallucinogen, or depressant, and for any xenobiotic designed as such.[27] In effect, this amendment eliminated the legal loophole that allowed the designer drug industry to flourish. Although the meaning of the term "designer drugs" has changed and is no longer legally relevant, many of these analogs are still illicitly available.[119,131,177]

From the late 1980s until today, a dramatic resurgence of metham-phetamine abuse spread throughout much of the United States. A high purity preparation of methamphetamine hydrochloride was marketed in a large crystalline form termed "ice" by abusers.[10,44,67,184] In fact, meth-amphetamine surpassed cocaine and became the primary substance of abuse among those seeking care in the drug treatment programs of San Diego and San Francisco counties in the 1990s.[101,116,188] From 1991 to

TABLE 75–1. Designer Amphetamines

Xenobiotic	Clinical Manifestations	Structure
4-Bromo-2,5-dimethoxyamphetamine (DOB)	Marked psychoactive effect potency > mescaline Delayed onset of action, peak 3–4 h Fantasy, mood altering for 10 h, resolution 12–24 h Agitation, sympathetic excess Sold as impregnated paper, like LSD	
4-Bromo-2,5-methoxyphenyl-ethylamine (2CB, MFT)	Relaxation Sensory distortion Agitation Hallucination Potency > mescaline	
Methcathinone (cat, Jeff, Khat, ephedrone)	Hallucinations sympathetic excess	
4-Methyl-2,5-dimethoxyamphetamine (DOM/STP) (serenity, tranquility, peace)	Narrow therapeutic index Euphoria, perceptual distortion Hallucinations, sympathetic excess	
3,4-Methylenedioxyamphetamine (MDA, love drug)	Empathy, euphoria Agitation, delirium, hallucinations, death associated with sympathetic excess	
3,4-Methylenedioxyethamphetamine (MDEA, Eve)	Comparable to MDMA Sympathetic excess	
3,4-Methylenedioxymethamphetamine (MDMA, Adam, ecstasy, XTC)	Psychotherapy "facilitator" Euphoria, empathy Nausea, anorexia Anxiety, insomnia Sympathetic excess	
para-Methoxyamphetamine (PMA)	Potent hallucinogen Sympathetic excess	
2,4,5-Trimethoxyamphetamine	Similar to mescaline	

1994, the number of methamphetamine-related deaths in the United States reported by medical examiners tripled from 151 to 433, with a disproportional distribution from the Los Angeles, San Diego, San Francisco, and Phoenix metropolitan areas. The number of methamphetamine-related emergency department (ED) visits also increased from 4900 in 1991 to 17,400 in 1994.[101] The number of methamphetamine-related ED visits has remained stable since the mid-1990s despite significant local geographical changes.[73] The 2007 national survey on drug use and health demonstrated a stabilization or slight decline in methamphetamine use.[261] Recently, methamphetamine use has become particularly prevalent among men having sex with men in New York City.[108] Although the initial source of methamphetamine was from Pacific Rim countries such as Korea and Taiwan, currently the majority is produced in the United States.[45,80,268] Methamphetamine is the most common illicit drug produced by clandestine laboratories in the United States at this time. Because of the ease and low cost of methamphetamine synthesis and the local production, the end user cost of methamphetamine is less than one-third that of cocaine.[80] Methamphetamine production in the United States was primarily located in California and Oregon in the late 1990s, but it has spread through every state, although it remains particularly prevalent in the midwest and western United States.[268] The number of clandestine methamphetamine laboratory seizures nationally increased from 327 in 1995 to 15,994 in 2004. Both the cost and the prolonged duration of effect may contribute to the increased popularity of methamphetamine.[101,268]

Beginning in the mid-1990s, MDMA became and remains the amphetamine most widely used by college students and teenagers. MDMA is used by this population in large gatherings, known as "rave" or "techno" parties in England, Australia, and the United States.[215,216,275] MDMA use is prevalent in parties and clubs worldwide. Other MDMA-like analogs are often used or sold as MDMA in these gatherings.[11,275] Despite the popularity of MDMA, recent data in the United States demonstrate a decline in its past year use.[262]

Reports of methcathinone (a Khat-derived substance) use in the midwestern United States,[96,286] and a resurgence of 4-bromo-2,5-methoxyphenylethylamine (2CB) in dance clubs occurred in the 1990s.[77,90] Fortunately, the fear for the widespread use of these agents never materialized. Although the trend of a particular amphetamine analog waxes and wanes, use and abuse of amphetamines in general has continued unabated for the last quarter century.

PHARMACOLOGY

The pharmacologic effects of amphetamines are complex but the primary mechanism of action is the release of catecholamines, particularly dopamine and norepinephrine, from the presynaptic terminals. Although there are conflicting mechanistic models of amphetamine induction of catecholamine release, the variable results may be directly correlated with the different concentrations of amphetamines used in experimental models.[189] The best models to study the mechanism of action of amphetamines are based on dopaminergic neurons; similar mechanisms are invoked for norepinephrine and serotonin. Two storage pools exist for dopamine in the presynaptic terminals: the vesicular pool and the cytoplasmic pool. The vesicular storage of dopamine and other biogenic amines is maintained by the acidic environment within the vesicles and the persistence of a stabilizing electrical gradient with respect to the cytoplasm. This environment is maintained by an adenosine triphosphate (ATP)-dependent active proton transport system.[243] At low doses, amphetamines release dopamine from the cytoplasmic pool by exchange diffusion at the dopamine uptake transporter site in the membrane. At moderate doses, amphetamines diffuse through the presynaptic terminal membrane and interact with the neurotransmitter transporter

on the vesicular membrane to cause exchange release of dopamine into the cytoplasm. Dopamine is subsequently released into the synapse by reverse transport at the dopamine uptake site.[243,264] At high doses, an additional mechanism is invoked as amphetamine diffuses through the cellular and vesicular membranes, alkalinizing the vesicles, and permitting dopamine release from the vesicles and delivery into the synapse by reverse transport.[264,265] Binding selectivity to the neurotransmitter transporters largely determines the range of pharmacologic effects for the particular amphetamine. The affinity of MDMA for serotonin transporters is 10 times greater than that for dopamine and norepinephrine transporters, hence it produces primarily serotonergic effects.[99]

Amphetamines may also block the reuptake of catecholamines by competitive inhibition.[104,124] However, the effects of this mechanism are considered to be minor. At higher doses, amphetamines can cause the release of serotonin (5-hydroxytryptamine [5-HT]) and affect central serotonin receptors. Certain amphetamines, such as MDMA and 4-bromo-2,5-dimethoxyamphetamine (DOB), have more significant serotonergic effects.[87,124] Amphetamines are structurally similar to nonhydrazine amine-derivative monoamine oxidase inhibitors such as phenelzine and tranylcypromine, and most amphetamines retain a weak monoamine oxidase-inhibiting activity, the clinical significance of which is unclear.[212]

The most identifiable effects of amphetamines are those caused by catecholamine release and the resultant stimulation of peripheral α- and β-adrenergic receptors. In the central nervous system, increased norepinephrine at the locus caeruleus mediates the anorectic and alerting effects, and also some locomotor stimulation.[103] The increase in central nervous system dopamine, particularly in the neostriatum, mediates stereotypical behavior and other locomotor activities.[53,94,104,141] The activity of dopamine in the neostriatum appears to be linked to glutamate release and inhibition of GABAergic efferent neurons.[94,140,141] Stimulation of the glutamatergic system contributes significantly to the stereotypical behavior, locomotor activity, and neurotoxicity of amphetamines.[19,25,140,141,257,258] The effects of serotonin and dopamine on the mesolimbic system alter perception and cause psychotic behavior.[94,123,263]

Because amphetamines directly interact with neurotransmitter transporters, minor modifications of the molecule may significantly alter its pharmacologic profile.[129] The α-methyl group in the amphetamine structure introduces chirality to the molecule. Except for MDMA and certain MDMA analogs, the *d*-enantiomers are typically 4–10 times more potent than the *l* forms of amphetamines. Substitutions at different positions of the phenylethylamine molecule alter the general clinical effects of amphetamines, as demonstrated by both animal and human observations. Xenobiotics with methyl substitution at the α carbon, such as amphetamine and methamphetamine, possess strong stimulant, cardiovascular, and anorectic properties.[93,196] Large group substitution at the α carbon reduces the stimulant and cardiovascular effects, but retains the anorectic properties (such as in phentermine).[13] Substitution at the *para* position of the phenyl ring enhances the hallucinogenic or serotonergic effects of amphetamines (such as in *para*-chloroamphetamine and MDMA).[13,84,181] Although some of these generalizations enable scientists to understand the effects of amphetamines, there are many exceptions, and such generalizations may not apply when large doses of a particular molecule are ingested.[74] In terms of the spectrum of activities, methamphetamine results in the most potent cardiovascular effects, and DOB results in the most consequential hallucinogenic and serotonergic effects.[93,196]

PHARMACOKINETICS AND TOXICOKINETICS

In general, amphetamines are relatively lipophilic and hence they can readily cross the blood–brain barrier. They have large volumes of distribution, varying from 3–5 L/kg for amphetamine and 3–4 L/kg for

methamphetamine and phentermine, to 11–33 L/kg for methylphenidate. Pemoline is the exception as it has a small volume of distribution (0.2–0.6 L/kg).[12] Amphetamines differ from catecholamines in that they lack the catechol structure (hydroxyl groups at the 3 and 4 positions of the phenyl ring) and are resistant to metabolism by catechol-O-methyltransferase (COMT).[124] The addition of an α-methyl group in amphetamines confers resistance to metabolism by monoamine oxidase. These characteristics permit better oral bioavailability and a longer duration of effects.[196]

Amphetamines are eliminated via multiple pathways, including diverse routes of hepatic transformation, and by renal elimination. For MDMA and its analogs, N-dealkylation, hydroxylation, and demethylation are the dominant hepatic pathways.[45,46,172] Depending on the particular xenobiotic, active metabolites of secondary amphetamines and ephedrine derivatives may be formed.[12,45] N-demethylation of methamphetamine and MDMA result in the formation of amphetamine and MDA, respectively.[45] Dealkylation and demethylation are mainly performed by cytochrome P450 (CYP) isoenzymes, including CYP1A2, CYP2D6, and CYP3A4, but they are also performed by flavin monooxygenases.[172] Polymorphism of CYP2D6 in humans was discovered as a result of decreased p-hydroxylation of amphetamine in certain individuals. Since its discovery, CYP2D6 polymorphism has been implicated in drug toxicity, substance use and abuse, and lack of drug efficacy in predisposed individuals.[246] Increased amphetamine toxicity is a potential concern in patients with decreased CYP2D6 activity. Although animals with CYP2D6 deficiency are more susceptible to MDMA toxicity,[51] limited studies in humans do not demonstrate an association of mortality and CYP2D6 deficiency.[88,199] In general, because multiple enzymes and pathways, including renal are involved in amphetamine elimination, it is less likely that CYP2D6 polymorphism or drug interactions with CYP3A4 alone will significantly increase toxicity. However, it is unclear if toxicity is enhanced in the simultaneous presence of altered drug metabolism and renal dysfunction.

Renal elimination is substantial for amphetamine (30%), methamphetamine (40%–50%), MDMA (65%), and phentermine (80%). Amphetamines are relatively strong bases with a typical pK_a range from 9–10, and renal elimination varies depending on the urine pH.[12] The half-life of amphetamines varies significantly: amphetamine, 8–30 hours; methamphetamine, 12–34 hours; MDMA, 5–10 hours; methylphenidate, 2.5–4 hours; and phentermine, 19–24 hours.[12,45] Repetitive administration, which typically occurs during binge use, may lead to drug accumulation and prolongation of the apparent half-life and duration of effect.[133]

CLINICAL MANIFESTATIONS

The clinical effects of amphetamines are largely related to the stimulation of central and peripheral adrenergic receptors. These clinical manifestations and their associated complications are similar to those from cocaine use and may be indistinguishable except for the duration of effect of amphetamines, which tends to be longer (up to 24 hours).[67]

Compared to cocaine, amphetamines are less likely to cause seizures, dysrhythmias, and myocardial ischemia. This may be related to the sodium channel–blocking effects and to the thrombogenic effect of cocaine.[95] Psychosis appears to be more likely with amphetamines than cocaine, which may be related to the more prominent dopaminergic effects of amphetamines.[9,94] Tachycardia and hypertension are the most common manifestations of cardiovascular toxicity. Most patients present to the ED, however, because of the CNS manifestations.[67,130,279] These patients are anxious, volatile, aggressive, and may have life-threatening agitation. Visual and tactile hallucinations, as well as psychoses, are common.[22,68,69,114,164,226,239] Other sympathetic findings include mydriasis, diaphoresis, and hyperthermia (Table 75–2).[68,72]

TABLE 75–2. Clinical Manifestations of Amphetamine Toxicity	
Acute	Mydriasis
Cardiovascular system	Tremor
Hypertension	Nausea
Tachycardia	**Other organ system manifestations**
Dysrhythmias	Rhabdomyolysis
Myocardial ischemia	Muscle rigidity
Aortic dissection	Acute lung injury
Vasospasm	Ischemic colitis
Central nervous system	**Laboratory abnormalities**
Hyperthermia	Leukocytosis
Agitation	Hyperglycemia
Seizures	Hyponatremia
Intracerebral hemorrhage	Elevated CPK
Headache	Elevated liver enzymes
Euphoria	Myoglobinuri
Anorexia	
Bruxism	**Chronic**
Choreoathetoid movements	Vasculitis
Hyperreflexia	Cardiomyopathy
Paranoid psychosis	Pulmonary hypertension
Other sympathetic symptoms	Aortic and mitral regurgitation
Diaphoresis	Permanent damage to dopaminergic
Tachypnea	and serotonergic neurons

Death from amphetamine toxicity most commonly results from hyperthermia, dysrhythmias, and intracerebral hemorrhage.[40,63,81,136,143,163,206,227] Direct CNS effects may result in seizures. Tachycardia, hypertension, and vasospasm may lead to cerebral infarction,[97,153,231] intraparenchymal and subarachnoid hemorrhage,[59,112,127,142,258,281] myocardial ischemia or infarction,[83,207,272] aortic dissection,[59,71] acute lung injury,[30,193,194] obstetrical complications, fetal death,[162] and ischemic colitis.[17,121,134] Dysrhythmias vary from premature ventricular complexes to ventricular tachycardia and ventricular fibrillation.[136,165] Agitation, increased muscular activity, and hyperthermia can result in metabolic acidosis, rhabdomyolysis,[56] acute tubular necrosis (acute renal failure), and coagulopathy.[72,89,135,144] Unless these systemic signs and symptoms are rapidly reversed, multiorgan failure and death may ensue.

Amphetamine users seeking intense "highs" may go on "speed runs" for days to weeks. Because of the development of acute CNS tolerance, they use increasing amounts of amphetamines during these periods, usually without much nutritional sustenance or sleep, attempting to achieve their desired euphoria.[18,54,155,253,266] Acute psychosis resembling paranoid schizophrenia may occur during these binges and has contributed to both amphetamine-related suicides and homicides.[75,151] Return to a normal sensorium occurs within a few days after discontinuation of the drug. Once an amphetamine user experiences psychosis, it is likely to be recurrent, even after prolonged abstinence, which may be related to a *kindling phenomenon*.[18,204,266] Amphetamine-induced psychosis has contributed to the understanding of the function of dopamine in schizophrenia. Typically after such binges, patients may sleep for prolonged periods of time, feeling hungry and depressed when awake. During this period of depression or withdrawal, the patient continues to crave amphetamines.[114,152,158]

There are some direct neurologic effects of amphetamines. Compulsive repetitive behavior patterns are reported in humans and animals. Individuals may constantly pick at their skin, grind their teeth (bruxism), or perform repetitive tasks, such as constantly cleaning their house or car.[18] MDMA users often carry pacifiers to relieve bruxism. Choreoathetoid movements, although uncommon, are reported with acute and chronic amphetamine usage.[150,167,171,219,238,252] The etiology of the choreoathetoid movements may be related to increased dopaminergic stimulation in the striatal area.

Necrotizing vasculitis is associated with amphetamine abuse.[20,48] Angiography typically demonstrates beading and narrowing of the small- and medium-sized arteries (see Fig. 5–25).[233,260] Progressive necrotizing arteritis[59] can involve multiple organ systems, including the central nervous, cardiovascular, gastrointestinal, and renal systems. Complications include cerebral infarction and hemorrhage, coronary artery disease, pancreatitis, and renal failure.[48,111,166,233,237,260,281,285] The etiology of the arteritis remains unclear. Although various contaminants associated with injection drug use were postulated as potential etiologies, oral and IV amphetamine use in animal models are also associated with vasculitis, suggesting that this is a direct amphetamine effect.[234,235,269] Cardiomyopathy is also reported with acute and chronic amphetamine abuse.[20,125,200,255] Excessive catecholamine exposure in patients with pheochromocytomas and chronic cocaine use may be responsible for their associated cardiomyopathies; amphetamine-induced cardiomyopathy may be produced by similar mechanisms.[103,138,278]

Valvular heart disease is also associated with the use of the appetite-suppressants fenfluramine, dexfenfluramine, and phentermine, particularly if the duration of therapy is greater than 4 months.[52,85,132,146,276] The initial reports, in 1997, implicated significant aortic and mitral regurgitation with the use of these drugs and the prevalence was as high as 32%.[38] These reports resulted in the withdrawal of fenfluramine and dexfenfluramine. Subsequent studies demonstrated mostly mild aortic regurgitation and possibly mitral regurgitation; the overall prevalence varies from study to study, ranging from 0.14% to 22.7%.[85,132,146,274,283] The highest risks appear to be in patients taking combination therapy with fenfluramine and phentermine, and those who used the drugs for prolonged periods (>4 months).[132] The dramatic differences in the overall prevalence rate in these studies may be related to differences in patient population, duration of therapy, and the timing of echocardiography (ie, during therapy or after the cessation of therapy). A meta-analysis demonstrated a 12% prevalence rate of valvular regurgitation (mostly aortic) with more than 90-day use of the appetite-suppressants, compared to 5.9% in the unexposed group. There was no difference when the appetite suppressants were used less than 90 days.[236] Echocardiographic findings of the valvular dysfunction typically improve following cessation of these drugs.[120] The exact etiology of the valvular disease is postulated to be related to increased serotonin or direct effects on 5-HT$_{2B}$ receptors. Similar valvular disorders are recognized in patients exposed to persistently increased serotonin concentrations with conditions such as malignant carcinoid syndrome; it is unclear why the carcinoid syndrome predominantly affects right-sided valves, whereas these drugs primarily affect left-sided valves.[228]

Primary pulmonary hypertension, a rare and potentially fatal disease, is reported with chronic methamphetamine and propylhexedrine use.[7,43,70,156,241] However, substantial epidemiologic risk for primary pulmonary hypertension is demonstrated only with fenfluramine, aminorex (2-amino-5-phenyl-2-oxazoline), and methamphetamine.[24,105,250] One recent study also linked methampetamine use with pulmonary hypertension.[43] Pulmonary hypertension was associated with the use of Aminorex—as an anorectic agent in Europe from 1965 to 1968.[106] In 1996, a case-controlled study substantiated the increased risk of pulmonary hypertension with the use of amphetamine appetite-suppressant drugs, particularly with fenfluramine.[1] The risk of pulmonary hypertension was increased 23-fold when the cumulative use of anorectics totaled more than 3 months,[1] but may develop following exposure to anorectics that may be as brief as 3 weeks.[105] Increased serotonin or direct effects on 5-HT$_{2B}$ receptors in the pulmonary vasculature is postulated to result in pulmonary vasoconstriction and endothelial proliferation.[122,193,229] Interestingly, although fenfluramine is a weak agonist for 5-HT$_{2B}$ receptors, its metabolite norfenfluramine is a potent agonist for 5-HT$_{2B}$ receptors and may be responsible for causing pulmonary hypertension.[126] Although MDMA use has not been associated with pulmonary hypertension, MDMA and its metabolite MDA have significant effects on 5-HT$_{2B}$ receptor activity and can induce cardiac valvular interstitial cell proliferation in vitro.[230] With widespread MDMA use, both pulmonary hypertension and valvular diseases are potential public health concerns.[247] Pulmonary hypertension that develops following the use of anorectics may be partially reversible after withdrawal of the xenobiotic; however, the median survival of patients studied during the European Aminorex epidemic was 3.5 years from the time of diagnosis.[105] With current advances in therapy, improved survival is expected.[232]

Although the chronic administration of MDMA and its analogs are better publicized, chronic administration of various amphetamines, including amphetamine and methamphetamine, to animals alters dopamine and serotonin transporter functions, depletes dopamine and serotonin in the neuronal synapses, and produces irreversible destruction of those neurons.[16,87,222,223,225,242,281] The etiology of neuronal toxicity may be related to the generation of oxygen free radicals, resulting in the generation of toxic dopamine and serotonin metabolites and neuronal destruction.[87,157,244,281,282] Based on animal models, dose, frequency and duration of exposure, and ambient temperature can affect neurologic injuries. Intact dopamine or serotonin transporters are necessary to produce neurologic injury. Xenobiotics that inhibit transporter function may prevent neurologic injuries in animals.[99] Significant differences are also noted across species; mice are typically resistant to MDMA-induced neurologic injury.[175] Although not as well studied as MDMA, studies of former methamphetamine users demonstrated impaired memory and psychomotor functions, as well as corresponding dopamine transporter dysfunction and abnormal glucose metabolism on PET scans.[245,270,271] However, it is still not clear as to the difference in species susceptibility to neurologic injuries, the duration of effects in primates and humans, and functional consequences of neurotoxicity in humans. The potential for permanent neurologic effects associated with chronic amphetamine use in humans requires further study. Despite the first report of neurologic injuries from methamphetamine in animals in 1976, many questions remain unanswered.

Finally, multiple medical complications can result from injection drug use and from the associated contaminants. Contamination with microbials may result in HIV infection, hepatitis, and malaria. Bacterial and foreign-body contamination may result in endocarditis, tetanus, wound botulism, osteomyelitis, and pulmonary and soft-tissue abscesses.[42]

DIAGNOSTIC TESTING

Diagnosis by history is rarely reliable as patients often do not know the exact xenobiotic they have used.[149] Also, there is no readily available xenobiotic-specific serum analysis. Qualitative urine immunoassay testing for amphetamines is available, but it is not valuable in the acute overdose setting. Typically, the turnaround time for the test result is at least several hours, which is far too long to be clinically useful. Both

false-positive and false-negative results are common. For example, many cold preparations contain structurally similar substances such as pseudoephedrine that may cross-react with the immunoassay.[50,57,82,213] Likewise, selegiline, a selective monoamine oxidase type B (MAO-B) inhibitor used for the treatment of parkinsonism, is metabolized to amphetamine and methamphetamine. Patients taking selegiline will have a positive screen with most amphetamine-testing techniques.[139] Even a true-positive result only means the patient has used an amphetamine analog within the last several days. In addition, most immunoassays do not react with all amphetamines, resulting in false-negative results. For example, MDMA frequently is unrecognized on standard urinary drug testing.[17,50] Although newer, rapid, serum qualitative drug screens are available, false-positive and false-negative results remain common and may be misleading. The gold standard for drug testing, gas chromatography–mass spectrometry analysis, can misidentify isomeric substances such as *l*-methamphetamine, which is present in nasal inhalers, with *d*-methamphetamine, if performed by inexperienced personnel.[254] In summary, the suspicion of amphetamine toxicity cannot be confirmed rapidly with a high degree of reliability by the laboratory.

The physical and psychological assessment is nonspecific, and polydrug use is quite common. As such, the prevalence of amphetamine use in the local geographic region should heighten the suspicion of amphetamine toxicity in patients with a suggestive presentation. Management decisions must be determined by the clinical manifestations and impressions.

Blood specimens should be sent for glucose, BUN, and electrolyte assays. Hyponatremia should be considered for any patient with an altered sensorium and suspected MDMA usage (Chap. 16).[173] An ECG should be obtained to exclude ischemia, hyperkalemia, and drug toxicity (cyclic antidepressant), and continuous cardiac monitoring should be initiated. A complete blood count, urinalysis, coagulation profile, chest radiograph, CT of the head, and lumbar puncture may be necessary, depending on the clinical presentation.

MANAGEMENT

Table 75–3 summarizes the therapeutic approach to a patient with amphetamine toxicity. The initial medical assessment of the agitated patient must include the vital signs and a rapid complete physical examination.

Hyperthermia, a frequent and rapidly fatal manifestation in patients with drug-induced delirium, requires immediate interventions to achieve cooling.[89,135,144] Some patients will require physical restraint to gain clinical control and prevent personal harm to themselves or others. Because agitation and resistance against physical restraint may lead to rhabdomyolysis and continued heat generation, intravenous chemical sedation should be instituted immediately. Intravenous (IV) glucose ($D_{50}W$, 0.5–1 g/kg) and thiamine 100 mg should be given as indicated.

Because the clinician cannot accurately distinguish the diverse etiologies of xenobiotic-induced delirium, the choice of chemical sedation should be safe and effective regardless of the etiology. The most appropriate choice of sedation is benzodiazepines because they have a high therapeutic index and good anticonvulsant activity. They are effective not only for the treatment of delirium induced by acute overdose of cocaine, amphetamines, and other xenobiotics but also the delirium associated with ethanol and sedative-hypnotic withdrawal (see A-24 Benzodiazepines).[65,68,95,205] The dose of the chosen benzodiazepine should be titrated rapidly intravenously until the patient is calm. In our clinical experience, cumulative benzodiazepine dosages required in the initial 30 minutes to achieve adequate sedation frequently exceed 100 mg of diazepam or its equivalent. Antipsychotics, particularly potent

TABLE 75–3. Management of Patients with Amphetamine Toxicity
Agitation
Benzodiazepines (usually adequate for the cardiovascular manifestations)
Diazepam 10 mg (or equivalent) IV, repeat rapidly until the patient is calm (cumulative dose may be as high as 100 mg of diazepam)
Seizures
Benzodiazepines
Barbiturates
Propofol
Hyperthermia
External cooling
Control agitation rapidly
Gastric decontamination and elimination
Activated charcoal for recent oral ingestions
Hypertension
Control agitation first
α-Adrenergic receptor antagonist (phentolamine)
Vasodilator (nitroprusside, nitroglycerin or possibly nicardipine)
Delirium or hallucinations with abnormal vital signs
If agitated: benzodiazepines
Delirium or hallucinations with normal vital signs
Consider risk/benefit of haloperidol or droperidol

dopamine antagonists such as haloperidol and droperidol, are frequently recommended by others for amphetamine-induced delirium. Antipsychotics may actually antagonize some of the effects of amphetamines via dopamine blockade.[65,66,78] In animal models, haloperidol may be superior to diazepam in preventing mortality from amphetamine toxicity.[35,61,65,66] In clinical experience, however, the benzodiazepines appear to be as efficacious as the antipsychotics in the management of amphetamine toxicity.[68] Antipsychotics may lower the seizure threshold, alter temperature regulation, may cause acute dystonia and cardiac dysrhythmias, and do not interact with the benzodiazepine–γ-aminobutyric acid (GABA)–chloride channel receptor complex. All of these effects may worsen the clinical outcomes related to occult or concomitant cocaine toxicity and ethanol withdrawal.[95,100,205]

Rhabdomyolysis from amphetamine toxicity usually results from agitation and hyperthermia.[84,144] Sedation prevents further muscle contraction and heat production. External cooling should be instituted for significant hyperthermia. Adequate IV hydration and cardiovascular support should maintain urine output of 1–2 mL/kg/h. Although urinary acidification can significantly increase amphetamine elimination and decrease the half-lives of amphetamine and methamphetamine,[12,14,15,60] this pH manipulation does not decrease toxicity, and, in fact, may increase the risk of renal compromise and acute tubular necrosis from rhabdomyolysis by precipitating ferrihemate in the renal tubules.[56] Patients with acute renal failure, acidemia, and hyperkalemia will likely require urgent hemodialysis.

Amphetamine body packers should be treated similarly to those who transport cocaine (Chap. 76 and Special Considerations: SC-4 Internal Concealment of Xenobiotics). Any sympathomimetic symptom suggesting leakage of the packets requires surgical intervention.[273] Intravenous fluids, benzodiazepines, intubation, and external cooling may be necessary to stabilize these patients.

INDIVIDUAL XENOBIOTICS

■ METHAMPHETAMINE

From the 1950s to the 1970s, there were multiple epidemics of methamphetamine abuse in the United States.[18] Methamphetamine was and sometimes still is referred to as "crack," "speed," "yaba," and "go." The pharmacologic profile of methamphetamine is quite similar to amphetamine, although the effects on the central nervous system are more substantial.[44] "Ice," the common name for methamphetamine in the 1990s because of the crystal forms, does not differ pharmacologically from other forms of methamphetamine. Methamphetamine is readily absorbed by the oral, parenteral, and inhalational routes. Because of a prolonged half-life of 19–34 hours, the duration of its acute effects can be greater than 24 hours.[44,67,68]

Since the 1990s, the activity and purity of methamphetamine available on the street is substantially higher than previous epidemics because of the improved methods of synthesis.[160] Methamphetamine is now typically greater than 80%–90% pure and almost exclusively in the dextroisomer form, which is most active on the CNS.

Methamphetamine is easily synthesized with the proper chemicals and minimal equipment.[86] The primary ingredient of methamphetamine synthesis is ephedrine, which can be hydrogenated into methamphetamine. The ephedrine method, using pharmaceutical grade L-ephedrine, produces a product with few contaminants that is stereochemically pure.[67,214] The production of the large crystal is possible by creating a supersaturated solution of methamphetamine hydrochloride.[67] Nonprescription sales of ephedrine are now restricted and monitored in many states.[268] Phenyl-2-propanone (P2P), as an alternative ingredient, can be methylated into ephedrine and then into methamphetamine.[29] Because of the strict control of ephedrine and P2P, illicit chemists use phenylacetic acid to synthesize P2P.[29,58] Lead acetate, which is used as a substrate for the reaction, resulted in an epidemic of lead poisoning associated with methamphetamine abuse in Oregon.[3,41] Lead concentrations reported in drug users were as high as 513 µg/dL, and some samples of illicitly manufactured methamphetamine had lead contents as high as 60% by weight.[41] Mercury contamination was also documented, although clinical mercury toxicity has not been reported.[27] The number of potential chemicals involved in the methamphetamine manufacturing process is significant, and without any legal monitoring, contamination of the product and the environment is inevitable.[4,29,128,154,217] In fact, in certain periods 20%–30% of the illicit methamphetamine manufacturing sites discovered were discovered because of laboratory explosions.[80] In San Bernardino County, California alone in 1995, 360 methamphetamine laboratories were identified and closed by drug enforcement agents.[80] These makeshift methamphetamine laboratories pose a significant health risk to law enforcement officers and the general public, causing respiratory and ophthalmic irritation, headaches, and burns.[36,259] Methamphetamine laboratory–related burns were well reported from burn centers and associated with increased mortality. Currently, the sale of other potential amphetamine synthetic ingredients, such as hydrochloric acid, hydrogen chloride gas, anhydrous ammonia, red phosphorus, and iodine, are also monitored and restricted in the United States.[29,37,268]

■ 3,4-METHYLENEDIOXYMETHAMPHETAMINE

MDMA was first synthesized in 1912, and was rediscovered in 1965 by Shulgin.[27] It is currently one of the most widely abused amphetamines by college students and teenagers.[49,208,275,279] It is commonly known as "ecstasy," "E," "Adam," "XTC," "M&M," and "MDM." Other structural relatives of MDMA, MDEA ("Eve") and MDA ("love

drug"), are also used or distributed as MDMA in areas of MDMA use. These xenobiotics have similar clinical effects and acute and chronic toxicity. Other MDMA-related xenobiotics have been found at "rave" scenes, 2CB, 2,4-dimethoxy-4-(*n*)-propylthiophenylethylamine (2C-T7), and N-methyl-1-(3, 4-methylenedioxyphenyl)-2-butanamine (MBDB).[34,77,90,147] The term, "ecstasy" may be used for all of these xenobiotics. Typically, MDMA is available in colorful and branded tablets that vary from 50 mg to 200 mg. MDMA and similar analogs are so-called entactogens (meaning touching within), capable of producing euphoria, inner peace, and a desire to socialize.[177,256] In addition, some psychologists used MDMA to enhance psychotherapy until the Controlled Substances Act of 1986.[195] People who use MDMA report that it enhances pleasure, heightens sexuality, and expands consciousness without the loss of control.[27,102,177] Negative effects reported with acute use included ataxia, restlessness, confusion, poor concentration, and impaired memory.[256] MDMA has about one-tenth the CNS stimulant effect of amphetamine. Unlike amphetamine and methamphetamine, MDMA is a potent stimulus for the release of serotonin.[31,62,104] The concentration of MDMA required to stimulate the release of serotonin is 10 times less than that required for the release of dopamine or norepinephrine. In animal models, the stereotypic and discriminatory effects of MDMA and its congeners can be distinguished from those of other amphetamines.[32,195]

The sympathetic effects of MDMA are mild in low doses. However, when a large amount of MDMA is taken, the clinical presentation is similar to that of other amphetamines and deaths can result from abuse.[72,118,119,191,279] Those patients at greatest risk develop dysrhythmias, hyperthermia, rhabdomyolysis, and disseminated intravascular coagulation.[72,117,251] Significant hyponatremia is reported with MDMA use.[2,115,174,197] MDMA and its metabolites increase the release of vasopressin (antidiuretic hormone) and may be related to their serotonergic effects.[79,117] Furthermore, substantial free-water intake combined with sodium loss from physical exertion in dance clubs may be crucial to the development of hyponatremia.

A major concern with MDMA usage is its long-term effects on the brain. In numerous animal models, acute administration of MDMA leads to the decrease in serotonin reuptake transporter (SERT) function and numbers. Recovery of SERT function may take several weeks. Repetitive administration of MDMA ultimately leads to permanent damage to serotonergic neurons, typically causing injury to the axons and the terminals while sparing the cell bodies.[174,178,180,201,220,222] Some regeneration of synaptic terminals can occur even with neuronal damage, but functional recovery is incomplete. Intact SERT function is necessary for MDMA-induced neurotoxicity. Xenobiotics that inhibit the uptake of serotonin prevent MDMA-induced neurotoxicity in animals. Animal data suggest that MDMA induces hydroxyl free-radical generation and decreases antioxidants in serotonergic neurons.[224,248] MDMA does not directly cause neurotoxicity, but its metabolites 3-methyldopamine and N-methyl-α-methyldopamine do produce neurotoxicity in animals.[186] When antioxidants are depleted, neuronal damage may occur.

The evidence for these potential neurotoxic effects in humans is less clear.[148] Indirect evidence of serotonergic effects in humans includes lower concentrations of 5-hydroxyindoleacetic acid (5-HIAA) in the cerebral spinal fluid of MDMA users than in controls.[221] Case reports and studies of MDMA users demonstrate alteration in mood, sleep, anxiety, cognition, memory, and impulse control—all functions that are believed to be affected by serotonin.[5,176,179,181,185] Either single-photon emission tomography (SPECT) or positron emission tomography (PET) demonstrates decreased SERT function in MDMA users, even after prolonged abstinence.[28,202,218] Memory deficits appeared to persist even when MDMA users were abstinent.[98,190] A major deficit in human

studies is finding appropriate control groups as people with psychiatric disease are also more likely to be or have been MDMA users.[182] MDMA users often are polydrug users. Currently, there are no available human postmortem histopathologic data for MDMA users.[147] Further studies are required to address the long-term neuropsychiatric effects of MDMA.

■ PROPYLHEXEDRINE
Smith, Kline, and French introduced propylhexedrine in 1949 as the primary active ingredient in the Benzedrex nasal inhaler, which was to replace the widespread abuse of amphetamine nasal inhalers.[8,84] Propylhexedrine is an alicyclic aliphatic sympathomimetic amine that is structurally similar to amphetamine, with a local vasoconstrictive effect and approximately 10% of the CNS stimulatory effect of amphetamine.[8] Propylhexedrine abuse became prevalent after the removal of amphetamine from nasal inhalers. The abusers disassembled the inhaler and ingested the cotton pledget vehicle of propylhexedrine itself, diluted it in beverages, or reconstituted the drug for intravenous injection. Numerous effects were reported with propylhexedrine abuse, including sudden death, myocardial infarction, cardiomyopathy, pulmonary hypertension, and acute psychosis.[7,8,55,70,84,161,169,170,277] Although propylhexedrine in nasal inhalers has largely been replaced by safer sympathomimetics (Chap. 50), the drug is still readily available and is abused as an inexpensive, legal "high."

■ KHAT, CATHINONE, AND METHCATHINONE

Khat (also known as quat and gat), the fresh leaves and stems from the *Catha edulis* shrub, is a commonly used drug in eastern and central Africa, and in parts of the Arabian peninsula. Attention to khat was highlighted in the early 1990s by war media coverage in Somalia and Ethiopia. Khat is sold in small bundles of leaves in the local markets of these countries. The leaves and the tender stems are chewed or occasionally concocted into tea. Khat chewing has a significant role at social gatherings in these countries.[168] There is a trend of increasing khat consumption and binges among adolescents in these countries.[202] When the dried leaves and stems were studied, the primary active ingredient was thought to be cathine (norpseudoephedrine), present as 0.1%–0.2% of the dried material. Cathine has about one-tenth the stimulant effects of D-amphetamine and numerous other amphetamine-like compounds were also isolated, but occur in minute quantities.[137] When the fresh leaves are analyzed, however, cathinone (benzylketoamphetamine), a more potent psychoactive compound, was demonstrated to be the primary active agent.[91,107,137] As the leaves age, cathinone is degraded into cathine, which also explains why dried khat is neither popular nor widely distributed. Imported fresh khat must be consumed within a week, before it loses much of its potency. The primary effects of khat are increased alertness, insomnia, euphoria, anxiety, and hyperactivity. Increased khat consumption is linked to psychosis. Significant adrenergic complications are much less frequent than those associated with amphetamine abuse. Epidemiological studies demonstrated an association among khat chewing, psychosis, and myocardial infarction.[6,203]

Methcathinone, the methyl derivative of cathinone, chemically synthesized from ephedrine, has been abused in Russsia and other former countries of the Soviet Union, for many years. The potency of methcathinone is comparable to that of methamphetamine.[92,284] Methcathinone—also termed ephedrone, or sold under the street names of "cat" or "Jeff"—currently remains widely abused in Russia (see Chap. 95). Methcathinone abuse was first reported in Michigan[76] in the early 1990s and is now reported in other states as well.

■ EPHEDRINE OR MA-HUANG HERBAL PRODUCTS
Ephedrine is commonly found in nonprescription cold preparations. Ephedrine is also the active substance in the Chinese plant ma-huang, which has been used for centuries for the treatment of asthma. Although ephedrine is much less potent than amphetamine, when combined with other catecholamine stimulating xenobiotics, or when taken in large quantities, significant toxicity may occur.[26,33,209,240] In the United States, numerous ephedrine products, such as "go," "ultimate xphoria," "up your gas," and "herbal ecstasy," are marketed primarily to teenagers. Some of these products contain more than 500 mg of ephedrine, which may be combined with pseudoephedrine, phenylpropanolamine, and caffeine; other products contain the plant extract ma-huang.[159,209,211] Many of these products are marketed as legal stimulants or safe herbal stimulants for a natural "high." Similarly, ma-huang is also widely marketed as a "safe" herbal weight-reducing product. Sales appeared to increase when it was recognized that phenylpropanolamine was associated with intracerebral hemorrhage in women.[145] Unfortunately, these products are linked to numerous deaths and adverse reactions.[109,110,192,211,267,280,286] Because these products are sold as food supplements, they are not regulated by the FDA unless a product can be demonstrated to be unsafe (Chap. 43). In 2004, the FDA finally banned the use of ephedra products. In April 2005, a federal judge in Utah reversed the ban of ephedra sales in Utah, illustrating the difficulty of the FDA in the regulation of herbal products.[113] Herbal products with *Citrus aurantium* (bitter orange), contain a number of adrenergic amines, including synephrine and have now supplanted ephedra products. *Citrus aurantium* has similar pharmacologic effects and toxicity as ephedra.[21,198]

SUMMARY

Amphetamine usage continues to increase dramatically throughout the United States. Similarly, ED visits and morbidity and mortality related to amphetamines parallel amphetamine usage. Many of these complications are similar to those of cocaine, such as agitation, hyperthermia, rhabdomyolysis, myocardial ischemia, and cerebral infarction. Physicians, more than ever, must understand the pathophysiology of amphetamines and be prepared to diagnose and treat its toxicity. The chronic effects of amphetamines as demonstrated in animal models pose serious concerns for humans, particularly as amphetamine usage becomes more prevalent; further studies are required to achieve prevention and management.

CHAPTER 76
COCAINE

Jane M. Prosser and Robert S. Hoffman
Cocaine is a naturally occurring alkaloid with unique local anesthetic and sympathomimetic activity, which served as the prototype for the synthesis of local anesthetics. Unlike other local anesthethics, cocaine has both anesthetic and vasoconstrictive properties, however many otolaryngologists no longer use cocaine because of its toxicity profile.[142] Cocaine is also a prevalent drug of abuse producing the characteristic sympathomimetic toxic syndrome that includes hypertension, tachycardia, tachypnea, hyperthermia, diaphoresis, mydriasis, and severe psychomotor agitation. The study of cocaine metabolism led early insights into pharmacogenetics, and the understanding of cocaine toxicity sheds light into the interactions of the control of the sympathetic nervous system.

HISTORY AND EPIDEMIOLOGY

Cocaine is contained in the leaves of *Erythroxylum coca*, a shrub that grows abundantly in Colombia, Peru, Bolivia, the West Indies, and Indonesia. As early as the 6th century, the inhabitants of Peru chewed or sucked on the leaves for social and religious reasons. In the 1100s, the Incas used cocaine-filled saliva as local anesthesia for ritual trephinations of the skull.[73]

In 1859, Albert Niemann isolated cocaine as the active ingredient of the plant. By 1879 Vassili von Anrep demonstrated that cocaine could numb the tongue.[120] However, Europeans knew little about cocaine until 1884, when the Austrian ophthalmologist Karl Koller introduced cocaine as an effective local anesthetic for eye surgery and Koller's colleague, Sigmund Freud, wrote extensively on the psychoactive properties of cocaine.[60] Following these revelations, Merck, Europe's main cocaine producer, increased production from less than 0.75 pounds in 1883 to more than 150,000 pounds in 1886.[114]

Simultaneously, reports of complications from the therapeutic use of cocaine began to appear. In 1886, a 25-year-old man had a "pulseless" syncopal event after cocaine was applied to his eye to remove a foreign body.[229] By 1887 more than 30 cases of severe toxicity were reported,[195] and by 1895 at least 8 fatalities resulting from a variety of doses and routes of administration were summarized in one article.[62] Recreational cocaine use was legal in the United States until 1914, when cocaine was restricted to medical use. It was not until 1982, however, that the first cocaine-associated myocardial infarction was reported in the United States.[29]

Currently, cocaine is an approved pharmaceutical. It is used primarily for topical anesthesia of cutaneous lacerations or during otolaryngology procedures as a vasoconstrictor and topical anesthetic. Although multiple factors have fostered a decline in the medicinal use of cocaine,[19,68,142] the recreational use of cocaine remains a significant problem. Recent estimates suggest that almost 34 million Americans have used cocaine at least once, with 1.7 million of those dependent or addicted.[43] European Union statistics estimate that cocaine has been used at least once by more than 12 million Europeans, representing almost 4% of all adults.[50]

PHARMACOLOGY

The alkaloid form of cocaine (benzoylmethylecgonine) is extracted from the leaf by mechanical degradation in the presence of a hydrocarbon. The resulting product is converted into a hydrochloride salt to yield a white powder (cocaine hydrochloride). Cocaine hydrochloride can be insufflated, applied topically to mucous membranes, dissolved in water and injected, or ingested; however, it degrades rapidly when pyrolyzed. Smokeable cocaine (crack) is formed by dissolving cocaine hydrochloride in water and adding a strong base. A hydrocarbon solvent is added, the cocaine base is extracted into the organic phase, and then evaporated. The term free-base refers to the use of cocaine base in solution.

Cocaine is rapidly absorbed following all routes of exposure; however, when applied to mucous membranes or ingested, its vasoconstrictive properties slow the rate of absorption and delay the peak effect. Bioavailability exceeds 90% with intravenous and smoked cocaine; it is approximately 80% following nasal application.[110] Data for ingested cocaine and application to other mucus membranes such as the urethra, vagina, or rectum are inadequately documented. Table 76–1 lists the typical onsets and durations of action for various uses of cocaine.

Following absorption cocaine is approximately 90% bound to plasma proteins, primarily α_1-acid glycoprotein.[182] Based on human volunteer studies, the volume of distribution is reported to be about 2.7 L/kg.[110] It is unclear if the volume of distribution changes with overdose.

The metabolism of cocaine is complex and dependent on both genetic and acquired factors. Three major pathways of cocaine metabolism are well described (Fig. 76–1). Cocaine undergoes *N*-demethylation in the liver to form norcocaine, a minor metabolite that rarely accounts for more than 5% of drug.[106,135,221,222] However, norcocaine readily crosses the blood–brain barrier and produces clinical effects in animals that are quite similar to cocaine.[13,35,113,159,160,166,206,209,245] Nearly half of a dose of cocaine is both nonenzymatically[222] and enzymatically hydrolyzed[41] to form benzoylecgonine (BE). When BE is injected into animals some reports suggest that it is virtually inactive,[115,159,160,206,217] while other studies demonstrate cerebral vasoconstriction[33] and seizures.[123,159] When either injected directly into the cerebral ventricles[160,209] or applied to the surface of cerebral arteries,[145] BE is a potent vasoconstrictor. Although BE traverses the blood–brain barrier poorly,[160] the potential effects are of concern as some BE is probably formed from cocaine that has already entered the CNS. In vitro, BE has little or no effect on cardiac sodium or potassium channels.[33,52] Finally, plasma cholinesterase (PChE) and other esterases metabolize cocaine to ecgonine methyl ester (EME). In normal individuals, between 32% and 49% of cocaine is metabolized to EME.[4,106] Like BE, EME crosses the blood–brain barrier poorly.[160] Although many authors state that EME has little or no pharmacologic activity,[35,52,159,160,206] diverse animal models demonstrate contradictory results, concluding that EME is a vasodilator,[145,180,207] sedative, anticonvulsant,[209] and protective metabolite against lethal doses of cocaine.[88]

TABLE 76–1. Pharmacology of Cocaine by Various Routes of Administration

Route of Exposure	Onset of Action (min)	Peak Action (min)	Duration of Action (min)	Relative Peak Concentrations (ng/mL)[111]
Intravenous	<1	3–5	30–60	180 ± 56
Nasal insufflation	1–5	20–30	60–120	220 ± 39
Smoking	<1	3–5	30–60	203 ± 88
Gastrointestinal	30–60	60–90	Unknown	Unknown
FIGURE 76–1. Metabolism of cocaine. The three principle metabolic pathways of cocaine are depicted.

The role of genetic or acquired alterations in PChE activity has been of interest for many years. Early in vitro studies showed that cocaine was poorly metabolized in serum from patients with succinylcholine sensitivity (low PChE activity). In subsequent studies and case series, patients with low PChE activity demonstrate increased sensitivity to cocaine,[45,86,175] findings that are corroborated in multiple animal models.[21,22,87,143,154,223,250]

Multiple other metabolites of cocaine are well characterized.[31] Several have clinical or diagnostic importance. In 1990, a unique metabolite was identified in patients who smoke cocaine, which has subsequently come to be known either as anhydroecgonine methyl ester (AEME) or methylecgonide.[108] The presence of this compound and its metabolite, ecgonidine, can be used to help determine the route of administration in cocaine users.[205] Additionally, AEME has demonstrable agonism at the muscarinic (M_2) receptors, which may have important clinical implications.[251]

Ethanol has a unique pharmacologic interaction with cocaine. A transesterification reaction between the two drugs produces benzoyl-ethylecgonine which is also called "ethyl cocaine" or "cocaethylene"

(CE).[14] In human volunteers given cocaine and ethanol, cocaethylene accounted for approximately 17% of the metabolites, producing a decrease in the amount of BE and an increase in the amount of EME formed.[77,78] Cocaethylene has a longer duration of action than cocaine and similar neurotoxic and cardiotoxic effects.

PATHOPHYSIOLOGY

■ NEUROTRANSMITTER EFFECTS

Cocaine blocks the reuptake of biogenic amines. Specifically, these effects are described on serotonin and the catecholamines dopamine, norepinephrine, and epinephrine. Several animal investigations have elucidated the particular roles of each neurotransmitter. Mice lacking the dopamine transporter are relatively insensitive to the locomotor effects of cocaine.[64] Tachycardia emanates from adrenally derived epinephrine, whereas hypertension results from neuronally derived norepinephrine.[227,228] Serotonin is an important modulator of dopamine and has a role in cocaine addiction and reward and seizures.[75,133,153,172]

Although much emphasis has been placed on the reuptake blockade of these biogenic amines, it is clear that this effect is insufficient to account for the clinical manifestations of cocaine toxicity. First, other xenobiotics that block the reuptake of biogenic amines, such as cyclic antidepressants, produce quite distinct clinical manifestations (Chap. 73).[230] Also, xenobiotics that block the effects of dopamine, epinephrine, and norepinephrine not only fail to protect against cocaine toxicity, they actually exacerbate it.[25,70,128,200] Although this may, in part, result from an unopposed α-adrenergic effect, hypertension and vasospasm fail to explain the increase in psychomotor agitation, seizures and hyperthermia that result.[25,70] These effects most likely result from an interaction between cocaine and excitatory amino acids. Cocaine increases excitatory amino acid concentrations in the brain,[216] and excitatory amino acid antagonists prevent both seizures and death in experimental animals.[15,192] Finally, because experimental evidence in animals[25,70,210] and clinical experience in humans demonstrate that sedation treats both the central effects of cocaine and the peripheral effects of biogenic amines, a newer model was proposed (Fig. 76–2). This model emphasizes the necessity of diffuse central nervous system excitation as a prerequisite for cocaine toxicity, explains experimental and clinical observations, and provides insight into the treatment of acute toxicity.

■ CARDIOVASCULAR EFFECTS

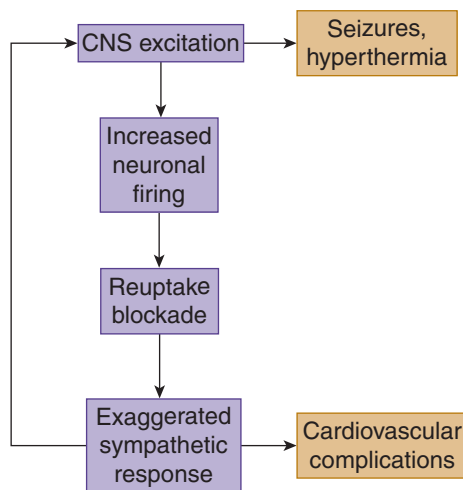
Cocaine use is associated with myocardial ischemia and myocardial infarction (MI). The increased risk of MI results from several different mechanisms. Hypertension and tachycardia increase myocardial


FIGURE 76–2. Cocaine-induced CNS effects modulate peripheral events.

oxygen demand. Cocaine use also leads to vasospasm, accelerated atherogenesis, and hypercoagulability.

Vasospasm Although increased myocardial oxygen demand may be sufficient to cause ischemia in some individuals, it is clear that cocaine also produces profound vasoconstriction. Evidence suggests that cocaine-induced vasoconstriction is mediated through both neuronal norepinephrine,[129,144] and benzoylecgonine (BE). BE has a direct effect on vessels that appears to be calcium mediated.[144] Additionally nicotine, which is simultaneously used by many substance users, has additive, if not synergistic, effects with cocaine.[165]

Atherogenesis Cocaine use accelerates atherosclerosis. Rabbits fed a normal diet supplemented with cholesterol do not develop atherosclerotic vascular disease. However, when that diet includes cocaine, rabbits develop classic atherosclerotic lesions.[121,131,132] Experiments with human endothelial cells demonstrate that cocaine directly increases the permeability to lipids by altering tight junctions.[122] This probably promotes the formation of subendothelial atherosclerotic plaques.

Dysrhythmias Like other local anesthetics (Chap. 66) cocaine blocks neuronal sodium channels, thereby preventing saltatory conduction. Because of homology between neuronal and cardiac sodium channels, cocaine also inhibits the rapid inward Na+ current responsible for phase 0 depolarization of the cardiac action potential (Chaps. 5, 23, and 73). Experimental evidence suggests that cocaine enters the sodium channel and binds on the inner membrane.[35,120,187] Like many sodium channel blockers, binding is both pH and use dependent (ie, binding increases as pH falls or heart rate increases; Chap. 63).[36,239] Furthermore, although norcocaine has a greater affinity for inactivated sodium channels, it has a much more rapid offset of action than cocaine.[35] Consequently, cocaine can be characterized as a Vaughan-Williams type IC antidysrhythmic (Chap. 63).[249] Cocaine-induced QRS prolongation is exacerbated by Vaughan-Williams type IA antidysrhythmics,[246] and ameliorated by hypertonic sodium bicarbonate or lidocaine.[9,69,181] Another effect of sodium channel blockade, the Brugada pattern, is also associated with cocaine use.[141,177]

In addition to its sodium channel-blocking properties, cocaine also blocks cardiac potassium channels (Chaps. 22 and 23). This results in QT prolongation [185,226,239] and may produce torsades de pointes.[208] Cocaethylene also has dysrhythmogenic effects.[173] In vivo experiments demonstrated inhibition of the myocardial HERG potassium channels which may explain this phenomenon.[52] Cocaethylene, in animal studies,

is associated with increased incidence of dysrhythmias, prolonged myocardial depression, and increased lethality.[115,244]

■ HEMATOLOGIC EFFECTS

Enhanced coagulation and impaired thrombolysis compound the effects of accelerated atherogenesis and vasospasm. Cocaine activates human platelets and causes α-granule release, resulting in platelet aggregation.[80,127] Thus even in the absence of endothelial injury, cocaine can initiate a thrombotic cascade while simultaneously enhancing the activity of plasminogen activator inhibitor type 1 (PAI-1), thereby impairing clot lysis.[164]

■ PULMONARY EFFECTS

Bronchospasm The association between cocaine use and asthma[195] was not recognized until smoked cocaine became prevalent.[49] Furthermore, experiments in human volunteers demonstrate that only smoked cocaine (not intravenous cocaine) produces bronchospasm.[225] Although it is possible that bronchospasm results from direct administration of cocaine to the airways, inhaled contaminants of cocaine, or thermal insult, and AEME (the unique pyrolytic metabolite of cocaine that acts as a muscarinic agonist) produces bronchospasm in experimental animals.[27]

CLINICAL MANIFESTATIONS

Many clinical manifestations of toxicity develop immediately following cocaine use. These are typically associated with the sympathetic overactivity, and their duration of effect is predictable based on the pharmacokinetics of cocaine use. Other manifestations, such as those associated with tissue ischemia, may present in a delayed fashion, with a clinical latency of hours to even days after last cocaine use. The reasons for this delay are not entirely apparent but may relate to the presence of an altered sensorium associated with acute cocaine use, anesthetic effects, changes in receptor regulation,[168] or affects on platelets, coagulation, and thrombolysis, which incite a slow cascade leading to thrombosis.

Vital sign abnormalities that develop during cocaine toxicity are characteristic of the sympathomimetic toxidrome. Thus, varying degrees of hypertension, tachycardia, tachypnea, and hyperthermia occur. Although any of these vital sign abnormalities can be life threatening, experimental and clinical evidence suggests that hyperthermia is the most critical.[25,70,150] Initially, with typically used doses, and at any time with a massive dose, apnea, hypotension, and bradycardia can result, all from direct suppression (anesthesia) of brainstem centers.[129,157] These effects are fleeting and rarely noted when patients present to healthcare as either the sympathetic overdrive rapidly ensues, or sudden death results. Additional sympathomimetic findings include mydriasis, diaphoresis, and neuropsychiatric manifestations.

Cocaine produces end-organ toxicity in virtually every organ system in the body. These events result from vasospasm, hemorrhage secondary to increased vascular sheer force (dP/dT), or enhanced coagulation. Each organ system is discussed separately in the following sections.

■ CENTRAL NERVOUS SYSTEM

Seizures, coma, headache, focal neurologic signs or symptoms, or behavioral abnormalities that persist longer than the predicted duration of effect of cocaine should alert the clinician to a potential catastrophic CNS event. Hemorrhage can occur at any anatomic site in the CNS. Subarachnoid, intraventricular, and intraparenchymal bleeding are all well described in association with cocaine use.[2,39,137,149,189,211] Early discussions suggested an underlying predisposition due to the presence of arteriovenous malformations or congenital aneurysms,[248] but

subsequent larger studies failed to support this analysis, suggesting that effects can occur independently of preexisting disease.[2,170,237] Recent data suggests that ruptured intracerebral aneurysms in cocaine users are almost exclusively in the carotid artery circulation.[237] Presumably CNS bleeding is a manifestation of abnormal sheer force. Spontaneous extra-axial bleeding is also associated with cocaine use.[199]

Both vasospastic infarction and transient ischemic attack (TIA) are reported in association with cocaine use.[39,40,137] In one epidemiologic study, women younger than age 45 years who had strokes were seven times more likely to report cocaine use than controls.[186] Patients can present with any of the classic physical findings associated with thrombotic or embolic stroke. Vasospasm can injure the spinal cord, resulting in paralysis from an anterior spinal artery syndrome.[39,163]

Seizures are commonly provoked by cocaine use.[91,167] It is clear that cocaine use can serve as a trigger in patients with epilepsy, although an underlying focus is not necessary for seizures to occur.[124]

Headache is also well described in cocaine users. While the exact mechanism is unclear, hypertension, vasospasm, or dysregulated neurotransmitters may all be contributory. In addition to typical tension headache, classic migraine and cluster headaches are also reported.[184,201]

■ EYES, NOSE, AND THROAT

Sympathetic excess produces mydriasis through stimulation of the dilator fibers of the iris with characteristic retention of the ability to respond to light. Like other mydriatics, cocaine can produce acute angle closure glaucoma.[76] Vasospasm of the retinal vessels causes both unilateral and bilateral loss of vision.[89,139] Additionally, although cocaine produces excellent corneal anesthesia, it is highly toxic to the corneal epithelium. Following application of cocaine to the eye, the superficial corneal layer is shed, resulting in pain and decreased acuity.[190] The loss of eyebrow and eyelash hair from thermal injury associated with smoking crack cocaine is called *madarosis*.[224]

Chronic intranasal insufflation of cocaine can produce perforation of the nasal septum. This finding most likely results from repeated ischemic injury with resultant tissue loss. This ischemia is usually asymptomatic and necrotic tissue is sloughed. At least one reported case of wound botulism (Chap. 46) has been associated with intranasal insufflation. Presumably this resulted from accumulation of necrotic tissue in the nose, serving as a culture medium for *Clostridium botulinum*.[126]

Angioedema and oropharyngeal burns, located as far distally as the esophagus, are associated with smoking crack cocaine.[23,28,117,158] These effects are most likely the result of inhalation or ingestion of superheated fumes and hot liquid (from the smoking apparatus) rather than direct toxicity from cocaine.

■ PULMONARY

Pneumothorax, pneumomediastinum, and pneumopericardium are reported following both smoked and intranasal cocaine use.[146,203,230,234] These findings do not result directly from cocaine toxicity, but rather are epiphenomena related to the mechanism of drug use. Following insufflation or inhalation, the user commonly performs a Valsalva maneuver in an attempt to retain the drug. Bearing down against a closed epiglottis increases intrathoracic pressure and an alveolar bleb can rupture against the pleural, mediastinal or pericardial surfaces.

Cocaine use exacerbates reversible airway disease and it is common for patients to present with shortness of breath and wheezing.[49,136,178,194] Like so many manifestations of cocaine toxicity, it is unclear whether this is a direct effect of cocaine or related to inhalation of some contaminant of the drug. However, as discussed above, the muscarinic (M2) agonistic effects of the pyrolysis metabolite AEME might be contributory.

Crack lung is the term given to an acute pulmonary syndrome that occurs after inhalational use of crack cocaine. The pulmonary syndrome is a poorly defined constellation of symptoms including fever, hemoptysis, hypoxia, acute lung injury, and respiratory failure. It is associated with diffuse alveolar and interstital infiltrates on chest radiography.[191] Histopathology shows diffuse alveolar damage and hemorrhage with inflammatory cell infiltration and hemosiderin-laden macrophages. Eosinophilia has been noted in several cases.[58] The syndrome has been variously attributed to impurities mixed with the crack, carbonaceous material generated from pyrolysis, and direct cocaine toxicity.

Vasospasm and subsequent thrombosis of the pulmonary artery or its branches can produce pulmonary infarction.[42] Patients present with shortness of breath and pleuritic chest pain characteristic of a pulmonary embolus. Clinical signs and symptoms of ventilation–perfusion (V/Q) mismatch (Chap. 21), as well as abnormalities on arterial blood gas analysis, are noted.

■ CARDIOVASCULAR

Chest pain or discomfort is a common emergency department complaint in cocaine users.[17] Cocaine use is associated with cardiac ischemia and infarction in young people, and may account for as much as 25% of myocardial infarctions in patients younger than 45 years old.[188] Although myocardial infarction is of concern, only approximately 6% of patients with complaints referable to the heart will manifest biochemical evidence of myocardial injury.[96,240] Many others will have an ischemic cardiac event, but for the remainder the differential diagnosis is broad.[130] Entities to consider include the pulmonary and esophageal etiologies described previously, referred abdominal symptoms (see Abdominal below), chest wall injury,[67] aortic dissection,[37,104,138,140] coronary artery dissection,[202,220] and dysrhythmias. No single sign or symptom or combination of signs and symptoms reliably identifies cardiovascular injury from among the discussed differential diagnosis.[96]

Catecholamine-induced direct myocardial catecholamine toxicity contributes to both acute and chronic cardiac disease. *Takotsubo cardiomyopathy* is a reversible form of left ventricular apical ballooning associated with myocardial ischemia in the absence of atherosclerotic lesions. It is thought to result from catecholamine toxicity on the myocardium during high levels of stress and is also reported after cocaine use.[5] Chronic cocaine use is associated with a dilated cardiomyopathy,[82,130,176,243] the etiology of which is presumed to be the result of repeated subclinical ischemic events. Patients may present with signs and symptoms of congestive heart failure or pulmonary edema. The pathologic finding of contraction band necrosis also suggests that there may be some direct catecholamine toxicity as this finding only commonly occurs with cocaine and amphetamine use, pheochromocytoma, and in patients receiving high-dose vasopressors.[55,238]

■ ABDOMINAL

Abdominal pain, or other gastrointestinal complaints, suggests a broad differential diagnosis. Cocaine users have a disproportionate incidence of perforated ulcers.[134,183,214] The etiology has not been elucidated, but may be related to local ischemia of the gastrointestinal tract or increased acid production associated with sympathetic activity. Vasospasm produces ischemic colitis that can present with abdominal pain or bloody stools.[140,169] More severe vasospasm, with or without thrombosis, can lead to intestinal infarction[61,83,101,179] with attendant hypotension and metabolic acidosis. Signs and symptoms of bowel obstruction such as vomiting or distension might suggest body packing (gastrointestinal drug smuggling). Although less common, splenic[44,171] and renal infarctions,[46,161,198] may also occur. Spontaneous hemoperitoneum was also reported, although occult trauma could not be definitively excluded.[10]

Animals frequently develop hepatotoxicity following cocaine administration. In human cocaine users, minor elevations of liver enzyme concentrations are common and rarely associated with symptoms.[20,125] When more severe liver injury occurs, it is usually associated with multisystem organ dysfunction from hyperthermia or another type of hepatic injury.[6] Isolated hepatic injury from cocaine is distinctly uncommon and may result from differences in metabolic pathways, as animals are known to make a hepatotoxic metabolite of cocaine that has not been described in humans.[236]

■ MUSCULOSKELETAL

Rhabdomyolysis is common in all conditions that produce an agitated delirium and/or hyperthermia; cocaine is no exception.[32,103,196] Unlike most other toxicologic disorders, however, psychomotor agitation is not a prerequisite for cocaine-associated rhabdomyolysis.[252] Muscle injury may result from vasospasm or direct muscle toxicity; however, the mechanism remains unclear. Patients with cocaine toxicity present with a spectrum of illness that ranges from asymptomatic enzyme and electrolyte abnormalities characteristic of rhabdomyolysis, to localized or diffuse muscle pain, to frank compartment syndrome and renal failure.[47,56]

Limb ischemia associated with cocaine use has been reported.[71,155] Vasospasm, accelerated atherogenesis, and increased thrombogenesis (see Pathophysiology) place users at increased risk.

Traumatic injury is also fairly common in the setting of cocaine use.[152] Clinicians should be aware of the possibilities of occult fractures or other injuries that may be masked by the anesthetic properties of cocaine.[142,151]

■ NEUROPSYCHIATRIC

The neuropsychiatric effects of cocaine are most likely dose dependent. Low-dose administration produces alertness, exhilaration, hypersexual behavior, and other "desired" effects. These effects rarely bring users to healthcare facilities. As the cocaine dose increases, agitation, aggressive behavior, confusion, disorientation, and hallucinations can develop.

Other possible manifestations include a variety of movement disorders that most likely result from depletion or dysregulation of dopamine. Patients may develop acute dystonias[24,53,235] or choreoathetoid movements that have been referred to as "crack-dancing."[38,72] Following binge use of cocaine, a "washed-out" syndrome occurs that is best described by dopamine depletion.[219,231] Patients complain of anhedonia, lethargy, and have trouble initiating and sustaining movement. However, they are arousable with minimal stimulation and usually remain cognitively intact.

■ OBSTETRICAL

The majority of obstetrical findings associated with cocaine use involve developmental problems in the fetus and neonate and are probably a result of a combination of chronic vascular insufficiency from cocaine-induced spasm of the uterine artery or distal vessels and other risk factors, such as poor maternal nutrition, cigarette smoking, and a lack of prenatal care. These events are extensively reviewed elsewhere.[26,51,213] Acute cocaine use during pregnancy is associated with abruptio placentae, causing patients to present with abdominal pain and vaginal bleeding.[1,57] The remaining maternal and fetal complications comprise every possible complication described in nonpregnant patients.

DIAGNOSTIC TESTING

Cocaine and benzoylecgonine, its principle metabolite, can be detected in blood, urine, saliva, hair, and meconium. Routine drug-of-abuse testing relies on urine testing using a variety of immunologic techniques (Chap. 6). Although cocaine is rapidly eliminated within just a few hours of use, benzoylecgonine is easily detected in the urine for 2–3 days following last use.[4] When more sophisticated testing methodology is applied to chronic users, cocaine metabolites can be identified for several weeks following last use.[243]

Urine testing, even using rapid point-of-care assays, offers little to clinicians managing patients with presumed cocaine toxicity because it cannot distinguish recent from remote cocaine use. In addition, false-negative testing can result when there is a large quantity of urine in the bladder with very recent cocaine use or when the urine is intentionally diluted by increased fluid intake[30] leading to a urine cocaine concentration below the cut-off value and interpretation of the test as negative. Under these circumstances, repeat testing is almost always positive. While false-positive tests do occur, they are more common with hair testing than urine or blood because of the increased risk of external contamination.[30,193] Because of the very low rate of false-positive results, confirmation of a positive urine is unnecessary for medical indications (Chap. 6).

The greatest benefit for cocaine testing is in cases of unintentional poisoning or suspected child abuse and neglect. Here confirmation of a clinical suspicion is essential to support a legal argument. In addition, there may be some usefulness for urine testing of body packers, especially when the concealed xenobiotic is unknown.[232] While many body packers will have negative urine throughout their hospitalization, a positive urine test is suggestive of the concealed drug but obviously not confirmatory. More importantly, a conversion from a negative study on admission to a positive study not only confirms the substance ingested, but also suggests packet leakage, which could be a harbinger of life-threatening toxicity (see SC4: Concealment). Another indication for urine testing for cocaine occurs in young patients with chest pain syndromes where the history of drug use, specifically cocaine, is not forthcoming.[92] Routine diagnostic tests such as a bedside rapid reagent glucose, electrolytes, renal function tests, and markers of muscle and cardiac muscle injury are more likely to be useful than urine drug screening. An ECG may show signs of ischemia or infarction, or dysrhythmias that require specific therapy. Unfortunately, in the setting of cocaine-associated chest pain, the ECG has neither the sensitivity nor the specificity necessary to permit exclusion or confirmation of cardiac injury.[99] Cardiac markers are therefore always required adjuncts when considering myocardial ischemia or infarction. Because cocaine use is associated with diffuse muscle injury, assays for troponin are preferred over myoglobin or myocardial band enzymes of creatine phosphokinase (CPK-MB).[98] Additionally, a chest radiograph may be useful to exclude certain etiologies in patients with chest discomfort, or to identify free air under the diaphragm when gastrointestinal perforation is suspected. Supplemental diagnostic studies, such as CT scans of the head, chest, or abdomen and functional cardiac imaging, should be guided by the clinical condition of the patient.[34,48,74]

MANAGEMENT

■ GENERAL SUPPORTIVE CARE

As in the case of all poisoned patients, the initial emphasis must be on stabilization and control of the patient's airway, breathing, and circulation. If tracheal intubation is required, it is important to recognize that cocaine toxicity may be a relative contraindication to the use of succinylcholine. Specifically, in the setting of rhabdomyolysis, hyperkalemia may be exacerbated by succinylcholine administration, and life-threatening dysrhythmias may result (Chap. 68). Additionally, it is essential to recognize that PChE metabolizes both cocaine and succinylcholine.[109] Thus their simultaneous use could either prolong cocaine toxicity or paralysis, or both. Human data are insufficient to predict

which interaction is more likely to occur. If hypotension is present, the initial approach should be infusion of intravenous 0.9% sodium chloride solution as many patients are volume depleted as a result of poor oral intake and excessive fluid losses from uncontrolled agitation, diaphoresis, and hyperthermia.

In the setting of cocaine toxicity it is important to recognize that both animal[25,70] and human[150] experience suggests that elevated temperature represents the most critical vital sign abnormality. Determination of the core temperature is an essential element of the initial evaluation, even when patients are severely agitated. When hyperthermia is present, preferably rapid cooling with ice water immersion, or the combined use of mist and fanning, is required to achieve a rapid return to normal core body temperature (Chap. 15). Sedation or paralysis and intubation may be necessary to facilitate the rapid cooling process. Pharmacotherapy including antipyretics, drugs that prevent shivering (chlorpromazine or meperidine), and dantrolene[59] are not indicated as they are ineffective and have the potential for adverse drug interactions such as serotonin syndrome (meperidine) or seizures (chloropromazine).

Sedation remains the mainstay of therapy in patients with cocaine-associated agitation. It is important to remember that cocaine use is associated with hypoglycemia and that many of the peripheral findings of hypoglycemia are the result of a catecholamine discharge.[16,162] Consequently, a rapid reagent glucose test should be obtained, or hypertonic dextrose should be empirically administered if indicated, prior to or while simultaneously achieving sedation. Both animal models[25,70] and extensive clinical experience in humans support the central role of benzodiazepines. Although the choice among individual benzodiazepines is not well studied, an understanding of the pharmacology of these drugs allows for rational decision making. The goal is to use parenteral therapy with a drug that has a rapid onset and a rapid peak of action, making titration easy. Using this rationale, midazolam and diazepam are preferable to lorazepam, because significant delay to peak effect for lorazepam often results in oversedation when it is dosed rapidly, or in prolonged agitation when the appropriate dosing interval is used. Drugs should be administered in initial doses that are consistent with routine practices and increased incrementally based on an appropriate understanding of their pharmacology. For example, if using diazepam, the starting dose might be 5–10 mg, which can be repeated every 3–5 minutes and increased if necessary. Large doses of benzodiazepines may be necessary (on the order of 1 mg/kg of diazepam). This may result from cocaine-induced alterations in benzodiazepine receptor function.[65,66,112] (see Antidote in Depth A24)

On the rare occasion when benzodiazepines fail to achieve an adequate level of sedation, either a rapidly acting barbiturate or propofol should be administered. Controlled animal studies clearly show that the use of phenothiazines or butyrophenones is contraindicated.[25,70,247] In animal models, these drugs enhance toxicity (seizures), lethality, or both. Additional concerns about these drugs include interference with heat dissipation, exacerbation of tachycardia, prolongation of the QT interval, induction of torsade de pointes, and precipitation of dystonic reactions.

Once sedation is accomplished, often no additional therapy is required. Specifically, hypertension and tachycardia usually respond to sedation and volume resuscitation. In the uncommon event that hypertension and/or tachycardia persists, the use of a β-adrenergic antagonist or a mixed α- and β-adrenergic antagonist is contraindicated. Again, in both animal models and human reports, these drugs increase lethality and fail to treat the underlying problem.[12,25,70,200,231] The resultant unopposed α-adrenergic effect may produce severe and life-threatening hypertension or vasospasm. A direct-acting vasodilator like nitroglycerin, nitroprusside or possibly nicardipine or an α-adrenergic antagonist (such as phentolamine) may be considered. Other nonspecific therapies for rhabdomyolysis such as intravenous fluid should also be considered.

■ DECONTAMINATION

The majority of patients who present to the hospital following cocaine use will not require gastrointestinal decontamination as the most popular methods of cocaine use are smoking, intravenous and intranasal administration. If the nares contain residual white powder presumed to be cocaine, gentle irrigation with 0.9% sodium chloride solution will help remove adherent material. Less commonly, patients may ingest cocaine unintentionally or[19] in an attempt to conceal evidence during an arrest (body stuffing)[84,111,148,218] or transport large quantities of drug across international borders (body packing).[63] These patients may require intensive decontamination and possibly surgical removal[54,90,147,204,232,233,242] (see Special Considerations SC4: Body Stuffers and Body Packers).

■ SPECIFIC MANAGEMENT

End-organ manifestations of vasospasm that do not resolve with sedation, cooling, and volume resuscitation should be treated with vasodilatory agents (such as phentolamine). When possible, direct delivery via intra-arterial administration to the affected vascular bed is preferable. Because this approach is not always feasible, systemic therapy is typically indicated. Phentolamine can be dosed intravenously in increments of 1–2.5 mg, and repeated as necessary until symptoms resolve or systemic hypotension develops.

Acute Coronary Syndrome A significant amount of animal, in vitro, and in vivo human experimentation has been directed at defining the appropriate approach to a patient with presumed cardiac ischemia or infarction. In some instances an approach that is similar to the treatment of coronary artery disease (CAD) is indicated, although there are certain notable exceptions. An overall approach to care is available in the American Heart Association guidelines and a number of reviews.[3,100,130,156]

High-flow oxygen therapy is clearly indicated as it may help overcome some of the supply–demand mismatch that occurs with coronary insufficiency. Aspirin is safe in patients with cocaine-associated chest pain and is recommended for routine use.[156] In addition, administration of morphine is likely to be effective as it relieves cocaine-induced vasoconstriction.[197] Morphine also offers the same theoretical benefits of preload reduction and reduction of catecholamine release in response to pain that is thought to be responsible for its usefulness in patients with CAD.

After these interventions, the treatment of patients with cocaine-associated chest pain begins to deviate from the standard accepted approach to patients with CAD. Nitroglycerin is clearly beneficial as it reduces cocaine-associated coronary constriction of both normal and diseased vessels and relieves chest pain and associated symptoms.[18,95] Interestingly, in several clinical trials of cocaine-associated chest pain, benzodiazepines are at least as effective or superior to nitroglycerin.[8,102] Although the reasons for this are unclear, possible etiologies include blunting of central catecholamines or direct effects on cardiac benzodiazepine receptors. Either or both drugs can be used in standard dosing (See Antidotes in Depth A24: Benzodiazepines).

Over the last decade, the benefits of β-adrenergic antagonism have been demonstrated in patients with CAD. In contrast, β-adrenergic antagonism increases lethality in cocaine-toxic animals[25,70] and in humans, exacerbates cocaine-induced coronary vasoconstriction,[128] and produces severe paradoxical hypertension.[200] Similarly, with regard to treatment of coronary constriction, labetalol is no better than placebo.[12] Thus, in the setting of cocaine use, β-adrenergic antagonism is absolutely contraindicated. The 2008 American Heart Association Guidelines for the treatment of cocaine-associated chest pain and MI state that use of β-adrenergic antagonists should be avoided in the acute setting.[156] If, after the measures mentioned previously have been

initiated, hypertension or vasospasm is still present and treatment is indicated, phentolamine is preferred based on its demonstrable experimental and clinical results.[94,129] If tachycardia does not respond to accepted therapies above, then diltiazem can be administered and titrated to effect.[11] Prior to the administation of any negative inotrope, it is essential to confirm that the tachycardia is not compensatory for a low cardiac output resulting from global myocardial dysfunction. Noninvasive methods of assessment of cardiac function have been used successfully in patients with cocaine-associated acute coronary syndromes.[7]

There are no data on the use of either unfractionated or low-molecular-weight heparins, glycoprotein IIb/IIIa inhibitors, or clopidogrel. The recent AHA guidelines recommend the administration of unfractionated heparin or low-molecular-weight heparin in patients with cocaine-associated MI.[156] The decision to use any of these medications should be based on a risk-to-benefit analysis. Consideration should be given to the possibility of underlying atherosclerotic heart disease. When acute thrombosis is likely, thrombolytic therapy should be considered. Mechanistically, cocaine inhibits endogenous thrombolysis through augmentation of the inhibitor of tissue plasminogen activator. Additionally, there is sufficient clinical evidence to support the safety of thrombolytic therapy in patients with cocaine-associated myocardial infarction.[85,93] Even though the number of patients treated with thrombolytic therapy is insufficient to demonstrate efficacy in terms of mortality, evidence of revascularization is encouraging. Similar to patients with ASHD, if available, cardiac catheterization with revascularization is preferable to thrombolysis.[212] Thrombolysis would not be expected to be useful in treating ischemia caused by vasospasm. Due to the high incidence of coexisting atherosclerotic disease and an increased hypercoaguable state in cocaine-associated MI, thrombolysis is an acceptable alternative when catheterization is unavailable. Standard contraindications such as persistent hypertension, aortic dissection, trauma, and altered mental status must be considered prior to thrombolysis.

Dysrhythmias Most patients present with sinus tachycardia that resolves following sedation, cooling, rehydration, and time to metabolize the drug. Other stable dysrhythmias should be treated similarly, and will often spontaneously revert because of the short duration of effect of cocaine. However, cocaine use is associated with atrial, supraventricular, and ventricular dysrhythmias including torsade de pointes.[107,130,208] Most notably, wide complex tachycardias result from sodium channel blockade. When approaching patients with cocaine-associated dysrhythmias, there are several important points to consider. The first is that β-adrenergic antagonism is contraindicated. Furthermore, classic types IA and IC antidysrhythmics are also contraindicated because of their ability to exacerbate cocaine-induced sodium and potassium channel blockade.[130,246] Additionally, although popular in many advanced cardiac life support dysrhythmia algorithms, the effects of amiodarone are largely unknown in the setting of cocaine toxicity. Because of the lack of data demonstrating a benefit for amiodarone, and because of concerns about its β-adrenergic antagonist effects, the use of this drug cannot be recommended. Finally, although adenosine and synchronized cardioversion may transiently help convert narrow complex tachycardias, if a substantial amount of cocaine is unmetabolized, the patient will likely revert back to the original dysrhythmia as these therapeutic interventions have short durations of effect. Thus for rapid atrial fibrillation and narrow complex reentrant tachycardias, a calcium channel blocker such as diltiazem is preferred. For wide-complex dysrhythmias, a trial of hypertonic sodium bicarbonate has demonstrable usefulness analogous to treating patients with cyclic antidepressant overdose (see Antidotes in Depth A5: Sodium Bicarbonate).[116,181,239,246] When the use of hypertonic sodium bicarbonate fails to treat the dysrhythmia, lidocaine can be used. Although lidocaine blocks sodium

channels, its fast-on, fast-off properties allow it to antagonize the effects of cocaine. The benefits and safety of lidocaine were demonstrated in multiple animal models[69,81,246] and in humans with cocaine-associated myocardial infarction.[215]

■ DISPOSITION

Patients who present to healthcare facilities with classic sympathomimetic signs and symptoms that resolve spontaneously in the absence of signs of end-organ damage can be safely discharged after short periods of observation. Once hyperthermia, rhabdomyolysis, or other signs of end-organ damage are evident, hospital admission is usually required. Patients who use cocaine are at increased risk for sudden death likely related in part to dysrhythmias and myocardial ischemia. In one series, patients with cardiac arrest after smoking crack cocaine were younger, more likely to survive, and less likely to have neurologic sequelae than case controls.[105]

For patients with chest pain, a specific management algorithm has been derived based on substantial clinical experience. Those patients with clearly diagnostic or evolving ECGs suggestive of ischemia or infarction, positive cardiac markers, dysrhythmias other than sinus tachycardia, congestive heart failure, or persistent pain require admission. Patients who become pain free and whose ECGs are stable are candidates for discharge if a single cardiac marker obtained at least 8 hours after the onset of chest pain is normal.[241] The AHA guidelines recommend 9–12 hours of observation for low and intermediate risk patients with cocaine-associated chest pain. For all patients it is essential to provide a referral for detoxification, as repeated cocaine use is the greatest risk factor for future cardiovascular complications.[97,243]

SUMMARY

Cocaine is a unique drug that combines local anesthetic, vasoconstrictive, and neuropsychopharmacologic properties. Although its legitimate pharmaceutical use has diminished because of its high abuse potential, it remains a common recreational drug of abuse. Cocaine produces the prototypical agitated delirium that characterizes the sympathomimetic toxic syndrome. Most patients can be treated with sedation and cooling, but others require more intensive individualized care. The most essential and difficult aspect of care is providing access to programs that support cocaine detoxification.

INTERNAL CONCEALMENT OF XENOBIOTICS

Jane M. Prosser

Internal concealment of illicit xenobiotics is a significant concern for local and international police efforts as well as medical, social, and public health practitioners. There are two distinct categories of concealment colloquially known as "body stuffers" and "body packers." The term body stuffer refers to individuals who hide drugs in a body cavity or ingest the drugs in an attempt to hide evidence from law enforcement officers. The xenobiotics are ingested in an unplanned manner and are often poorly wrapped. The term body packer refers to individuals who conceal xenobiotics, typically in large quantities, in a premeditated fashion almost exclusively for the purposes of international smuggling.

BODY PACKERS

Internal concealment of drugs for the purpose of smuggling was first reported in Canada in 1973. A 21-year-old man presented with a small bowel obstruction as a result of swallowing a condom filled with hashish. He had swallowed the condom in order to transport it into Canada after a trip to Lebanon.[13] Internal drug smuggling has become a worldwide problem as increased surveillance at international borders has made conventional transportation of illegal drugs more difficult. Improved detection of smugglers has increased the number of patients brought to the attention of healthcare providers. Pregnant women and children as young as 6 years of age have been used as body packers.[2,6,9]

Airline and airport personnel are trained to identify people who may be drug couriers. Suspicious behavior includes not eating or drinking on the airplane, abnormal behavior while going through customs, and overt signs of drug toxicity.[76,87]

COMPOSITION OF PACKAGES

Body packers typically swallow large numbers of well prepared packages, each filled with substantial amounts of drug. Packets may also be concealed by insertion into the vagina and rectum.[14,92] The most frequently smuggled cargo is either heroin or cocaine, but other drugs have been reported (Table SC4–1). Body packers often swallow 50 to 100 packages and ingestion of as many as 500 has been reported.[93] Each package typically contains from 0.5 to 10 g of drug. Therefore, one person may carry as much as 1.5 kg of drug.[84] Lethal doses of cocaine and heroin are difficult to determine based in part on sparse data and on widely variable purity. For reference, death from cocaine toxicity is reported after ingestion of as little as 2 to 3 g.[71] As such, each packet should be considered to contain a potentially lethal dose.

A number of materials have been used for drug packaging. Some, like latex, are used as wrappers. Others such as carbon paper and aluminum foil are used to change the radiodensity and decrease the likelihood of detection with diagnostic and forensic imaging studies. Packages have been made using plastic bags, plastic wrap, condoms, finger cots, balloons, cellophane, wax, tape, rubber gloves, surgical ligatures, paraffin, and fiberglass.[5,23,31,58,68]

Initial reports suggested a high rate of complications due to packaging failure.[58] More recently however, advances in constituents and technology of packet construction have decreased rates of rupture.[68] A typical packet in current use is composed of a core of compacted drug covered by several layers of latex and encased in an outer wax coat.[87]

Important historical details include the number and contents of packets, the constitution of the wrapping, time of ingestion, and any associated symptoms. Body packers often know exactly how many packets they are carrying in order to know when delivery is complete. However, they may be reluctant to give an accurate clinical history to the healthcare provider or legal authorities.

BIOAVAILABILITY

The oral bioavailability of cocaine hydrochloride is approximately 30% to 40%, which is similar to intranasal administration.[19,96] Rectal and vaginal bioavailability of cocaine hydrochloride and the oral, rectal and vaginal bioavailability of crack cocaine have not been studied.

Oral exposure to heroin results in rapid first pass metabolism to morphine[25] and can be considered a morphine prodrug.[19,39] The peak concentrations after 10 mg of oral heroin are similar to those expected from 10 mg of oral morphine.[3] The rectal bioavailability of morphine has a 1:1 ratio with oral administration. Although heroin is rectally bioavailable,[75] one study examining the bioavailability after rectal suppository administration in 2 opioid dependent patients found it to be approximately 50% less than the oral bioavailability.[27]

CLINICAL MANIFESTATIONS

Body packers undergoing medical examination may be asymptomatic or may have clinical manifestations consistent with either drug toxicity or mechanical obstruction. Physical examination should be thorough, with a focus on findings related to these problems (Chaps. 38 and 76).

The packets may be too large to pass and obstruction can occur at any point in the gastrointestinal tract. Couriers carrying packets containing opioids appear to be at higher risk of gastrointestinal obstruction even with intact packets.[24] The reason for this is unclear, but may be related to microperforation or contamination of the outside of the package during manufacture, resulting in opioid induced gastrointestinal stasis. Patients with a history of abdominal surgery may also be at increased risk of obstruction.[37,11] Gastrointestinal perforation and peritonitis can result if the obstruction is untreated.[11] Gastric ulcers,[62] gastric hemorrhage,[15] esophageal obstruction,[47] esophageal perforation and mediastinitis,[41] hematemesis,[37] hematochezia,[89] incarcerated hernias,[83] dysphagia,[7] uterine ischemia,[7] and septic shock[24] have resulted following packet rupture.

LABORATORY EVALUATION

Drug screening results may be difficult to interpret. Although generally, a positive result should raise concern for a ruptured packet, positive

---

TABLE SC4-1. Xenobiotics Associated with Internal Concealment

Substances reported in body stuffer ingestion

Cannabis[86]

Cocaine hydrochloride[72]

Crack cocaine[72]

Heroin[44]

Methamphetamine[32]

Prescription drugs[73]

Substances reported in body packer ingestion

Cannabis[54]

Cocaine[12]

Hashish [67] and hasish oil[59]

Heroin[23]

Methamphetamine[54]

Methylenedioxymethamphetamine (ecstasy)[85]

Oxycodone[2]

---

results may also be due to external contamination of the packet, from a microperforation or prior utilization. Thus, patients with packets that appear externally intact may have a positive urine drug screen.[24,59] The rate of positive drug screens in asymptomatic patients may be as great as 52% to 72%.[12,15] Screening typically correlates closely with the drug carried,[23] but may be misleading as patients transporting any product may ingest opioids for the purpose of slowing gastrointestinal transit time.[63] Additionally patients may be carrying a combination of drugs, known as "double breasting."[24]

A subsequent urine drug screen may be particularly useful in the setting of a patient with an initially negative screen. A screen that later becomes positive suggests a ruptured packet and is an indication for very close monitoring. This is of particular concern in the setting of a cocaine body packer when a change from a negative to a positive screen might indicate the potential for a precipitous decline.

■ RADIOGRAPHIC EVALUATION

All suspected body packers should undergo radiographic evaluation. Plain abdominal radiographs have a sensitivity of 75% to 95%, but this varies based on the number of packets and their methodology of construction.[5,58,91] Several authors suggest increased sensitivity with supine abdominal films.[56,93] Packets can be visualized as multiple radiodense foreign bodies. (Figs. 5-8 A–C) The "double condom sign" is a lucent ring surrounding the packet and results from air trapped in between layered wrappings.[69] The "rosette-like" sign results from the air trapped in the knot when the condom or balloon is tied.[80] Caution must be used when interpreting plain radiographic studies. In one series, 19% of patients had false negative radiographs, with one patient subsequently passing 135 packets.[58] False positives have also been reported from constipation,[46] intraabdominal calcifications[88] and bladder stones.[97] Contrast enhancement may increase the sensitivity of plain radiography.[22,35,56]

Several authors suggest that CT scanning has a higher sensitivity than plain radiographs,[30,49] but precise data on sensitivity is lacking. Although likely to identify patients with multiple packets, a false negative contrast CT scan following WBI was reported in a body packer who subsequently passed a single packet per rectum.[28] Retrospective

review of the CT could not identify the packet. One study found a difference in Hounsfield units between packets containing cocaine (−219 HU) and heroin (−520 HU) suggesting that CT scanning can also potentially distinguish between package contents.[95]

Ultrasonography may be another useful screening tool particularly for evaluation of pregnant women. However, its utility has only been evaluated in a few small case series.[34,60] In one series of patients arrested on suspicion of body packing at an international airport, ultrasound examination correctly identified 40 of 42 body packers with positive plain radiographs. The 2 false negative results occurred when packets were located low in the rectum.[60] More investigation is needed to determine the sensitivity and specificity of ultrasound for use in these patients.

Magnetic resonance imaging (MRI) is not likely to provide any additional information when evaluating the gastrointestinal tract. The utility of MRI may be limited for examining the bowel because of the presence of air and normal peristalsis.[33]

Pregnant women may be targeted as body packers due to hesitation from customs officials and health care providers to obtain radiographs. However, the average radiation dose of 100 millirads from an abdominal radiograph is much less than the threshold thought to induce fetal malformations. Therefore, radiography should be obtained when medically indicated. Consideration should also be given to the use of ultrasonography in this situation.[9]

■ MANAGEMENT

Gastrointestinal decontamination is a vital element in the management of body packers. Initially, surgical intervention was thought to be necessary in all body packers secondary to perceived high rates of toxicity and death.[21,82] The incidence of life-threatening complications has decreased due in part to better packaging[58,68] and to increased rates of detection of asymptomatic carriers. Currently, a more conservative nonsurgical approach is suggested for asymptomatic patients[87] and is supported by a several large series.[4,5,12,58,76,91,93] (Fig. SC4–1)

Treatment with activated charcoal (AC) is frequently suggested on the basis that cocaine and heroin are both well adsorbed to activated charcoal.[55] There are no data showing an actual benefit, and the large doses needed to adsorb the many grams of drug released during packet rupture make AC impractical for use. Furthermore, AC may be detrimental if contamination of the peritoneal cavity occurs after gastrointestinal rupture or during surgery or if it obscures visualization during endoscopy. The risks and benefits must be weighed in each patient. Activated charcoal is of questionable value in cocaine packers given the higher risk of the need for surgical intervention. Activated charcoal is also not likely to improve the outcome of symptomatic heroin body packers, as these patients can be successfully managed with opioid antagonists and mechanical ventilation. Therefore, the administration of AC is not likely to be of benefit.

The utility of whole bowel irrigation (WBI) to enhance elimination is generally accepted, but has not been rigorously evaluated. There is a theoretical concern that polyethylene glycol could increase the water solubility of heroin should it leak,[91] and that it may decrease the adsorption of cocaine to AC if AC is given.[55] Given the lack of in vitro data to support these risks,[18] and its generally accepted benefit, WBI is recommended to decrease intestinal transit time (Antidotes in Depth A3: Whole Bowel Irrigation and other intestinal evacuants). Orogastric lavage is not indicated as packets are too large to fit though holes in the lavage tube.

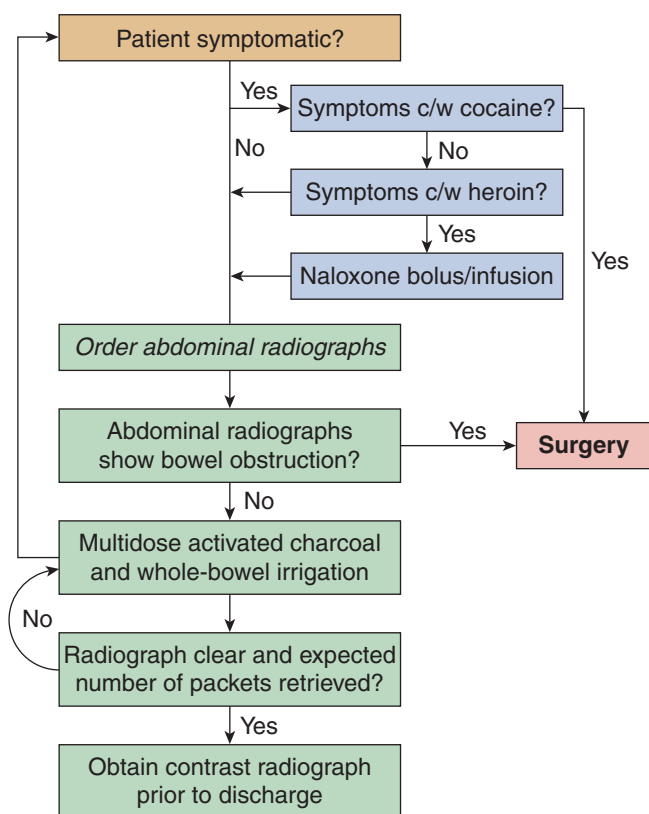
Cathartics are sometimes recommended for gastrointestinal decontamination. Although oil based cathartics were frequently used in the past,[5,57] a non-oil based medication such as magnesium citrate is preferred. Paraffin oil may actually dissolve some packet wrappers


FIGURE SC4–1. Algorithm for managing cocaine or heroin body packers.

resulting in drug toxicity.[94] Safe use of promotility agents, such as metoclopramide and erythromycin, is also reported.[90] Enemas and manual disimpaction should be avoided or used with great caution as packet rupture may occur.[43,50]

Treatment for symptomatic patients depends on the nature of the drug ingested. Patients manifesting opioid toxicity should be treated with the opioid antagonist, naloxone and mechanical ventilation if necessary. Opioid antagonists also improve gastrointestinal motility (Antidotes in Depth A6: Opioid Antagonists). Surgical decontamination is generally not indicated for opioid poisoning, as optimal medical therapy should be adequate.

Rupture of a cocaine packet however, is a life-threatening emergency that requires aggressive medical and surgical therapy (Chap. 76). Benzodiazepines or other sedatives such as propofol may be used as a temporizing measure, but surgical decontamination should be performed emergently in body packers with *any* sign of cocaine toxicity. Indications for surgery include, but are not limited to, hypertension, tachycardia, agitation or other alteration in mental status, myocardial ischemia, bowel ischemia, seizures, respiratory distress and the transition of a urine drug screen from negative to positive.

Surgical removal of the packets is the therapy of choice in the case of cocaine toxicity or mechanical obstruction, but may not be definitive.[31,65,79] In one series, 6 of 70 patients were found to have retained packets postoperatively.[11] Also, emergent surgical removal is associated with a high rate of postoperative infection.[11,79] Endoscopy[74,78,91] and proctoscopy[26] have been used successfully for removal of packets in several cases. However, caution must be used as attempted endoscopic removal can cause packet rupture and resultant toxicity.[82]

It is essential to assure the passage of all packets prior to discharging a patient from medical care. Packets may remain even in patients with

clear rectal effluent following WBI.[36] After negative plain radiographs are obtained, a confirmatory study should be done using contrast plain radiography or CT scan. However these modalities do not have 100% sensitivity and retained packets may be missed.[28] It is therefore recommended that patients be observed for twenty-four hours after the passage of 2 packet free stools[5] and a negative confirmatory radiograph or CT Scan (see Fig. SC4-1) (For more information see Antidotes In Depth A3: Whole Bowel Irrigation and Other Intestinal Evacuants and A6: Opioid Antagonists.). Complete GI decontamination must be assured before releasing the patient from close medical observation.

BODY STUFFERS

Body stuffers usually present to healthcare when they are taken into custody by law enforcement officers. Typically the person has hastily ingested the xenobiotic or inserted them into the rectum or vagina to hide the evidence from the police. Since the person was not planning to conceal the xenobiotic, they may be unwrapped, as in the case of crack cocaine "rocks,"[61] or poorly wrapped in materials intended for distribution. Although the overall incidence of toxicity is low, body stuffers are probably more likely to have symptoms, but are also probably less likely to have significant morbidity and mortality, as they typically ingest much smaller amounts of drug.

Pertinent historical information includes time of ingestion, xenobiotic, amount ingested, packaging and symptoms consistent with drug ingestion. Unfortunately, an accurate history is often difficult to obtain. Patients who are recent arrestees may anticipate a secondary gain of delayed incarceration by reporting the ingestion of drugs; alternatively the individuals may deny ingestion to avoid prosecution. Complicating the clinical picture is the possibility that law enforcement officers may assume internal concealment of illicit substances when they are unable to find the drugs after the arrest.

■ COMPOSITION OF PACKAGES

Since drugs are typically transported locally in plastic bags, condoms,[81] balloons,[8] glycine envelopes, aluminum foil[73] or crack vials,[35] these are the most frequently reported wrappers. Reported amounts vary from one dose to up to 30 packages of unspecified dose.[44] Cocaine, either in crack rocks or the hydrochloride salt form are most commonly ingested,[72] but other xenobiotics are also reported (see Table SC4-1). Typically, the drugs are ingested although other routes of exposure include the external auditory canal, rectum, and vagina.[48,53,86]

The importance of obtaining a precise history related to packaging material is highlighted by an in vitro study examining the effects of packet medium and pH on release of cocaine from drug packets. Cocaine was released almost immediately from paper packaging, and least readily from condoms. Cellophane packing led to intermediate concentrations; when double or triple wrapped in cellophane, decreased concentrations were noted. All packets released more drug in an acidic medium.[1]

■ CLINICAL MANIFESTATIONS

After oral ingestion of drug packets or crack rocks, toxicity is most frequently absent or mild.[44,45] However, although most case series report low rates of complications, both significant toxicity and death occur.[20,38,45,63] The time of onset of symptoms in body stuffers is typically within several hours.[44,45] Following the ingestion of cocaine in crack vials onset of symptoms may be delayed by 3 to 4 hours.[35]

Most patients with onset of symptoms greater than 6 hours have symptoms at the time of medical contact. Two exceptions are noted in

the literature. A 50-year-old woman reported ingesting drugs at the time of incarceration. Seven hours later, a prison physician noted normal pulse and mental status and she was placed in her cell to be observed by staff members every half hour. Prison staff documentation noted that she was "correct" and sat up one-half hour before being found dead in the cell 11 hours after the time of ingestion. Postmortem examination revealed an open cocaine packet in the intestine.[64] A patient who placed methamphetamine in a plastic bag with a small hole in an attempt to create a sustained release mechanism presented for care of abdominal pain ten hours later. This patient remained without symptoms of methamphetamine intoxication until 42 hours after ingestion.[32]

■ LABORATORY EVALUATION

Laboratory drug testing may be difficult to interpret in body stuffers, as these patients are often habitual substance users. Thus a positive drug screen could be equally indicative of either prior use or current toxicity or both. Likewise, a negative result does not exclude recent ingestion or leaking packages. One study of 50 suspected body stuffers, found that urine drug screening correctly classified the presence or absence of packets only 57% of the time.[57] Several authors report drug toxicity or death occurring in the presence of a negative urine screen.[24,32] One explanation is that patients may die of drug toxicity before substantial urinary excretion occurs.

■ RADIOGRAPHIC EVALUATION

Although detection of stuffed xenobiotics may be possible by diagnostic imaging studies, the sensitivity is very poor.[16,44,57] Plastic bags, crack vials, and staples (enclosing plastic bags) are rarely visualized.[44] In one series of patients with crack vial ingestions, only 2 of 23 of abdominal radiographs were positive[35] in patients who subsequently passed vials. In two other series of cocaine body stuffers, all plain radiographs were negative.[45,81] Several authors suggest that radiographic detection can be increased with oral contrast though its utility has not been established.[10,45] Although CT scanning may identify some packets missed on plain radiographs, the sensitivity has not been investigated and missed packets have been reported with this modality as well.[16] Therefore, CT scanning is not likely to be clinically useful in these patients.

■ MANAGEMENT

Body stuffers who are exhibiting drug toxicity should be managed according to standard principles for managing that xenobiotic or suspected xenobiotic (Chaps. 38 and 76).

Patients with gastrointestinal complaints should be evaluated for ileus or obstruction. Removal of packets has been performed by endoscopy,[10,44,70] but is useful only for a small number of packets, as each package requires an additional passage of the endoscope. Endoscopy should be used with extreme caution as it may cause packet rupture with subsequent toxicity or aspiration of the packet with airway obstruction.[82] Bronchoscopic removal of pieces of a balloon wrapping in the airway was successful in one patient after attempted orogastric lavage led to balloon aspiration.[8] Use of colonoscopy[76] is also reported but carries a risk of rupture similar to that associated with upper endoscopy. The need for surgical intervention has been reported in only 1 case. This patient presented with complaint of epigastric pain 3 days after ingesting a large plastic bag filled with 15 to 20 smaller bags of cocaine. He showed no signs of cocaine toxicity, but required surgical removal, as the bag was still retained in the stomach 4 days postingestion.[16]

Management of asymptomatic body stuffers has not been rigorously evaluated. Treatment with AC and WBI was often advocated for high risk patients. Although these methods have not been proven to reduce morbidity or mortality, they offer theoretical benefits.[35,44,45,81] Activated charcoal may reduce the absorption of liberated drug as both heroin and cocaine are well adsorbed to AC. Whole bowel irrigation may reduce intestinal transit time leading to earlier passage of packets. However, it is unlikely to offer any clinical benefits, unless life threatening amounts of xenobiotic (in packages) are ingested.

A therapeutic endpoint has not been established in part because packages are often not recovered from body stuffers. Review of more than 600 published cases of body stuffers involving a variety of packaging methods, reveals only a few cases in which onset of toxicity occurred more than 6 hours after ingestion (when the time of ingestion is reported) and was not present at the time of initial medical evaluation. There are several cases reported when onset of symptoms occurred between 8 and 10 hours postingestion of crack rocks, however in all of these cases except in the two cases noted above, symptoms were present upon health care contact.[10,70]

Management strategies should consider the potential dose ingested, time since ingestion, and therapy administered. Because the vast majority of patients remain asymptomatic, or develop symptoms shortly after medical contact, it is reasonable to observe asymptomatic patients given activated charcoal for 6 hours. Because rare patients may have more delayed presentations, patients who have ingested large, potentially lethal doses should be observed for a longer period in a closely monitored setting. Multiple stools devoid of packages or a lack of symptoms after 24 hours are reasonable endpoints for monitoring these patients.

LEGAL PRINCIPLES

Because clinical errors have the potential for life-threatening consequences, it is essential to evaluate patients within the constructs of their unique social and legal settings. It is important to remember there may be significant motivation to deny ingestion altogether or secondary gain from over-reporting the dose in order to delay incarceration. Often, patients will refuse medical care either as an assertion of innocence, or over concerns that evidence produced might be incriminatory.

In the United States, patients may refuse care if they are competent to do so. This includes body stuffers and body packers who are under arrest. Patients with decisional capacity can not be forced to take AC, WBI, or any other form of therapy. If in police custody, they may however be kept in the hospital for an extended observation period. This strategy maintains patient's medical autonomy as well as assures clinical and legal stability. If signs of life-threatening toxicity subsequently develop, the patient will most likely have lost decisional capacity and therapy can proceed as medically necessary.

If a body packer who is not in legal custody presents for medical care, physicians may face an ethical dilemma. Calling the authorities is a violation of the patient's right to confidentiality. However, possession of large amounts of drugs may theoretically endanger the hospital staff as criminal elements expect drug delivery. Consultation with hospital legal counsel, risk management, and the ethics committee may be helpful in this situation (Chap. 140).

SUMMARY

Patients with intestinal concealment of drugs present a diagnostic and therapeutic challenge. History, laboratory and radiology studies must be interpreted with caution. Management strategies should focus on the drug ingested and be tailored to the needs of each individual patient. Gastrointestinal decontamination is the most important consideration in asymptomatic patients. A complex patient physician relation is common and must be effectively and rapidly developed to assure reliable and high quality care.

ANTIDOTES IN DEPTH (A24)

BENZODIAZEPINES

Robert S. Hoffman, Lewis S. Nelson, and
Mary Ann Howland

Since the introduction of chlordiazepoxide in 1960,[53] benzodiazepines have gained acceptance as safe and effective drugs for a large variety of clinical indications. Specifically in medical toxicology, benzodiazepines are used as the first-line anticonvulsants for virtually all xenobiotic-induced seizures; as the sedatives of choice for most forms of xenobiotic-induced agitation; as muscle relaxants for diverse disorders such as serotonin syndrome, neuroleptic malignant syndrome, and poisoning from strychnine or black widow spider envenomation; and as sedative hypnotics for withdrawal from ethanol, γ-hydroxybutyric acid (GHB), and a variety of sedatives. Additional distinct indications for benzodiazepines can be found in overdose from chloroquine and possibly other quinine-derived antimalarials, and in patients with cocaine-associated myocardial ischemia and infarction.

This Antidotes in Depth provides a summary of the clinical pharmacology of benzodiazepines in order to provide the reader with the background necessary to administer these drugs as safely and effectively as possible.

CHEMISTRY

All benzodiazepines share a common chemical structure shown in Figure A24–1. This structure links a benzene ring with a diazepine ring and gives rise to the name used to describe the drug class. The additional phenyl ring is present in all clinically important benzodiazepines and serves as a site of substitution that modulates some pharmacologic characteristics. The pyrazolopyrimidines (zolpidem, zopiclone, and zaleplon) lack the typical benzodiazepine structure, but have similar pharmacologic effects.[20] Since these pharmaceuticals are largely unstudied for the antidotal indications described above, they are not discussed in depth here. A discussion of the manifestations and treatment of overdose of benzodiazepines and similar xenobiotics can be found in Chapter 74.

GABA RECEPTORS

Benzodiazepines target the γ-aminobutyric acid type A ($GABA_A$) receptor, which is a ligand-gated chloride channel (see Chap. 13, Fig. 13-10), but have no appreciable binding to $GABA_B$. In the absence of GABA, benzodiazepines have no effect on chloride conductance. However, when GABA is present on its $GABA_A$ receptor, benzodiazepines increase the frequency of channel opening resulting in enhanced flow of negatively charged chloride ions into the cell with resultant hyperpolarization.[56]

The $GABA_A$ receptor is assembled from five subunits that span the cell membrane in a circular fashion to create the chloride channel.[40]

These subunits are coded as α, β, γ, δ, ε, Φ, π, or ρ, and at least 19 isoforms of these subunits (such as $α_1$, $α_2$, $α_3$, $α_4$, and $α_5$) are identified.[12] If the isoforms of the known subunits could assemble randomly, several hundred thousand possible configurations of the $GABA_A$ receptor would be possible.[58] However, it appears that a minimum of at least one α, one β, and either one γ or one δ subunit are required to form a functional chloride channel,[62] and as a result the actual number of configurations is limited. The most common configuration consists of one α, two β, and two γ isoforms.[58,62]

BENZODIAZEPINE RECEPTORS

Rapidly evolving neuroscience has resulted in an exponential expansion in the understanding of benzodiazepine receptors. As a result multiple, potentially confusing nomenclatures have developed.

■ CENTRAL

The term "central benzodiazepine receptors" is used to refer to benzodiazepine binding sites on GABAergic neurons of the nervous system. Although benzodiazepine binding to the $GABA_A$ receptor cannot occur unless at least one γ subunit is present,[15] the actual site of benzodiazepine binding is believed to be located at the interface of the α and γ subunits.[12] Since most receptors only contain a single α subunit, only one benzodiazepine binding site usually exists on each $GABA_A$ receptor. Anatomical variations in the α isoforms produce two common patterns of expression that account for some of the clinical variations between benzodiazepines and the pyrazolopyrimidines mentioned earlier.

Benzodiazepine type 1 (BZ1) receptors are also called $ω_1$ receptors. They have a predominance of the $α_1$ isoform, are located in the sensory and motor areas of the brain, and mediate sedative and hypnotic effects. Benzodiazepine type 2 (BZ2) receptors are also called $ω_2$ receptors. They have a predominance of the $α_2$, $α_3$, or $α_5$ isoforms; are located in the subcortical and limbic areas of the brain; and mediate anxiolytic and anticonvulsant effects.[39] Most typical benzodiazepines have substantial affinity for the $α_1$, $α_2$, $α_3$, and $α_5$ isoforms, which explains their combined sedative-hypnotic, anxiolytic, and anticonvulsant effects. In contrast, the pyrazolopyrimidines (such as zolpidem) have high affinity for $α_1$, intermediate affinity for $α_2$ and $α_3$, and low affinity for $α_5$ isoforms, which explains their lack of anticonvulsant effect.[20,41] The $α_4$ confers resistance to benzodiazepines.

■ PERIPHERAL

The term "peripheral benzodiazepine receptors" was originally used in the 1970s to define benzodiazepine binding sites outside of the nervous system.[10] Since peripheral benzodiazepines are now identified in most tissues including the central nervous system, the term best applies to binding sites not located on GABAergic neurons. These receptors have also been called BZ3 or $ω_3$ receptors to distinguish them from the "central receptors" described above.[31] However, numerous non-benzodiazepines have high-affinity binding for these receptors, and their structure and function are so dissimilar from $GABA_A$-associated benzodiazepine binding sites that other names such as translocator
FIGURE A24–1. Generic structure of benzodiazepines.

protein (18 kDa), mitochondrial translocator protein (18 kDa), nuclear translocator protein (18 kDa), or simply translocator protein (18 kDa) may be more appropriate.[47,57,63] For simplicity and consistency they will be referred to as peripheral benzodiazepine receptors (PBRs) in the remainder of this discussion.

Peripheral benzodiazepine receptors are heterotrimers composed of an isoquinoline binding protein, which is the actual 18-kDa translocator protein or the actual receptor; a voltage-dependent anion channel (VDAC); and an adenine nucleotide transporter (ANT).[47] Although the actual function of each subunit is not well appreciated, the minimal functional unit of the PBR is the 18-kDa protein.[29] Sequencing of PBRs demonstrates that they are highly conserved in nature, with DNA from bacteria and fungi having a nearly 50% homology of the isoquinoline binding domain with human DNA.[19] Homology among mammals exceeds 75%.[19] These findings suggest that the PBRs perform a "housekeeping function," that is, they are involved in a process or processes that are essential for life. In higher life forms PBRs can be found primarily in the brain, adrenal glands, heart, and kidney. The translocator protein and the VDAC span the outer mitochondrial membrane, while the ANT bridges the outer and inner membranes (Fig. A24–2). PBRs are implicated in cholesterol and protoporphyrin transport required for the synthesis of steroids, heme, and bile salts; ischemia and reperfusion; regulation of calcium channels; mitochondrial respiration; apoptosis; microglial activation; and the immune response.[19,47,57]
ROLE OF PERIPHERAL BENZODIAZEPINE RECEPTORS IN THE MANAGEMENT OF POISONING

Many chapters in this text discuss the use of benzodiazepines as $GABA_A$ agonists in the management of poisoned patients (see Chaps. 14, 18, 75, 76, and 78). In contrast to the highly evidence-based support for $GABA_A$ agonists in sympathomimetic overdose, xenobiotic-induced seizures, and sedative-hypnotic withdrawal, the use of benzodiazepines as modulators of PBRs for the treatment of poisoned patients is highly speculative. However, as this field is rapidly evolving, discussion of two xenobiotics, chloroquine (see Chap. 58) and cocaine (see Chap. 76) is warranted.

■ CHLOROQUINE

Although chloroquine overdose is uncommon, case fatality rates are extremely high, and ingestion of 5 g or more was once considered universally fatal. However, in 1988 a case series of patients with chloroquine overdose who survived with the use of an aggressive new regimen was described.[50] The protocol, consisting of early endotracheal intubation, high-dose epinephrine infusion, and intravenous diazepam (2 mg/kg over 30 minutes), resulted in the survival of 10 of 11 patients who ingested at least 5 g of chloroquine. This regimen was based on a controlled trial where diazepam improved the hemodynamic and electrocardiographic manifestations of chloroquine poisoning in pigs.[51] Although the study was not designed to determine the mechanism of effect of diazepam, there was no difference in the chloroquine concentrations between the treated and control groups, suggesting that diazepam did not change the distribution of chloroquine.

In isolated perfused hearts, high-dose diazepam has positive inotropic effects that are suppressed by a PBR antagonist.[34] Unfortunately, translation of these findings in an isolated rat heart to doses used in human poisoning is not necessarily valid. Also, benzodiazepines, chloroquine, and experimental PBR agonists share some structural elements (Fig. A24–3). Functional similarity is also suggested by evidence that both flurazepam and PK 11195 (a PBR agonist) have antimalarial

FIGURE A24–2. The peripheral benzodiazepine receptor has three main components: the 18-kDa translocator protein, a voltage-dependent anion channel (VDAC), and an adenine nucleotide transporter (ANT) which are shown on the mitochondrial membrane.
FIGURE A24–3. Comparative structures of flurazepam, PK 11195 (a PBR agonist) and chloroquine. Note the similarity and particularly the shared isoquinoline rings of chloroquine and PK 11195.

activity.[17] Thus, one could speculate that it is possible that the beneficial effects of high-dose diazepam result from competitive inhibition of an undefined interaction between chloroquine and PBRs.

■ COCAINE

Patients who use cocaine frequently present to emergency departments with either chest pain, or signs or symptoms that could represent myocardial ischemia or infarction.[11] Unlike most patients with acute cocaine toxicity, however, these patients often present hours after their last drug use and without the classic sympathomimetic findings of acute cocaine toxicity.[26] While the pathophysiology of cocaine-induced myocardial ischemia is complex and multifactorial (see Chap. 76), one component of delayed myocardial ischemia may result from the vasoconstrictive actions of benzoylecgonine, the principal metabolite of cocaine.[37] Benzoylecgonine is distinct from cocaine in that it has a much longer half-life,[3,4] does not produce central nervous system stimulation,[43,44] and directly vasoconstricts through modulation of calcium channels.[36]

Limited research suggests that chronic cocaine use is associated with an increased number of PBRs on human platelets.[14] Also in humans, cocaine withdrawal is associated with a decrease in PBRs on neutrophils. In the myocardium, PBRs are either present on mitochondria, or coupled to calcium channels.[42] Specifically, PBR ligands have demonstrable inhibitory effects on myocardial L-type calcium channels.[13] Also in a cardiac model of ischemia and reperfusion injury, an experimental PBR agonist limited myocardial infarction size following coronary artery occlusion.[32] This effect most likely occurs through inhibition of the opening of the mitochondrial permeability transition pore,[45] which is a common final mechanism of cell death. Additionally, although the exact mechanism is unclear, PBR agonists directly antagonize the vasoconstrictive effects of norepinephrine in rat aortic tissue.[21]

Benzodiazepines are commonly used to treat the agitation associated with sympathomimetic overdose (see Chaps. 75 and 76). While it is assumed that the normalization of vital signs results from a decrease in central nervous system stimulation and psychomotor agitation, effects on PBRs may be contributory. In the same isolated perfused hearts described above, low-dose diazepam has a negative inotropic effect that results from an interaction with calcium currents.[33] As noted above, interpreting the implications of varied benzodiazepine doses in an isolated rat model with regard to human beings may not be valid. More importantly, two randomized controlled studies evaluated the use of benzodiazepines in patients with cocaine-associated chest pain.[8,27] In the first study, patients were randomized to receive nitroglycerin, diazepam, or combined therapy.[8] Both drugs were associated with an improvement in chest pain, and combined therapy appeared to offer no additional benefit. The second study randomized patients to nitroglycerin or combined nitroglycerin with lorazepam therapy.[27] In this trial combined therapy was better than either therapy alone, possibly suggesting that benzodiazepines and nitroglycerin relieve chest pain by different mechanisms.

PHARMACOKINETICS AND PHARMACODYNAMICS

As mentioned above, in medical toxicology benzodiazepines are usually administered to treat seizures, psychomotor agitation, or sedative-hypnotic withdrawal. Since these disorders often represent life-threatening emergencies, the initial approach to treatment involves the use of parenteral drugs. Parenteral therapy provides guaranteed absorption with a relatively rapid onset of action. As such, this Antidotes in Depth: A24 focuses on the most commonly used parenteral benzodiazepines: diazepam, lorazepam, and midazolam. Clinically important pharmacologic parameters of these three drugs are listed in Table A24–1. Of note, since the existing literature is insufficient to

TABLE A24–1. Pharmacologic Properties of Select Benzodiazepines

Parameter	Diazepam	Midazolam	Lorazepam
Lipid solubility	++++	++++ (initially water soluble but becomes lipophilic at physiologic pH)	+++
Partition ratio (octanol/pH 6)	309	34	73
Volume of distribution (healthy adults) (L/kg)	0.89 ± 0.18	0.80 ± 0.19	1.28 ± 0.34
Protein binding (%)	97–99	96	85
Hepatic metabolism	Phase 1	Phase 1	Phase 2
Active metabolites	Yes (several)	Yes: Alpha hydroxymidazolam (10% of parent, but accumulates with chronic dosing)	No
Average dose (mg) in 70-kg adult[a]			
Sedation	10 mg over 2 min	2 mg over >2 min (not >1.5 mg in elderly or debilitated patients and over >>2 min)	2 mg over 1 min (dilute with equal volume of NS or D$_5$W prior to injection)
		Wait 2 min before titrating	Wait 15 min before redosing
Status epilepticus (Initial dose)	10 mg	Not established	4 mg
Diluent	Alcohol 10% Benzyl alcohol 1.5% Propylene glycol 40%	Benzyl alcohol 1.0% Edetate Na$_2$ 1%	Benzyl alcohol 2% Propylene glycol 80%
Available	5mg/mL Rectal gel 5 mg/mL	1 mg/mL 5 mg/mL	2 mg/mL 4 mg/mL

[a]Avoid intraarterial administration since severe spasm may occur with resulting ischemia or gangrene. Also avoid extravasation.

D$_5$W = 5% dextrose in water

NS = 0.9% NaCl.

absolutely differentiate individual roles for specific benzodiazepines in specific disorders, these three drugs are often used interchangeably for a variety of indications based on availability within the hospital and regional historic preferences. Only through an understanding of the pharmacology can the clinician select the optimal drug, dose, route, and interval to ensure adequate response and limit adverse reactions. As discussed below, it is important to note that the onset and peak effects of sedative and anticonvulsant activity are distinctly different for each drug and among drugs, so pharmacodynamic data are an important adjunct to the interpretation of pharmacokinetic data.

Intravenous administration guarantees complete and immediate absorption. When intravenous access is unavailable, intramuscular lorazepam or midazolam should be considered as they both have good absorptive profiles.[24,28,61] In contrast, the absorption following intramuscular diazepam is best described as slow, incomplete, erratic, and dependent on the site of administration.[16,28,59] Intramuscular injection of diazepam should therefore not be considered unless no other alternatives exist.

Other routes of administration are used for rapid drug delivery when intravenous access is not available. For example, and especially in children, intranasal and rectal administration can be considered. When rectal diazepam was compared with intravenous diazepam in children with seizures, the peak concentration was more variable and was delayed by about 20 minutes.[46] Additionally, failure rates are higher when rectal diazepam is compared with intravenous diazepam.[46,49] Similarly, although midazolam is more rapidly absorbed than diazepam following both nasal and rectal administration, the kinetic profile of nasal or rectal midazolam is still inferior than the intravenous administration or either diazepam or midazolam.[38,49]

Once absorbed, benzodiazepines must distribute into the central nervous system in order to produce their sedative and anticonvulsant effects. The differences among individual drugs can be evaluated in terms of their pharmacokinetics, such as cerebral drug concentrations, or pharmacodynamics, such as changes in either consciousness or electroencephalographic (EEG) findings. A cat model was used to compare cerebrospinal fluid (CSF) concentrations of benzodiazepines with EEG effects.[5] Following intravenous administration, diazepam, midazolam, and lorazepam all appeared rapidly in the CSF. However, the times to peak concentration, onset, and duration of EEG activities were remarkably different among the three drugs (Table A24–2).

In a similar study, human volunteers were given a 1-minute intravenous infusion of either diazepam (0.15 mg/kg) or midazolam (0.1 mg/kg) and EEG analysis was used as a surrogate for the pharmacodynamic effects of sedation. Peak EEG effects were present immediately at the end of the diazepam infusion, but were delayed for 5- to 10 minutes after the midazolam infusion.[23] These EEG effects lasted for 5 hours

TABLE A24–3. Relative Pharmacodynamic Properties of Benzodiazepines in Humans

	Diazepam	Midazolam	Lorazepam
Anticonvulsant			
Onset of action			
IV	Quick (min)	Quick (min)	Quick (min)
IM	Not advisable	2–10 min	9 min
Duration of action			
IV	1–2 h	30-80 min	Many hours
IM	Unpredictable	1–2 h	Many hours
Sedative			
Onset of action			
IV	Quick (min)	Quick (min)	5–20 min
IM	Unpredictable	5–10 min	20-30 min

in diazepam-treated volunteers in comparison to only 2 hours in midazolam-treated volunteers. The same investigators compared the EEG effects of either intravenous lorazepam (low dose, 0.0225 mg/kg; high dose, 0.045 mg/kg) or diazepam (0.15 mg/kg) in human volunteers.[22] In comparison to diazepam, the EEG effects of lorazepam were slower in onset, delayed in peak (30 minutes), and prolonged in duration of effect. The relative effects of diazepam, lorazepam, and midazolam are shown in Table A24–3.

DOSING AND ADMINISTRATION

In theory, an analysis of the pharmacokinetic and pharmacodynamic parameters presented in Tables A24–1 and A24–3 should allow clinicians to choose among the benzodiazepines based on the particular clinical situation. In reality, however, these choices may be difficult in patients with complex clinical presentations of uncertain etiologies. In addition, clinical studies seem to suggest less variability than might be predicted based on pharmacokinetic and pharmacodynamic modeling. For example, in an analysis of 28 studies of conscious sedation, 19 failed to demonstrate a significant difference in the times to recovery between diazepam and midazolam.[6] Likewise although multiple studies demonstrate that lorazepam is at least as effective and likely superior to diazepam in terminating status epilepticus, its onset of action does not appear to be delayed.[2,35,55]

Some of the observed inability to translate controlled pharmacologic analyses into clinical practice may result from imprecision in determining equivalent doses of these drugs. We offer the following guidance. Each of these three benzodiazepines discussed will likely have some efficacy in all clinical scenarios for which a benzodiazepine is indicated. It may therefore be preferable for many clinicians to understand and master the pharmacology and limitations of a single drug rather than attempt to use all three

TABLE A24–2. Selected Pharmacokinetic and Pharmacodynamic Properties of Benzodiazepines in Animals[5]

Parameter	Diazepam	Midazolam	Lorazepam
Time to peak CSF concentration (min)	3.7 ± 1.3	3.7 ± 1.3	7.0 ± 4.2
Onset of EEG activity (min)	0.89 ± 0.31	0.29 ± 0.04	3.8 ± 3.1
Duration of EEG activity (min)	7.5 ± 1.4	6.3 ± 1.9	28.3 ± 10.1

drugs selectively and run the risk of an improper dose or suboptimal therapeutic interval leading to an adverse effect. For those who wish to use these drugs selectively, three variables should be considered: onset of effect, peak effect, and duration of effect. For example, in patients with extreme psychomotor agitation intravenous diazepam or midazolam would be prefered both for their rapid onset and rapid peak effects. The relatively slow onset and delayed peak of lorazepam might lead to administration of multiple doses before the full effect of the first dose is appreciated, with resultant oversedation. When a short duration of sedation is anticipated, such as when treating a patient with toxicity following intravenous or inhaled use of cocaine, midazolam might be preferable over diazepam or lorazepam in that the duration of the effects of midazolam better matches the duration of effects of cocaine, thereby limiting oversedation after cocaine has been rapidly metabolized. For disorders where very long periods of agitation are expected, such as alcohol withdrawal, the choice of diazepam with its very active metabolites (desmethyldiazepam and oxazepam) may be preferable over lorazepam and midazolam in that less frequent dosing may be required and an auto-tapering effect may result at the end of therapy, because these metabolites persist longer than diazepam alone. When status epilepticus is present in the absence of substance use or withdrawal, lorazepam seems to offer a clear advantage. It is important to note that switching from one benzodiazepine to another is rarely indicated, and increases the risk of an adverse drug event from unpredictable peak effects, or improper therapeutic doses or dosing intervals. Specific recommendations can be found in Chapters 14, 18, 75, 76, and 78.

ADVERSE EFFECTS

The most common adverse effect of benzodiazepines is central nervous system depression. While this is unavoidable in some cases, it can generally be limited by selecting the optimal drug and the proper dose and dosing interval for the drug being used. Extra caution is advised in elderly patients as they appear to be more sensitive, particularly to the sedative and respiratory depressant effects of midazolam.[1] In contrast, paradoxical reactions may occur where patients become more agitated following benzodiazepine administration.[52,54,60] These infrequent reactions probably result from disinhibition and may respond to larger doses of benzodiazepines. Although paradoxical agitation also responds to flumazenil, reversal would be inappropriate following the antidotal use of benzodiazepines (see Antidotes in Depth A23–Flumazenil).

Intravenous benzodiazepines produce a mild reduction in heart rate and both systolic and diastolic blood pressure. The effects of midazolam may be greater than diazepam,[48] but this may merely be based on an inability to determine an equivalent dosing regimen. While these reductions result in part from diminished sympathetic tone, direct myocardial effects are rarely severe and are often considered desirable in the overdose setting.[48]

Whereas respiratory depression is generally not a concern with oral benzodiazepines, parenteral administration is documented to impair ventilation. Early investigations demonstrated that intramuscular diazepam (10 mg) blunted the hypoxic ventilatory drive in normal subjects.[30] Intravenous diazepam impaired the ventilatory response to a rising Pco_2 in normal volunteers.[7] The impaired response to a rising Pco_2 was evident almost immediately and lasted for at least 25 minutes following injection of 0.4 mg/kg of diazepam in healthy volunteers.[25] Studies with midazolam demonstrate similar alterations in respiratory physiology[18] that are comparable in magnitude to those reported with diazepam.[9] Apnea is reported following intravenous midazolam and appears to be dose and rate related, with doses greater than or equal to 0.15 mg/kg being of particular concern.[48] Individuals with preexisting pulmonary disorders, extremes of age, or other central nervous system or respiratory depressants may be more susceptible.

AVAILABILITY

Parenteral benzodiazepines are available from multiple manufacturers in varying concentrations. It is essential to recognize that some formulations contain several significant and varied excipients (see Table A24–1). Large doses or prolonged continuous infusions of benzodiazepines may result in toxicity from these excipients (see Chap. 55).

SUMMARY

Although benzodiazepines are commonly used in a variety of medical settings, subtle differences exist in their pharmacokinetics and pharmacodynamics. Optimal use of these drugs requires a thorough understanding of these differences. Clinicians should consider the desired onset of action, peak effect, and duration of action when choosing among different benzodiazepines. In general, intravenous administration is preferred in an emergency because of rapid and reliable absorption. Because of a rapid onset of action and short time to peak effect, sedation is best achieved with diazepam. When intravenous access is not available, pharmacokinetic and pharmacodynamic parameters favor the use of midazolam for sedation. A prolonged anticonvulsant effect is the major benefit of lorazepam. However, when used for sedation, the delayed peak effect of lorazepam (regardless of route of administration) is undesirable. Although the use of benzodiazepines as peripheral benzodiazepine receptor agonists may explain some unique therapeutic effects of these drugs, existing research is too limited to offer guidance with regard to choice of drug, dose, or dosing interval required to optimize peripheral benzodiazepine receptor response.

CHAPTER 77
ETHANOL

Luke Yip

Ethanol, or ethyl alcohol, is commonly referred to as "alcohol." This term is somewhat misleading since there are numerous other alcohols to which a patient may be exposed. However, ethanol is probably the most commonly used and abused xenobiotic in the world. Its use is pervasive among adolescents and adults of all ages and socioeconomic groups, and represents a tremendous financial and social cost.[3,209]

HISTORY AND EPIDEMIOLOGY

The ethanol content of alcoholic beverages is expressed by volume percent or by proof. Proof is a measure of the absolute ethanol content of distilled liquor, made by determining its specific gravity at an index temperature. In the United Kingdom, the Customs and Excise Act of 1952 declared proof spirits (100 proof) as those in which the weight of the spirits is 12/13 the weight of an equal volume of distilled water at 11°C (51°F). Thus, proof spirits are 48.24% ethanol by weight or 57.06% by volume. Other spirits are designated over or under proof, with the percentage of variance noted. In the United States, a proof spirit (100 proof) is one containing 50% ethanol by volume. The derivation of proof comes from the days when sailors in the British Navy suspected that the officers were diluting their rum (grog) ration and demanded "proof" that this was not the case. They achieved this by pouring a sample of grog on black granular gunpowder. If the gunpowder ignited by match or spark, the rum was up to standard, 100% proof that the liquor was 50% ethanol. This became shortened to 100 proof (Table 77–1). In addition to beverages, ethanol is present in hundreds of medicinal preparations used as a diluent or solvent in concentrations ranging from 0.3% to 75%.[28,44,52,106,164,208] Mouthwashes may have up to 75% ethanol (150 proof) and colognes typically contain 40% to 60% ethanol (80 to 120 proof).[16,104,164,177] These products occasionally cause intoxication, especially when unintentionally ingested by children.[31,49,88,210]

Veisalgia, "alcohol hangover," comes from the Norwegian *kveis*, "uneasiness following debauchery," and the Greek *algia*, pain. The "hangover" syndrome has been attributed to congeners, substances that appear in alcoholic beverages in addition to ethanol and water.[26,33,34] Congeners contribute to the special characteristics of taste, flavor, aroma, and color of a beverage. The combinations and exact amounts of congeners vary with the type of beverage, ranging from 33 mg/L in vodka, to averages of 500 mg/L in some whiskies and as much as 29,000 mg/L in specially aged whiskies or brandies.[26,33,34] The conventional listing of congeners includes fusel oil (a mixture containing amyl, buytyl, propyl, and methyl alcohol), aldehydes, furfural, esters, low-molecular-weight organic acids, phenols, and other carbonyl compounds, tannins, solids, and a relatively large number of additional organic and inorganic compounds, usually in trace amounts.[26,34]

Consumption of illicitly produced ethanol ("moonshine") has resulted in methanol, lead, or arsenic poisoning.[46,66,101,120,126,144,16]
[1] Incidental lead contamination is also reported in draught beers or wine contained in lead-capped bottles.[183,184] Of historic interest is that the addition of cobalt salts to beer to stabilize the "head" (foam) led to outbreaks of congestive cardiomyopathy among heavy beer drinkers in Canada and Belgium in the 1960s (see Chap. 92).

The clinical-pathological pattern of this disease is distinct from the classical alcoholic cardiomyopathy.[136,138]

Alcoholism is the leading cause of morbidity and mortality in the United States. The prevalence of ethanol dependence in the United States has been relatively stable, at around 6% for men and 2% for women.[25] The overall estimated annual cost of health expenses related to ethanol is $185 billion.[151] More than 70% of the estimated costs were attributed to lost productivity, most of which resulted from ethanol-related illness or premature death. Most of the remaining estimated costs were expenditures for health care services to treat ethanol-induced disorders (14.3%), property and administrative costs of ethanol-related motor vehicle crashes (8.5%), and criminal justice system costs of ethanol-related crime (3.4%). More than 200,000 Americans die annually of alcoholism, far more than those who die of all illicit drugs of abuse combined. Ethanol is the leading cause of mortality in people 15 to 45 years of age. In 2007 there were 12,998 ethanol-related traffic fatalities in the United States that accounted for 31.7% of total traffic fatalities; 67% of ethanol-impaired driving fatalities were drivers with blood ethanol concentration 80 mg/dL or higher and 17% were passengers riding with the ethanol-impaired drivers.[149] Drivers age 21 to 34 accounted for 44% and drivers between 16 to 20 years accounted for 10% of all ethanol-impaired drivers in fatal crashes. Among 16- to 20-year-old male drivers, an increase of 20 mg/dL in blood ethanol concentration was estimated to more than double the relative risk of fatal single-vehicle crash injury compared with sober drivers of the same age and gender.[222,223] When the blood ethanol concentration was between 80 and 100 mg/dL (17–22 mmol/L), 100 and 150 mg/dL (22–33 mmol/L) and greater than 150 mg/dL (33 mmol/L), the relative risk of fatal single-vehicle crash injury was 52, 241, and 15,560 respectively.

The Global Burden of Disease Study identified three effects of ethanol: harmful effects in relation to injuries, harmful effects in relation to disease, and the protective effect in relation to ischemic heart disease.[151] Overall ethanol accounted for 3.5% of mortality and disability, 1.5% of all deaths, 2.1% of all life years lost, and 6% of all the years lived with disability.[151] In the United States, according to National Highway Traffic Safety Administration (NHTSA) information, all jurisdictions have enacted per se blood ethanol concentration for adults operating non-commercial motor vehicles.[150] The term *illegal per se* refers to state laws that make it a criminal offense to operate a motor vehicle at or above a specified ethanol (or drug) concentration in the blood, breath, or urine, which may or may not reflect clinical intoxication (Table 77–2). For example, while ethanol-tolerant patients may not exhibit impairment even at serum ethanol concentrations greater than 300 mg/dL (65 mmol/L), they are still considered impaired with regard to the laws that govern motor vehicle operation.[1]

There appears to be a dose–response relationship between ethanol consumption and risk of death in men aged 16–34 and in women aged 16–54. The level at which the risk is lowest increases with age, reaching 64–80 grams per week in men over 65 and 24–30 grams per week in women over 65. The level at which the risk is increased by 5% above this minimum is 40–50 grams per week in men aged 16–24 and 64–80 grams per week in women aged 16–24, increasing to 272–340 g and 160–200 g per week in men and women over 65, respectively.[214] Meta-analysis of aggregate data from epidemiologic dose–response ethanol and mortality cohort studies suggests that the level of ethanol consumption at which all-cause risk is lowest is approximately 5 g/d and that ethanol exerts a protective effect (J-shaped dose response curve) up to a daily intake of approximately 45 grams.[9] It is suggested that sensible drinking of ethanol for men is 8–10 g/d up to age 34, 16–20 g/d between 34 and 44 years of age, 24–30 g/d between 44 and 54 years of age, 32–40 g/d between 54 and 84 years of age, and 40–50 g/d over age 85. Women would be advised to limit their drinking to 8–10 g/d up to age 44, 16–20 g/d between 44 and

TABLE 77–1. Clinical Pharmacology and Pharmacokinetics of Ethanol

Ethanol MW: 46 daltons

$$mmol = \frac{mg}{MW} = \frac{mg}{46}$$

$$mmol/L = \frac{mg/dL}{4.6}$$

Specific gravity: 0.7939 (~0.8) g/mL

Volume of distribution (V_d): 0.6 L/kg

$$Serum\ ethanol\ concentration\ (mg/dL) = \frac{dose\ (mg)}{V_d(L/kg) \times body\ weight\ (kg) \times 10}$$

Average reduction in blood ethanol concentration (elimination phase):
  Nontolerant adult: 3.26–4.35 mmol/L/h (15–20 mg/dL/h, 100–125 mg/kg/h)
  Tolerant adult: 6.52–8.70 mmol/L/h (30–40 mg/dL/h, 175 mg/kg/h)

For a 70-kg individual:

Dose of ethanol	Serum ethanol concentration[a]
10 mL/kg of 10% (20 proof)	167 mg/dL (36.30 mmol/L)
3 mL/kg of 10% (20 proof)	50 mg/dL (10.87 mmol/L)
1.5 mL/kg of 10% (20 proof)	25 mg/dL (5.43 mmol/L)
150 mL (5 "shots") of 40% (80 proof)	143 mg/dL (31.09 mmol/L)
30 mL (1 "shot") of 40% (80 proof)	27 mg/dL (5.87 mmol/L)
A "standard drink" (15 g of ethanol), defined as 1 oz (30 mL) of 100 proof liquor, 4-oz (120 mL) glass of wine (12% ethanol), or 10-oz bottle (300 mL) of beer (5% ethanol)	43 mg/dL (9.35 mmol/L)

[a]This is the theoretical maximum concentration, based on instantaneous and complete ethanol absorption and no distribution or metabolism.

Blood concentration consistent with legal intoxication = 10.87–17.39 mmol/L (50–80 mg/dL or 0.05–0.08 g/dL [%]).

The legal breath ethanol concentration to blood ethanol concentration ratio has been set at 1:2100; the amount of ethanol in 1 mL of blood is the same amount in 2100 mL of exhaled air: Measured breath ethanol concentration (mmol/L) × 2100 = (calculated) blood ethanol concentration (mmol/L).

TABLE 77–2. Acute Ethanol Effects in Most Nontolerant Individuals

Serum Ethanol Concentration	Effects
20 mg/dL (4.35 mmol/L)[151,223]	Impairs driving-related skills
50 mg/dL (10.87 mmol/L)[142]	Gross motor control and orientation may be significantly affected
	Clinical ethanol intoxication is usually apparent

74 years of age, and 24–30 g/d over age 75.[214] However, no safe level of prenatal ethanol exposure has been established. The combination of a national tolerance of drinking and heavy advertising of ethanol makes it especially appealing to young people. In a society increasingly concerned with drug abuse, the excessive use of ethanol constitutes a serious and pervasive problem as well as a major health issue.

PHARMACOKINETICS/TOXICOKINETICS

Ethanol is rapidly absorbed from the gastrointestinal (GI) tract, with approximately 20% absorbed from the stomach and the remainder from the small intestine.[153] Factors that enhance absorption include rapid gastric emptying, ethanol intake without food, the absence of congeners, dilution of ethanol (maximum absorption occurs at a concentration of 20%), and carbonation. Under optimal conditions for absorption, 80% to 90% of an ingested dose is fully absorbed within 60 minutes. Factors that delay or decrease ethanol absorption include high concentrations of ethanol (by causing pylorospasm), presence of food, coexistence of GI disease, co-ingestion of drugs such as, aspirin,[102,158] time taken to ingest the drink, and individual variation. When any of these factors is present, absorption may be delayed for 2 to 6 hours. The relative amount of ethanol that is absorbed from the stomach is determined by the presence of alcohol dehydrogenase (ADH) in the gastric mucosa, which oxidizes a proportion of the ingested ethanol, thus reducing the amount available for absorption. This effect is more pronounced in men than in women and in nonalcoholics than in alcoholics.[11,58] Histamine$_2$ (H$_2$) receptor antagonists (ie, cimetidine and ranitidine) inhibit ADH activity in the gastric mucosa resulting in decreased first-pass metabolism and increase the bioavailability of imbibed ethanol.[7,22,24,40,51]

Following complete distribution, ethanol is present in body tissues in a concentration proportional to that of the tissue water content. Ethanol freely passes through the placenta, exposing the fetus to ethanol concentrations comparable to that achieved in the mother.

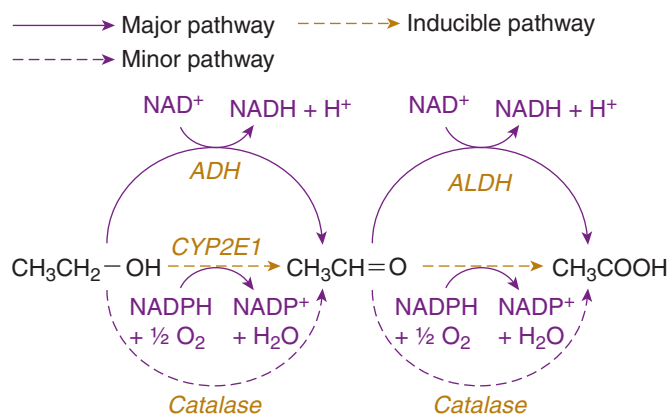
Ethanol is primarily eliminated by the liver, with 5%–10% excreted unchanged by the kidneys, lungs, and sweat. Ethanol is metabolized via at least three different pathways: the aforementioned alcohol dehydrogenase (ADH) pathway located in the cytosol of the hepatocytes, the microsomal ethanol oxidizing system (MEOS; CYP2E1), located on the endoplasmic reticulum, and the peroxidase-catalase system associated with the hepatic peroxisomes (Fig. 77–1.).[153]


FIGURE 77–1. Ethanol (CH$_3$CH$_2$OH) is metabolized to acetaldehyde (CH$_3$CHO) and then to acetic acid (CH$_3$COOH) through major, minor and inducible pathways. ADH = alcohol dehydrogenase, ALDH = aldehyde dehydrogenase.

For a given ethanol dose 95%–98% is metabolized in the liver, first to acetaldehyde by ADH and then further to acetic acid by aldehyde dehydrogenase (ALDH).[94] The end products of ethanol oxidation are carbon dioxide and water. The remaining 2%–5% is excreted unchanged in urine, sweat, and expired air. In addition, less than 0.1% undergoes phase II conjugation reactions to produce ethyl glucuronide and ethyl sulfate, catalyzed by uridine diphosphate-glucuronosyltransferase and sulfotransferase, respectively.[32,56,78,179,180]

The ADH system is the main pathway for ethanol metabolism and is also the rate-limiting step. ADH is a zinc metalloenzyme that uses oxidized nicotinamide adenine dinucleotide (NAD$^+$) as a hydrogen ion acceptor to oxidize ethanol to acetaldehyde. In this process, hydrogen ion is transferred from ethanol to NAD$^+$, converting it to its reduced form, NADH. Subsequently, hydrogen ion is transferred from acetaldehyde to NAD$^+$. Under normal conditions acetate is converted to acetylcoenzyme A (acetyl-CoA), which enters the Krebs cycle and is metabolized to carbon dioxide and water. The entry of acetyl-CoA into the Krebs cycle is thiamine dependent (see Antidotes in Depth A25: Thiamine Hydrochloride).

The ADH gene family encodes enzymes that metabolize a wide variety of substrates. There are at least 7 genetic loci code for human ADH arising from the association of different subunits, and there are over 20 ADH isoenzymes.[2] These ADH forms have been divided into five major classes (I-V) according to their subunit, isoenzyme composition, and physicochemical properties.[97] Two of these gene loci exhibit polymorphism and they both involve Class I ADH genes; three alleles exist for ADH2 (ADH1B) ADH2*1 (ADH1B*1), ADH2*2 (ADH1B*2), and ADH2*3 (ADH1B*3)] and three for ADH3: (ADH1C) ADH3*1 (ADH1C*1), ADH3*2 (ADH1C*2), and ADH3*3 (ADH1C*3).[30] Class I enzymes are inducible intracellular hepatic enzymes and are believed to play a major role in ethanol metabolism.[123] Class IV ADH6 (σ-ADH) is the major ADH expressed in human gastric mucosa.[11,58] σ-ADH is usually present in non-Asians, whereas in a majority of Pacific Rim Asians the enzyme activity is either low or not detectable.[11,12,42] The ADH1B*2 allele is present in 90% of Pacific Rim Asians but occurs infrequently in most Caucasians, except for people of Jewish and perhaps Hispanic descent.[215] It appears to be responsible for the unusually rapid conversion of ethanol to acetaldehyde. People carrying ADH1B*2 alleles are about one-third as likely to be alcoholic compared with people without this allele.[215]

In the liver, ADH metabolizes ethanol to acetaldehyde, which is then converted to acetate by mitochondrial NAD-dependent ALDH. Human ALDH is divided into nine major gene families. There is a functional polymorphism of the mitochondrial ALDH2 gene and expression of an inactive form of the ALDH2, glutamate to lysine substitution at position 487 (E487K), results in impaired acetaldehyde metabolizing capacity. The variant allele ALDH2*2 encodes a protein subunit that confers low activity to the enzyme resulting in marked differences in the steady-state kinetic constants, which appears to be most prevalent in Pacific Rim Asians.[2,30,68,192,193] These metabolic polymorphisms contribute to differences in ethanol and acetaldehyde elimination rate; high-activity ADH variants are predicted to increase the rate of acetaldehyde generation, while the low-activity ALDH2 variant is associated with an inability to metabolize this compound, and may explain differences in ethanol-related behavior. Asians possessing an atypical ALDH2 gene are more sensitive to acute adverse responses to ethanol and tends to discourage ethanol consumption. Homozygous ALDH2*2 individuals are strikingly sensitive to small doses of ethanol (0.2 g/kg), as evidenced by the intense flushing, pronounced cardiovascular hemodynamic effects as well as subjective perception of general discomfort.[48,68,162,198,203] This effect may also be associated with the ADH2*2 and ADH3*1 allele, and is similar to that induced by disulfiram (see Chap. 79). The ethanol flushing response may involve prostaglandin and histamine release. Both prostaglandin antagonists (aspirin)[200] and anithistamines (H$_1$ and H$_2$)[139,188,195] may attenuate this response.

The MEOS (CYP2E1) is responsible for very little ethanol metabolism in the nontolerant drinker, but becomes more important as the ethanol concentration rises or as ethanol use becomes chronic (Fig. 77–1.). CYP2E1 uses oxidized nicotinamide adenine dinucleotide phosphate (NADP$^+$) as an electron acceptor to oxidize ethanol to acetaldehyde.[112] In this process, electrons are transferred from ethanol to NADP$^+$, converting it to its reduced form, NADPH. Subsequently, acetaldehyde is further oxidized to acetate as hydrogen ion is transferred from acetaldehyde to NADP$^+$. The ability of ethanol to induce the MEOS system forms the basis for the well-established interactions between ethanol and a host of other xenobiotics metabolized by this system.[41,57] In alcoholics and those with higher ethanol concentrations, cimetidine may also delay ethanol clearance by inhibiting the MEOS (CYP2E1).[74] However, the increase in blood ethanol concentration from such an interaction is of questionable clinical significance.[6,7,22,23]

ADH is saturated at relatively low blood ethanol concentrations. As the system is saturated, ethanol elimination changes from first-order to zero-order kinetics (see Chap. 8). In adults, the average rate of ethanol metabolism is 100 to 125 mg/kg/h in occasional drinkers and up to 175 mg/kg/h in habitual drinkers.[19,67] As a result, the average-sized adult metabolizes 7 to 10 g/h and the blood ethanol concentration falls 15 to 20 mg/dL/h (3.26–4.35 mmol/L/h). Tolerant drinkers, by recruiting CYP2E1, may increase their clearance of ethanol to 30 mg/dL/h (6.52 mmol/L/h).[19,67] Studies of ethanol intoxicated patients indicate that although the average ethanol clearance rate is about 20 mg/dL/h (4.35 mmol/L/h), there is considerable individual variation (standard deviation of about 6 mg/dL/h [1.30 mmol/L/h]).[19,67]

XENOBIOTIC INTERACTIONS

Ethanol interacts with a variety of xenobiotics (Table 77–3).[100,208] The most frequent ethanol–drug interactions occur as a result of ethanol-induced increase in hepatic xenobiotic-metabolizing enzyme activity. In contrast, acute ethanol use may inhibit metabolism of other xenobiotics and this may be due to competitive inhibition of hepatic enzyme activity or a reduction in hepatic blood flow. The interaction between ethanol and disulfiram (Antabuse) is well described and it can be rarely life threatening (see Chap. 79).

Concomitant use of cocaine and ethanol leads to the formation of an active metabolite, cocaethylene, through transesterification of cocaine by the liver.[169] Cocaethylene has a longer half-life than cocaine itself (2 hours versus 48 minutes), and this may explain some of the delayed cardiovascular effects attributed to cocaine use.[8,216] Both ethanol and cocaethylene inhibit the metabolism of cocaine, thereby prolonging the elimination of cocaine and enhancing its effect (see Chap. 76).[159]

Case reports and retrospective case series suggest that chronic ethanol consumption may predispose a person to acetaminophen (APAP) hepatotoxicity (see Chap. 34)[47,129,135,178,226] even when APAP has been taken according to the manufacturer's recommended dosage of not more than 4 grams daily.[225] Because ethanol induces cytochrome P450, the enzyme involved in the metabolism of acetaminophen to its hepatotoxic intermediate, NAPQI, a theoretical basis for this association exists. However, in a double-blind placebo control study where confirmed alcoholics were given acetaminophen 4 grams daily or placebo for three consecutive days there were no differences between the two groups with regard to liver enzymes or to their coagulation profile.[111] Recent fasting, common in alcoholics, was also associated with a predisposition

TABLE 77–3. Ethanol Xenobiotic Interactions

Xenobiotics	Adverse Effects
Antihistamines (H$_1$)	Additive sedative effect
Aspirin	Enhance antiplatelet effect
Carbamates	Disulfiram-like effect
Cephalosporins[a]	Disulfiram-like effect
Chloral hydrate	Additive sedative effect
Chloramphenicol	Disulfiram-like effect
Chlorpropamide	Disulfiram-like effect
Coprinus mushrooms	Disulfiram-like effect
Cyclic antidepressants	Additive sedative effect
Disulfiram (Antabuse)	Nausea, vomiting, abdominal pain, flushing, diaphoresis, chest pain, headache, vertigo, palpitations
Griseofulvin	Disulfiram-like effect
Isoniazid	Increased incidence of hepatitis; increased metabolism[b]
Methadone	Increased methadone metabolism[b]
Metronidazole	Disulfiram-like effect
Nitrofurantoin	Disulfiram-like effect
Opioids	Additive sedative effect
Oral hypoglycemics	Potentiates hypoglycemic effect
Phenothiazines	Additive sedative effect
Phenytoin	Increased phenytoin metabolism[b]
Ranitidine, cimetidine	Increased ethanol concentration
Sedative-hypnotics	Additive sedative effect
Thiram derivatives	Disulfiram-like effect
Vasodilators	Potentiates vasodilator effect
Warfarin	Increased warfarin metabolism[b]

[a] Those containing a *N*-methylthiotetrazole side chain.

[b] Effect possibly associated with chronic alcohol consumption.

to acetaminophen hepatotoxicity, likely due to depletion of glutathione (see Chap. 34).[213] However, in a retrospective study, heavy drinkers did not develop more severe hepatotoxicity following APAP overdose than nondrinkers.[130]

PATHOPHYSIOLOGY

Despite ethanol's long history of use and study, no specific receptor for ethanol has been identified, and the mechanism of action leading to intoxication remains the subject of debate.[163] Ethanol has been shown to affect a large number of membrane proteins that participate in signaling pathways, eg, neurotransmitter receptors, enzymes, and ion channels,[148,205] and there is extensive evidence that ethanol interacts with a variety of neurotransmitters.[50,201,202] The major actions of ethanol involve enhancing the inhibitory effects of gamma-aminobutyric acid (GABA) at GABA$_A$ receptors and blockade of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate, an excitatory amino acid (EAA) receptor.[37,109,110,205] Animal studies indicate that the acute effects

of ethanol result from competitive inhibition of glycine's binding to the NMDA receptor and disruption of glutamatergic neurotransmission by inhibiting the response of the NMDA receptor. Persistent glycine antagonism and attenuation of glutamatergic neurotransmission by chronic ethanol exposure results in tolerance to ethanol by enhancing EAA neurotransmission and NMDA receptor upregulation.[89,147,197,201,202] The latter appears to involve selective increases in NMDA R2B subunit expression and other molecular changes in specific brain loci.[4] The abrupt withdrawal of ethanol thus produces a hyperexcitable state that leads to the ethanol withdrawal syndrome and excitotoxic neuronal death.[17,37,202] GABA mediated inhibition, which normally acts to limit excitation is eliminated in the absence of ethanol during ethanol withdrawal syndrome, and further intensifies this excitation (see glutamate and NMDA receptors sections of Chaps. 13 and 78). In addition, NMDA receptors function to inhibit the release of dopamine in the nucleus accumbens and mesolimbic structures, which modulates the reinforcing action of addictive agents like ethanol.[20,21,187] By inhibiting NMDA receptor activity, ethanol could increase dopamine release from the nucleus accumbens and ventral tegmental area and could thus create dependence.[20] Chronic ethanol administration also results in tolerance, dependence, and an ethanol withdrawal syndrome, mediated, in part, by desensitization and/or downregulation of GABA$_A$ receptors.[191]

Chronic alcoholism has multiorgan system effects (Table 77–4), and the relationships between ethanol use, nutrition, and liver disease have been reviewed elsewhere.[122] In addition to the harmful effects of ethanol itself (eg, impairment of protein synthesis), its metabolite, acetaldehyde, is inherently toxic to biologic systems.[117,124,204,224] Acetaldehyde directly impairs cardiac contractile function, disrupts cardiac excitation-contractile coupling, inhibits myocardial protein synthesis, interferes with phosphorylation, causes structural and functional alterations in mitochondria and hepatocytes, and inactivates acetylcoenzyme A. Acetaldehyde can also react with intracellular proteins to generate adducts. Acetaldehyde adducts are believed to play an important role in the early phase of alcoholic liver disease, and in advanced liver disease they contribute to the development of hepatic fibrosis.

Ethanol metabolism through the hepatic CYP2E1 pathway generates highly reactive oxygen radicals, including the hydroxyethyl radical (HER) molecule.[38] Elevated oxygen radical concentrations generate a state of oxidative stress, which leads to cell damage. Oxygen radicals can also initiate lipid peroxidation resulting in reactive molecules such as malondialdehyde (MDA) and 4-hydroxy-2-nonenal (HNE). These reactive molecules react with proteins or acetaldehyde to form adducts, which contribute to the development of alcoholic liver injury.

Oxidation of ethanol generates an excess of reducing potential in the cytosol in the form of NADH with the ratio of NADH to NAD$^+$ being dramatically increased. This ratio, also known as the redox potential, determines the ability of the cell to carry on various oxidative processes. The unfavorable change in redox potential due to ethanol metabolism contributes to the development of metabolic disorders (eg, impaired gluconeogenesis, alterations in fatty acid metabolism, fatty liver, hyperlipidemia, hypoglycemia, metabolic acidosis with elevated lactate concentration, hyperuricemia (gouty attacks), increased collagen and scar tissue formation associated with alcoholism, and a clinical syndrome of alcoholic ketoacidosis.

Recent studies in alcoholic liver disease have focused on Kupffer cell activation by endotoxin that is released by intestinal bacteria. When Kupffer cells are activated they produce regulatory nuclear factor kappa β (NFκβ) and generate significant amounts of superoxide radicals (O$_2^-$) and cytokines (tumor necrosis factor and interleukin-8), which has been shown to be an essential factor in the injury to hepatocytes associated with alcoholic liver disease.[134,212]

TABLE 77–4. Systemic Effects Associated With Alcoholism

Cardiovascular	Esophagus	Genitourinary	Korsakoff psychosis
Cardiomyopathy	Boerhaave syndrome	Hypogonadism	Wernicke encephalopathy
"Holiday heart" (dysrhythmias)	Cancer of the esophagus	Impotence	Marchiafava-Bignami disease
"Wet" beriberi (thiamine deficiency)	Diffuse esophageal spasm	Infertility	Myopathy
	Esophagitis	**Hematologic**	Polyneuropathy
Endocrine and metabolic	Mallory-Weiss tear	Coagulopathy	Pellagra
Hypoglycemia	Stomach and duodenum	Folate, B_{12}, iron deficiency anemias	**Ophthalmic**
Hypophosphatemia	Gastritis	Hemolysis (Zieve syndrome, stomatocytosis, spur cell anemia)	Tobacco–ethanol amblyopia
Hypokalemia	Chronic hypertrophic gastritis	Leukopenia	**Psychiatric**
Hypomagnesemia	Diarrhea	Thrombocytopenia	Animated behavior
Hypothermia	Hematemesis	**Neurologic**	Loss of self-restraint
Hypertriglyceridemia	Malabsorption	Alcohol amnestic syndrome	Depression
Hyperuricemia	Peptic ulcer	Alcoholic hallucinosis	Mania
Metabolic acidosis	Liver	Alcohol withdrawl	Suicide
Malnutrition	Steatosis	Central pontine myelinolysis	**Respiratory**
Gastrointestinal	Hepatitis	Cerebral atrophy (dementia)	Atelectasis
Mouth	Cirrhosis	Cerebellar degeneration	Pneumonia
Cancer of the mouth, pharynx, larynx	Pancreas	CVA (SAH, infarction)	Respiratory depression
Cheilosis	Pancreatitis (acute or chronic)	Intoxication	Respiratory acidosis
Nutritional stomatitis			

ACUTE CLINICAL FEATURES

Ethanol is a selective central nervous system (CNS) depressant at low doses and a general depressant at high doses. Initially it depresses those areas of the brain involved with highly integrated functions. Cortical release leads to animated behavior and the loss of restraint. This paradoxical CNS stimulation is due to disinhibition. In cases of mild intoxication the signs of ethanol inebriation are quite variable. The patient may be energized and loquacious, expansive, emotionally labile, increasingly gregarious or may appear to have lost self-control, exhibit antisocial behavior, and be ill tempered. As the degree of intoxication increases, there is successive inhibition and impairment of neuronal activity.[142] The patient may become irritable, abusive, aggressive, violent, dysarthric, confused, disoriented, or lethargic. With severe intoxication, there is loss of airway protective reflexes, coma, and increasing risk of death from respiratory depression. An ethanol naïve adult with a blood ethanol concentration of greater than 250 mg/dL (54 mmol/L) is usually stuporous.[1]

The acute effects of ethanol ingestion also depend on the habituation of the drinker. This is mainly due to the development of tolerance, which has both a metabolic (pharmacokinetic) and a functional (pharmacodynamic) component.[191] Metabolic tolerance to ethanol is based on enhanced elimination by the ADH enzyme and CYP2E1 system. Functional tolerance (resistance to the effects of ethanol at the cellular level) is a more important determinant of habituation and may be mediated through alterations in $GABA_A$ and NMDA receptors as well as serotonergic and adrenergic neurons.[89,105,106,147,190,197,201,202] Acute ethanol tolerance may be demonstrated by the Mellanby effect, which involves the comparison of physiologic responses or behavioral effects at the same blood ethanol concentration on the ascending and descending limbs of the blood ethanol curve. Impairment is greater at a given blood ethanol concentration when it is increasing than for the same blood ethanol concentration when it is falling.[152,207] Although individuals who are acutely intoxicated move through a progressive sequence of events, the association of a particular aspect of intoxication with a specific blood ethanol concentration is not usually possible without knowing the pattern of ethanol use of the patient. Acute ethanol intoxication occurs in habitual drinkers when they raise their ethanol concentration an equivalent amount above baseline, and specific clinical manifestations of inebriation typically occur with significantly higher blood ethanol concentration than nontolerant individuals. Regardless, the absolute change above baseline may be important.

A patient may present with obvious signs and symptoms consistent with ethanol intoxication that include flushed facies, diaphoresis, tachycardia, hypotension, hypothermia, hypoventilation, mydriasis, nystagmus, vomiting, dysarthria, muscular incoordination, ataxia, altered consciousness, and coma. However, an ethanol-intoxicated patient may present to the ED with a broad range of diagnostic possibilities and should prompt a careful evaluation for a variety of covert clinical and metabolic disorders. A meticulous and systematic approach to the evaluation and management of an inebriated patient will help avoid the potential pitfalls in such a situation.[61] The presence or absence of an odor of ethanol on the breath is an unreliable means of ascertaining whether a person is intoxicated or whether ethanol was recently consumed.[146] Diplopia, visual disturbances, and nystagmus may be evident, which may be due to the toxic effects of ethanol or may represent Wernicke encephalopathy. Hypothermia may be exacerbated by

environmental exposure, from malnutrition and loss of carbohydrate or energy substrate, and ethanol-induced vasodilation. Ethanol intoxication can impair cardiac output in patients with preexisting cardiac disease,[70] and dysrhythmias such as atrial fibrillation and nonsustained ventricular tachycardia as well as atrioventricular block are documented in binge drinkers.[45,71,72] The association between ethanol use and cardiac dysrhythmias, particularly supraventricular tachydysrhythmias in apparently healthy people, is called *holiday heart syndrome*.[107,113,137] The syndrome was first described in people with heavy ethanol consumption, who typically presented on weekends or after holidays, and it may also occur in patients who binge but who usually drink little ethanol. The most common dysrhythmia is atrial fibrillation, which usually reverts to normal sinus rhythm within 24 hours. Although the syndrome may recur, the clinical course is benign in patients without anatomic cardiac pathology and specific antidysrhythmic therapy is usually not warranted.[59,72] Acute heavy ethanol drinking may precipitate silent myocardial ischemia in patients with stable angina pectoris.[174] Variant angina is reported to occur in patients following ethanol ingestion at a time when the blood ethanol concentration has decreased almost to zero.[53,99,132,140,157,176,194] Ethanol induced seizures are reported in adults, but are more frequent in children with ethanol-induced hypoglycemia.[31,88] Patients presenting with acute ethanol intoxication commonly have decreased serum ionized magnesium concentrations while their total serum magnesium concentration is within the normal range.[221] However, total body magnesium may be depleted due to poor dietary intake, decreased GI absorption secondary to ethanol, and renal wasting due to the ethanol-related diuresis.[54,98,171,182,189]

DIAGNOSTIC TESTS

There are numerous qualitative and quantitative assays for ethanol in biological fluids and exhaled breath. Immunoassay or gas chromatography is commonly used for determination of ethanol in liquid specimens in most hospitals. Hospital laboratory analysis of blood samples for ethanol content is usually based on serum (liquid portion of whole blood after the cellular components and clotting factors have been removed), or rarely plasma (acellular liquid portion of whole blood). In contrast, forensic casework expresses ethanol concentration in whole blood. Serum contains slightly more water than does plasma and whole blood and will have a slightly higher ethanol concentration. In a study of ED patients the serum-to-whole blood ethanol concentration ratios range from 0.88 to 1.59 with the median ratio being 1.15.[168] As a result, a whole blood ethanol concentration of 100 mg/dL (22 mmol/L) might be equivalent to a serum ethanol concentration that ranges between 88 and 159 mg/dL (19–35 mmol/L). In patients receiving intravenous ethanol the mean ratio of plasma to whole blood ethanol concentration is 1.10, range 1.03:1 to 1.24:1.[96]

A fraction of ethanol is excreted by the lungs. Breath ethanol concentration measurement as a surrogate for blood ethanol concentration is popular with emergency departments and law-enforcement agencies because of the noninvasive nature and the ability to provide an immediate result. The use of breath to estimate blood ethanol concentration is based on respiratory physiology concepts and assumptions from the 1940s and 1950s, which are derived from initial exhaled air volume from the lungs and comes from the conducting airways and has little "alveolar air." Further exhalation results in air exhalation from the alveoli containing gas in equilibrium with pulmonary capillary blood. Extrapolation of data from low solubility gases (ie, nitrogen), and end tidal ethanol concentration is independent of exhaled volume after exhalation beyond anatomic dead space volume. Aveolar ethanol concentration is in thermodynamic equilibrium with the arterial blood

ethanol concentration. Ethanol (gas phase) concentration remains constant throughout the respiratory tract; this relationship could be described by a partition coefficient—ratio between breath and blood ethanol concentration.[82] The mean breath-to-blood ratio is reported as 1:2300 during the postabosorptive phase of ethanol kinetics, and a ratio of 1:2100 is used in forensic casework, which is the programmed ratio used in breath analyzers.[153] There are significant individual and interindividual variations (±20%) in the breath-to-blood ethanol ratio.[91,95] Log-transformation of the normal breath-to-blood values has been used to calculate means and confidence intervals.[73,114] However, ethanol breath tests should be interpreted with caution. Breath ethanol concentration may not reflect the concentration of ethanol in blood. Confounding variables include recent use of ethanol containing products, belching or vomiting of gastric ethanol contents, breath holding or hyperventilation immediately prior to providing a breath sample, inadequate exhalation, prolonged expiration, obstructive pulmonary disease, mouth ethanol retained in the bridges or periodontal spaces, and poor technique.[5,92,93,118,199] Multidose inhalers (eg, Tornalate [bitolterol mesylate with 38% ethanol], Bronkometer [isoetharine mesylate with 30% ethanol], Primatene Mist [adrenaline with 34% ethanol], and salbutamol) and mouth washes (eg, Listerine [26.9% ethanol], Scope [18.9% ethanol], and Lavoris [6.0% ethanol]) may contain significant concentration of ethanol, and may cause elevations of breath ethanol above the legal criteria for intoxication.[13,69,127,141] However, these effects are transient and may be prevented by a 10- to 15-minute interval between the use of multidose inhaler or mouth wash and breath ethanol testing.[69,127,141]

Ethanol saliva testing is a promising alternative to breath ethanol analysis in the rapid assessment of blood ethanol concentrations in patients regardless of their mental status.[35,185] Fatty acid ethyl esters (FAEEs) may be a highly sensitive test for recent ethanol use.[15,43,186] Because FAEEs remain in the system for at least 24 hours they may have a role as a marker of recent ethanol use even after ethanol is completely metabolized. However, their availability is limited and their place in patient management is undefined.

Ethyl glucuronide and ethyl sulfate are nonoxidative direct ethanol metabolites and are excreted for a considerably longer time than ethanol.[18,32,77,175,179] Testing for these metabolites in urine has gained popularity as a sensitive method to detect recent ethanol intake and is favored over tests such as gamma glutamyl transferase (GGT) or carbohydrate-deficient transferrin (CDT) particularly by agencies concerned with monitoring an individual for recent ethanol consumption or relapse, confirming abstinence in treatment programs, workplaces, and schools, and providing legal proof of drinking.[76,166] The presence of ethyl glucuronide and ethyl sulfate provides a strong indication of recent drinking even when ethanol is no longer detectable.[77] However, caution should be applied in the interpretation of ethyl glucuronide testing results. Ethyl glucuronide may be sensitive to degradation or may be synthesized by bacteria (eg, *E coli*)-infected urine resulting in either a false-negative or false-positive test particularly when specimens have been improperly stored; ethyl sulfate degradation or formation has not been detected under similar conditions.[79,81] Detection windows for ethyl glucuronide and ethyl sulfate after drinking may be limited and dependent on the amount of ethanol consumed. For example, these metabolites are detectable in urine for less than or equal to 24 hours after intake of 0.25 g/kg ethanol and less than or equal to 48 hours after intake of 0.50 g/kg ethanol.[32,75,77,85,86,219] Depending on the analytical cut-off limit unintentional exposure to ethanol-based mouthwash and hand sanitizers may result in a urine positive for ethyl glucuronide or ethyl sulfate.[29,173] There appears to be a marked interindividual variation in the concentration-time profiles for both metabolites. In situations where the times for ethanol intake and urine

specimen collection between drinking and sampling are uncertain, it would not be possible to link a single ethyl glucuronide and sulfate result to a specific ethanol dose taken at a specific time.[80] A common cut-off or reporting limit has yet to be determined for urinary ethyl glucuronide and ethyl sulfate when used as ethanol biomarkers.

Blood tests that should be considered for patients with ethanol intoxication include a rapid reagent glucose test, CBC, electrolytes, BUN, creatinine, ketones, acetone, lipase, liver enzymes, INR, ammonia, calcium, and magnesium. Patients with an anion gap metabolic acidosis should have urine ketones and a serum lactate concentration determined (see Chaps. 16 and 107). High serum acetone concentrations may be indicative of isopropanol intoxication whereas elevated serum or urinary ketones may be indicative of alcoholic ketoacidosis, starvation ketosis or diabetic ketoacidosis. Because the laboratory nitroprusside reaction detects only ketones (acetoacetate and acetone) and not β-hydroxybutyrate, the assay for urinary ketones in patients with alcoholic ketoacidosis may be only mildly positive.[60-64]

A blood ethanol concentration should be included in the initial laboratory studies.[87] If the blood ethanol concentration is inconsistent with the patient's clinical condition, prompt reevaluation of the patient is indicated to elucidate the etiology of the altered mental status including toxic-metabolic (eg, hypoglycemia, electrolyte or acid-base disorder, toxic alcohols, therapeutic or illicit drug overdose, ethanol withdrawal, hepatic encephalopathy, and Wernicke-Korsakoff syndrome), trauma-related, neurologic (eg, post-ictal condition), and infectious etiologies. Comatose patients with levels below 300 mg/dL (65 mmol/L) and those with values in excess of 300 mg/dL (65 mmol/L) who fail to improve clinically during a limited period of close observation should have a head CT scan, followed by a lumbar puncture if clinically indicated. Because chronically ethanol tolerant patients are prone to trauma and coagulopathies, both of which can cause intracerebral bleeding, the threshold for head CT scanning should be low.

MANAGEMENT OF THE INTOXICATED PATIENT

Ethanol is rapidly absorbed from the gastrointestinal tract. In situations where recent ingestion (within 1 hour of presentation), delayed absorption, and concomitant ingestions are under consideration gastrointestinal decontamination may be considered. Occasionally, the extremely intoxicated or comatose patient may have severe respiratory depression necessitating endotracheal intubation and ventilatory support.

Any patient with an acute altered mental status mandates immediate investigation and treatment of reversible etiologies such as hypoxia, hypoglycemia, and opioid intoxication. In addition, Wernicke encephalopathy should be considered. Supplemental oxygen should be administered if the patient is hypoxic; intravenous dextrose (0.5–1.0 g/kg), thiamine 100 mg, and naloxone should be administered as clinically indicated. Abnormal vital signs should be addressed and stabilized. Patients who are combative and violent should be both physically and then chemically (eg, benzodiazepine) restrained. Caution should be taken because of additive effects of ethanol and benzodiazepines on respiratory depression. Attempts by those who are clinically intoxicated to sign out against medical advice or attempt to leave should also be prevented (see Chap. 140). The patient's fluid and electrolyte status should be assessed and abnormalities corrected. Multivitamins with folate, thiamine, and magnesium may be added to the maintenance IV solution.

A variety of therapies have been advocated either to reverse the intoxicating effects of ethanol or to enhance its elimination. Those proven to be either ineffective or unreliable include coffee, caffeine,

naloxone, flumazenil, and rapid intravenous saline loading.[55,121,154,155,172] Hemodialysis is an effective means of enhancing the systemic elimination of ethanol because of the small volume of distribution and low molecular weight of ethanol. In severe ethanol poisoning resulting in respiratory failure or coma, hemodialysis may be an adjunct treatment to supportive care. However, the risk–benefit of hemodialysis should be considered.

INDICATIONS FOR HOSPITALIZATION

A patient with uncomplicated ethanol intoxication can be safely discharged after a careful observation often with social service or psychiatric counseling. An individual should not be discharged while still clinically intoxicated. However, consideration may be given to a situation where the intoxicated patient is discharged to a protected environment under the supervision of a responsible nonintoxicated adult. In this case the clinical assessment of the patient is more important than the blood ethanol concentration. Indications for hospital admission include persistently abnormal vital signs, persistently abnormal mental status with or without an obvious cause, a mixed overdose with other concerning xenobiotics, concomitant serious trauma, consequential ethanol withdrawal, and those with an associated serious disease process such as pancreatitis or gastrointestinal hemorrhage.

Chronic alcoholism may result in an organic brain syndrome that is irreversible. The patient's socioeconomic condition and lack of ability to comply with a treatment plan are critical in making a disposition. Alcoholics requesting ethanol detoxification can be admitted for rehabilitation. Inpatient detoxification programs differ substantially from outpatient programs but their most consequential advantages may be that they enforce abstinence, provide more support and structure, and separate the patient from the social surroundings associated with drinking.[151,206] For patients who are not admitted, a referral should be offered to Alcoholics Anonymous or another suitable ethanol rehabilitation program.

ETHANOL-INDUCED HYPOGLYCEMIA

Hypoglycemia associated with ethanol consumption is believed to occur when ethanol metabolism increases the cellular redox ratio. The higher redox state favors the conversion of pyruvate to lactate, diverting pyruvate from gluconeogenesis (Fig. 77–2). Hypoglycemia typically occurs when there is a reduced caloric intake and only after the hepatic glycogen stores are depleted, as in an overnight fast. The mechanism by which hypoglycemia is associated with ethanol consumption in the well-nourished individual is less well defined.

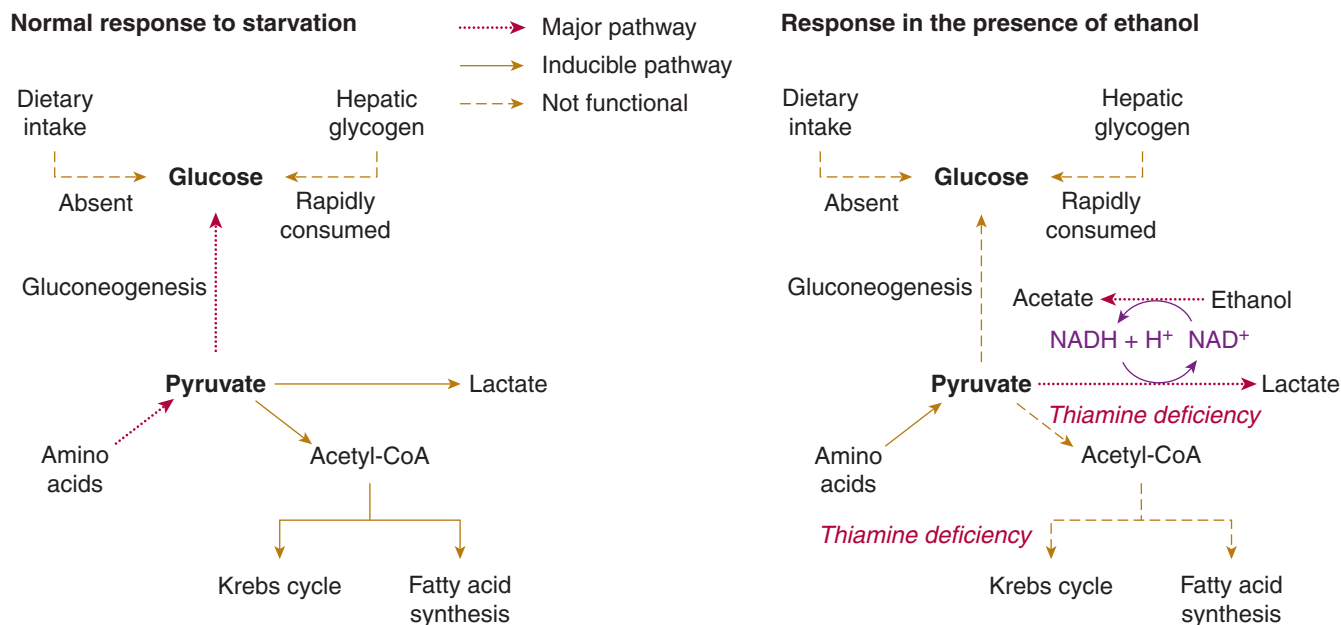
Although the conditions that cause hypoglycemia in adults may also be present in infants and children, children with their smaller livers have less glycogen stores than adults and are more likely to develop hypoglycemia. Hypoglycemia associated with ethanol consumption usually occurs in malnourished chronic alcoholics and in children (see Chap. 48). It may also occur in binge drinkers who do not eat. A 22% incidence of hypoglycemia was reported in one retrospective study of children with documented ethanol ingestion.[119] In another retrospective study of children and adolescents there was a 3.4% incidence of hypoglycemia (serum glucose concentration less than 67 mg/dL [3.7 mmol/L]).[49] Ethanol-intoxicated children under 5 years of age have an increased risk of developing hypoglycemia and it is the most common reported clinical abnormality related to ethanol ingestion in this age group.[115,116]


FIGURE 77–2. Central role of pyruvate in ethanol-induced hypoglycemia. Thiamine deficiency interrupts metabolism at the indicated steps.

■ CLINICAL FEATURES

Patients with ethanol associated hypoglycemia usually present with an altered consciousness 2 to 10 hours following ethanol ingestion. Other physical findings include hypothermia and tachypnea. Laboratory findings, in addition to hypoglycemia, usually include a positive blood ethanol concentration, ketonuria without glucosuria, and mild acidosis.

■ MANAGEMENT

Acute treatment of ethanol-induced hypoglycemia is similar to other causes of hypoglycemia (see Chap. 48), and should prompt a systematic evaluation for coexisting clinical and metabolic disorders. Hospital admission is indicated as this represents serious metabolic impairment.

ALCOHOLIC KETOACIDOSIS (AKA)

The development of AKA requires a combination of physical and physiologic events to occur. The normal response to starvation and depletion of hepatic glycogen stores is for amino acids to be converted to pyruvate. Pyruvate serves as a substrate for gluconeogenesis by being converted to acetyl-CoA, which enters the Krebs cycle, or undergoes conversion to fatty acids. As described earlier, ethanol metabolism generates NADH resulting in an excess of reducing potential. This high redox state favors the conversion of pyruvate to lactate, diverting pyruvate from being a substrate for gluconeogenesis. To compensate for the lack of normal metabolic substrates, the body mobilizes fat from adipose tissue and increases fatty acid metabolism as an alternative source of energy. This response is mediated by a decrease in insulin and an increased secretion of glucagon, catecholamines, growth hormone, and cortisol. Fatty acid metabolism results in the formation of acetyl-CoA and it combines with the excess acetate that is generated from ethanol metabolism to form acetoacetate

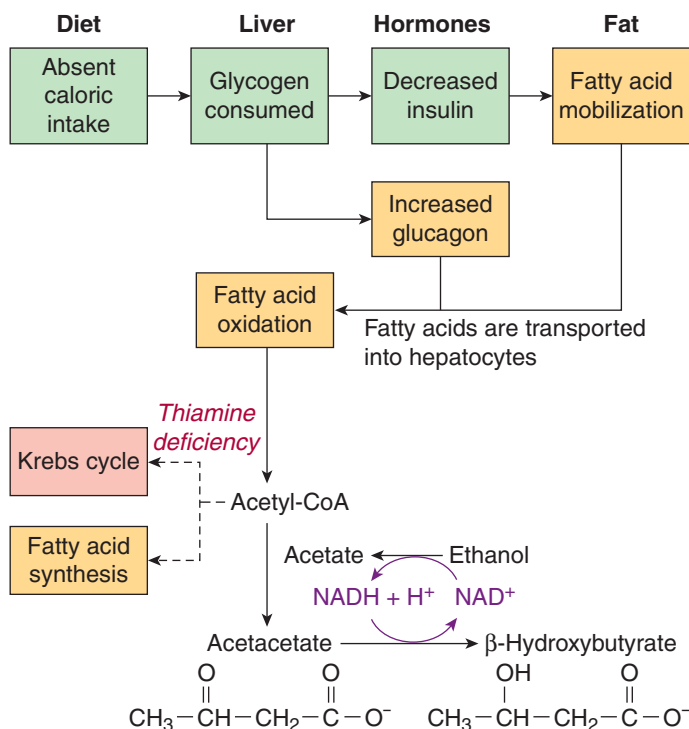
(Fig. 77–3).[84] Most of the acetoacetate is reduced to β-hydroxybutyrate due to the excess reducing potential or high redox state of the cell. Volume depletion interferes with the renal elimination of acetoacetate and β-hydroxybutyrate and contributes to the acidosis. Metabolic acidosis with elevated lactate concentration due to hypoperfusion or infection may coexist with the underlying ketoacidosis.


FIGURE 77–3. Mechanism of alcoholic ketoacidosis. Thiamine deficiency interrupts metabolism at the indicated steps.

■ CLINICAL FEATURES

Patients with AKA are typically chronic ethanol users, presenting after a few days of binge drinking, who become acutely starved because of cessation in oral intake due to binging itself or to nausea, vomiting, abdominal pain from gastritis, hepatitis, pancreatitis or a concurrent acute illness.[61,62,64] The patient may appear acutely ill with salt and water depletion, tachypnea, tachycardia, and hypotension. Underlying medical conditions such as sepsis, meningitis, pyelonephritis, or pneumonia may be present, and ethanol withdrawal may develop, all of which should be considered and systematically excluded. The diagnosis of AKA is a diagnosis of exclusion.

The blood ethanol concentration is usually low or undetectable because ethanol intake ceased substantially earlier in the clinical course. The hallmarks of AKA include an elevated anion gap metabolic acidosis with an elevated serum lactate concentration insufficient to account for the gap. However, some patients will have a normal arterial pH or be even alkalemic because of an associated primary metabolic alkalosis due to vomiting and a compensatory respiratory alkalosis (see Chap. 16).[60] When patients with AKA are compared with patients with diabetic ketoacidosis (DKA), those with AKA tended to have a higher blood pH, lower serum potassium and chloride concentrations, and a higher serum bicarbonate concentration.[60,63] The etiology of anion gaps in patients with AKA and DKA is very similar, with β-hydroxybutyrate being the primary anion contributor and lactate having a less consequential role.[63]

The nitroprusside test used to detect the presence of ketones in serum and urine may be negative or mildly positive in patients with AKA because the nitroprusside reaction detects only molecules containing ketone moieties. This includes acetone and acetoacetate but not β-hydroxybutyrate. Reliance on the nitroprusside test alone may underestimate the severity of ketosis. Specific assays for β-hydroxybutyrate may be performed in some hospital laboratories, and may be available as point of care testing at bedside. The blood glucose concentration may be low or mildly elevated. It is postulated that ethanol-induced hypoglycemia occurs first, causing increased levels of cortisol, growth hormone, glucagon, and epinephrine; this may correct the hypoglycemia and mobilize fatty acids, which are converted to ketones.[36] Therefore, alcoholic hypoglycemia and alcoholic ketoacidosis may be sequential events of the same process depending on the point in this process at which the patient is evaluated.

■ MANAGEMENT

Treatment should begin with adequate crystalloid fluid replacement, dextrose, and thiamine. Supplemental multivitamins, potassium, and magnesium should be instituted on an individual basis. The administration of dextrose will stimulate the release of insulin, decrease the release of glucagon, and reduce the oxidation of fatty acids. Exogenous glucose also facilitates the synthesis of adenosine triphosphate (ATP), which reverses the pyruvate-to-lactate and $NADH/NAD^+$ ratios. The provision of thiamine facilitates pyruvate entry into the Krebs cycle, thus increasing ATP production. Volume replacement restores glomerular flow and improves excretion of ketones and organic acids. Administration of either insulin or sodium bicarbonate in the management of AKA is usually unnecessary.[64]

During the recovery phase of AKA, β-hydroxybutyrate is converted to acetoacetate. As this process occurs, the nitroprusside test may become more positive because of higher concentrations of acetoacetate resulting in a transient hyperketonemia that actually represents improvement of the metabolic status.

Patients presenting with AKA are manifesting serious metabolic impairment and require hospital admission. They may succumb to other precipitating or coexisting medical or surgical disorders[61] such as occult trauma, pancreatitis, gastrointestinal hemorrhage or hepatorenal dysfunction, and infections. However, mortality is rare from ethanol-induced ketoacidosis.

ALCOHOLISM

Alcoholism is traditionally defined as a chronic, progressive disease characterized by tolerance and physical dependence to ethanol and pathologic organ changes. Alcoholism is a multifactorial, genetically influenced disorder.[30,83,151,162,170,181,196]

Concern for early detection and intervention led to attempts to create reliable diagnostic screening systems. The Brief Michigan Alcoholism Screening Test (MAST)[165] and the CAGE questions[133,211] represent two such tools (Tables 77–5 and 77–6). The presence of physical tolerance and/or dependence is not essential for a diagnosis of alcoholism.

TABLE 77–5. The Brief Michigan Alcoholism Screening Test

Question	Circle Correct Answer		Points
1. Do you feel you are a normal drinker?	Yes	No	N2
2. Do friends or relatives think you are a normal drinker?	Yes	No	N2
3. Have you ever attended a meeting of Alcoholics Anonymous?	Yes	No	Y5
4. Have you ever lost friends or girlfriends/boyfriends because of drinking?	Yes	No	Y2
5. Have you ever gotten into trouble at work because of drinking?	Yes	No	Y2
6. Have you ever neglected your obligations, your family, or your work for 2 or more days in a row because you were drinking?	Yes	No	Y2
7. Have you ever had delirium tremens (DTs) or severe shaking, or heard voices, or seen things that weren't there after heavy drinking?	Yes	No	Y2
8. Have you ever gone to anyone for help about your drinking?	Yes	No	Y5
9. Have you ever been in a hospital because of drinking?	Yes	No	Y5
10. Have you ever been arrested for drunk driving after drinking?	Yes	No	Y2
Score 6 = Probable diagnosis of alcoholism.

TABLE 77–6. The CAGE Questions

1. Have you ever felt you should **c**ut down on your drinking?
2. Have people **a**nnoyed you by criticizing your drinking?
3. Have you ever felt bad or **g**uilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (**e**ye-opener)?

Two or more affirmatives = probable diagnosis of alcoholism.

Reprinted, with permission, from West LJ, Maxwell DS, Noble EP, Soloman DH. Alcoholism. *Ann Intern Med* 1984;100:412-420.

Emphasis instead is placed on the social and behavioral concomitants of heavy drinking.[145] In the ED setting, questions concerning the patient's ability to function physically and psychologically are just as appropriate as quantifying the amount of ethanol consumed per day.

Alcoholism is commonly associated with affective disorders, especially depression.[143,167] There is a higher rate of alcoholism among patients with bipolar disorder than in the general population and there may be a genetic relationship between alcoholism and depression.[103,156,217,218] Ethanol affects mood, judgment, and self-control, creates a clinical condition conducive to violence directed at self and others, and is an important risk factor for suicide. Although many people drink in an attempt to ameliorate their depression, all available evidence suggests that alcoholism adversely affects mood and cognitive ability. Research indicates alcoholism may be partly under genetic control.[10,103,108,125] Chromosomal linkage analysis has implicated chromosomes 9, 15, and 16 in the genetic predisposition to alcoholism.[14,39,128] Polymorphism in ADH and ALDH genes appears to be a marker for risk of alcoholism.[27,30,48,196,198] The ADH1B*2, ADH1C*1, and ALDH2*2 alleles have been associated with reduced risk of alcoholism. Genetic epidemiologic studies strongly correlate Asians with homozygous ADH1B*2 and ALDH2*2 alleles with reduced ethanol consumption and incidence of alcoholism.[30,162,215] The incidence of both homozygous ADH1B*1 and ALDH2*1 alleles was significantly higher in patients with ethanol dependence and in patients with alcoholic liver disease.

Various strategies are employed to treat alcoholism including psychosocial interventions, pharmacological interventions, or both. Pharmacologic treatment of ethanol dependence that is of potential collateral toxicologic consequence include the opioid antagonists naltrexone and nalmefene and, disulfiram, serotonergic agents, and topiramate.[65,90]

Although it is a serious disease with important health and economic consequences, alcoholism remains underdiagnosed and remains a treatment challenge.[131,206,220]

SUMMARY

Ethanol is widely used in our society and ethanol use problems impose a staggering personal, social, and economic burden on our society. Most people are responsible drinkers of ethanol. However, some people drink ethanol in ways that are detrimental to themselves or others. Domestic violence, child abuse, fires, falls, rape, and other crimes such as robbery and assault, and medical consequences such as cancer, liver disease, and heart disease have all been associated with ethanol misuse. One interesting area in ethanol research has been the finding that genetics may be an important determinant in vulnerability to ethanol dependence. This finding suggests the biological basis of alcoholism.

Acute ethanol intoxication and chronic alcoholism are among the most common and complex toxicologic and societal problems. These patients may present with a diversity of clinical problems that challenge the clinician to be meticulous and systematic in their evaluation and management of these patients.

ANTIDOTES IN DEPTH (A25)

THIAMINE HYDROCHLORIDE

Robert S. Hoffman
Thiamine (vitamin B$_1$) is a water-soluble vitamin found in organ meats, yeast, eggs, and green leafy vegetables that is essential in the creation and utilization of cellular energy. While there is no toxicity associated with thiamine excess, thiamine deficiency is responsible for "wet" beriberi (congestive heart failure) and "dry" beriberi (Wernicke encephalopathy and the Wernicke-Korsakoff syndrome). Patients at risk include those with poor oral intake (human immunodeficiency virus [HIV], chemotherapy, fad diets, hyperemesis gravidarum) and those with impaired absorption (alcoholism). Typical signs of Wernicke encephalopathy include ataxia, altered mental status, and ophthalmoplegia. Although administration of 100 mg of parenteral thiamine hydrochloride will protect against thiamine deficiency for more than 1 week, patients with clinical deficiencies may require larger doses.

BIOCHEMISTRY

As a coenzyme in the pyruvate dehydrogenase complex, thiamine diphosphate, the active form of thiamine, accelerates the conversion of pyruvate to acetylcoenzyme A (acetyl-CoA). This reaction occurs at the C2 atom of thiamine, which is located between the nitrogen and sulfur atoms on the thiazolium ring.[25] In the protein-rich environment of the enzyme complex, this C2 atom is deprotonated to form a carbanion that rapidly attaches to the carbonyl group of pyruvate, thereby stabilizing it for decarboxylation.[32] In a series of subsequent reactions, the hydroxyethyl group that remains bound to thiamine diphosphate is transferred to lipoamide, where an acetyl group is later broken off and attached to coenzyme A (CoA). This overall process links anaerobic glycolysis to the Krebs cycle, where subsequent aerobic metabolism produces the equivalent of 36 mol of adenosine triphosphate (ATP) from each mole of glucose (Fig. A25–1). When pyruvate cannot be converted to acetyl-CoA because of thiamine deficiency, for example, only 2 mol of ATP can be generated by anaerobic metabolism

from each mole of glucose. Thiamine is also required as a cofactor for α-ketoglutarate dehydrogenase, a second enzyme in the Krebs cycle, and for transketolase, an enzyme in the pentose phosphate pathway, in which nicotinamide adenine dinucleotide phosphate (NADPH) is formed for subsequent use in reductive biosynthesis. In addition, thiamine is important in maintaining normal neuronal conduction.[67,84]

Naturally occurring thiamine is a base composed of a substituted pyrimidine ring and a substituted thiazole ring connected by a methylene bridge. This connection between the two rings is weak, and the molecule is unstable in an alkaline milieu and in a high temperature environment. In addition, thiamine is highly water soluble, allowing it to leach out of foods following prolonged washing or cooking in water. However, thiamine, which is synthesized as a hydrochloride salt, is usually quite stable. Thiamine requirements are determined by total caloric intake and energy demand, with a minimum daily requirement of 0.5 mg/1000 calories.[67]

PHARMACOLOGY

Thiamine is well absorbed from the human gastrointestinal tract by a complex process.[38,58] At low concentrations, thiamine absorption occurs through a saturable mechanism that is most effective in the duodenum, with absorption occurring to a lesser degree in the large bowel and stomach.[38] As thiamine concentrations increase, however, the majority of absorption occurs through simple passive diffusion. Although synthesized analogs such as thiamine propyl disulfide, benfotiamine, and fursultiamine have enhanced bioavailability, their use remains largely experimental.[25,76] Chronic liver disease, folate deficiency, steatorrhea, and other forms of malabsorption all significantly decrease the absorption of thiamine. Recently, bariatric surgery was recognized to predispose patients to thiamine deficiency.[2,23,63] Malabsorption has even greater clinical relevance in alcoholics.[5,75] In experimental studies, when healthy volunteers were given small amounts of ethanol, a 50% reduction in gastrointestinal thiamine absorption resulted.[75]

Thiamine is eliminated from the body largely by renal clearance, which consists of a combination of glomerular filtration, flow-dependent tubular secretion, and saturable tubular reabsorption.[82] In an animal model, furosemide, acetazolamide, chlorothiazide, amiloride, mannitol, and salt loading all significantly increased urinary elimination of thiamine.[43] This nonspecific flow-dependent elimination was confirmed in humans given small doses of furosemide.[57] Additionally, both furosemide and digoxin appear to inhibit thiamine uptake into myocardial cells.[87]

THIAMINE DEFICIENCY

■ PATHOPHYSIOLOGY

Mice develop signs of encephalopathy 10 days after being rendered thiamine deficient. Immunohistochemistry in these animals demonstrates destruction of the blood–brain barrier with resultant extravasation of albumin.[28] Similarly, rats develop symptoms after 10 days of thiamine deficiency, and subsequently demonstrate deterioration of the blood–brain barrier with hemorrhage into the mammillary bodies and other areas of the brain.[12] This pattern is similar to findings described in humans with Wernicke encephalopathy.[54]
FIGURE A25–1. Thiamine links anaerobic glycolysis to the Krebs cycle. Anaerobic glycolysis only yields 2 mol of ATP as each mole of glucose is metabolized to 2 mol of pyruvate. To obtain the 36 additional ATP equivalents that can be derived as the Krebs cycle converts pyruvate to CO_2 and H_2O, pyruvate must first be combined with CoA to form acetyl-CoA and CO_2. This process is dependent on the thiamine-requiring enzyme system known as pyruvate dehydrogenase complex.

The exact cause of Wernicke encephalopathy is unclear. In human autopsy studies, brain samples from alcoholic patients with Wernicke-Korsakoff syndrome demonstrate decreased function of pyruvate dehydrogenase, α-ketoglutarate dehydrogenase, and transketolase when compared with controls.[11] However, a similar decrease in enzyme activity of neuronal tissue was demonstrated in alcoholics who died from hepatic coma without ever manifesting signs of Wernicke encephalopathy.[42] Likewise, the activity of thiamine-requiring Krebs cycle enzymes is reduced in thiamine-replete patients with neurodegenerative diseases.[8] Thus, while thiamine deficiency produces deficits in critical enzymes in humans, it is unclear whether these deficits are either necessary or sufficient to produce clinical disease.

Animal models offer insight into the mechanisms involved in developing thiamine-deficient neurologic injury. While the exact chain of events leading to these structural abnormalities is unclear, several models demonstrate key portions of the pathway. Thiamine deficiency in rats produces 200% to 640% increases in concentrations of glutamate,[41] which presumably results from blockade of α-ketoglutarate dehydrogenase. Excess α-ketoglutarate is shunted away from the Krebs cycle to form glutamate. Rats subsequently develop increases in lactate in vulnerable regions of the brain marked by the induction of the protooncogene c-fos. Both the histochemical lesions and the gene induction can be blocked

by the administration of the calcium channel blocker nicardipine.[46] This suggests a strong role for excitatory amino acid–induced alterations in calcium transport in the genesis of thiamine-deficient encephalopathy. In other animal models of thiamine deficiency, neuronal tissues are also directly injured by oxidative stress and lipid peroxidation.[13] Additional investigations demonstrate roles for triggered mast cell degranulation,[22] histamine,[40] and nitric oxide[35] in the generation of neuronal injury. The final common pathway is localized cerebral edema, which may result from altered expression of aquaporin.[17]

■ CLINICAL MANIFESTATIONS

When thiamine is completely removed from the human diet, clinical manifestations of thiamine deficiency typically develop within 2 to 3 weeks, although tachycardia, the first sign of deficiency, may occur as early as 9 days after cessation of thiamine intake.[84] The clinical symptoms of thiamine deficiency present as two distinct patterns: "wet" beriberi or cardiovascular disease, and "dry" beriberi, the neurologic disease known as Wernicke-Korsakoff syndrome. Although some patients display symptoms consistent with both disorders, usually either the cardiovascular or the neurologic manifestations predominate. A genetic variant of transketolase activity, combined with low physical activity and low-carbohydrate diet, may predispose to neurologic symptoms, whereas high-carbohydrate diets and increased physical activity lead to cardiovascular symptoms.[7,84] Thus, cardiovascular disease is more common in the Asian population, and neurologic disease predominates in the northern European population.

Wet beriberi results from high-output cardiac failure induced by peripheral vasodilation and the formation of arteriovenous fistulae secondary to thiamine deficiency. These patients complain of fatigue, decreased exercise tolerance, shortness of breath, and peripheral edema. The classic triad of oculomotor abnormalities, ataxia, and global confusion defines dry beriberi or Wernicke encephalopathy. Other manifestations include hypothermia and the absence of deep-tendon reflexes.[81] Additionally, patients develop a peripheral neuropathy with paresthesias, hypesthesias, and an associated myopathy, all related to axonal degeneration.[67] Laboratory studies may reflect a metabolic acidosis with elevated lactate concentration brought on by excessive anaerobic glycolysis resulting from blocked entry of substrate into the Krebs cycle.[16,18,33,34,39,51,59,81] Interestingly, a primary respiratory alkalosis of unclear etiology seems to be simultaneously present.[20] Korsakoff psychosis, an irreversible disorder of learning and processing of new information characterized by a deficit in short-term memory and confabulation, often occurs together with Wernicke encephalopathy.[79] A 10% to 20% mortality rate is associated with Wernicke encephalopathy, with survivors having an 80% risk of developing Korsakoff psychosis.[56]

■ POPULATIONS AT RISK

In the United States, a healthy diet and mandatory thiamine supplementation of numerous food products protect most people from the manifestations of thiamine deficiency. This is, unfortunately, not true in other countries. A survey of the 17 major public hospitals in the Sydney, Australia, area identified more than 1000 cases of either acute Wernicke encephalopathy or Korsakoff psychosis between 1978 and 1993.[44] Similarly, a single Australian hospital identified 32 cases of Wernicke encephalopathy during a 33-month period.[85] In Australia, mandatory supplementation of flour with thiamine in 1991 resulted in a dramatic reduction in hospitalized cases during 1992 and 1993,[44] as well as of those subsequently identified by postmortem studies.[29] Current areas at risk include Ireland and New Zealand where lack of a mandatory supplementation program is correlated with a high prevalence of biochemical evidence of thiamine deficiency.[49]

Alcoholic patients, whose consumption of ethanol is their major source of calories, are the best described and most easily recognized patients at risk for thiamine deficiency.[56] Consequential thiamine deficiency is also described in incarcerated prisoners,[31] patients in drug rehabilitation,[24] patients receiving hemodialysis,[19] patients with hyperemesis gravidarum or anorexia nervosa,[74] patients receiving parenteral nutrition,[13,14,39,51,71,80] patients with acquired immunodeficiency syndrome (AIDS),[3,8,9,62] patients with malignancies,[6,36,60,71,78] the institutionalized elderly,[38,50,52] and patients with congestive heart failure on furosemide therapy.[37] Thus, despite routine dietary supplementation, many people are still at risk because of dietary limitations, alcohol abuse, or underlying medical conditions.

THIAMINE DOSING

Thiamine hydrochloride is included in the initial therapy for any patient with an altered mental status, potentially acting as both treatment and prevention of Wernicke encephalopathy. Many patients with altered levels of consciousness have had or will have a poor nutritional status, or will be hospitalized without oral intake for a number of days because of gastrointestinal disorders or altered mental status. Although thiamine concentrations can be either directly measured or functionally assessed by measuring erythrocyte transketolase activity at baseline and in response to thiamine diphosphate,[30] these determinations are unavailable for clinical use. Likewise, although clinical prediction models have been developed, they are cumbersome and unvalidated.[65] Glucose loading increases thiamine requirements, which can exacerbate marginal thiamine deficiencies, elevate lactate concentrations,[48] or even precipitate coma in the absence of parenteral thiamine supplementation.[56] Although it is commonly believed that acute glucose loading, in the form of a bolus of hypertonic dextrose, can precipitate Wernicke encephalopathy over several hours in normal individuals, there is only evidence to support this effect in patients who already have grave manifestations of thiamine deficiency.[81] Previously healthy patients require prolonged dextrose administration in order to develop Wernicke encephalopathy. Because the morbidity and mortality associated with Wernicke encephalopathy are so severe, and treatment is both benign and inexpensive, thiamine hydrochloride should be included in the initial therapy for all patients who receive dextrose, all patients with altered consciousness, and every potential alcoholic or nutritionally deprived individual who presents to the emergency department or other clinical setting.

Initial therapy consists of the immediate parenteral administration of 100 mg of thiamine hydrochloride. This can be given either intramuscularly or intravenously, but the oral route should be avoided because of its unpredictable absorption. In countries where thiamine propyl disulfide (a lipid-soluble thiamine preparation) is available, the oral route may be considered equally efficacious for the replacement of serious thiamine deficiencies.[5,75,76] In some patients, symptoms such as ophthalmoplegia are reported to respond rapidly to as little as 2 mg of thiamine; however, the other neurologic and cardiovascular manifestations of thiamine deprivation may necessitate higher doses and may respond more slowly, if at all. Although many sources recommend that daily doses of 100 mg of thiamine are sufficient as preventive therapy, others recommend initial doses as high as 200 or 250 mg,[1,77] based on limited data. Because of the safety of thiamine hydrochloride, and the urgency to correct the manifestations of thiamine deficiency, up to 1000 mg of thiamine hydrochloride can be used in the first 12 hours if a patient demonstrates persistent neurologic abnormalities.[47]

The practice of requiring the administration of parenteral thiamine prior to hypertonic dextrose in patients with altered consciousness is illogical.[26] Besides the fact that the first dose of dextrose is unlikely to cause thiamine deficiency, thiamine uptake into cells and activation of enzyme systems is slower than that of glucose uptake, which

suggests that even pretreatment with thiamine offers little benefit over posttreatment.[73] Despite these limitations it is prudent to administer 100 mg of parenteral thiamine at the time of initial dextrose administration. The biochemical link between dextrose and thiamine is obvious, which demonstrates to the clinician the scientific basis for the administration of thiamine. Although thiamine is unlikely to offer immediate benefits for patients with altered consciousness, it will offer some long-term protection for these individuals at risk and initiate therapy for an uncommon, serious, insidious, and easily overlooked disorder.

A supplementary indication for the administration of thiamine hydrochloride occurs in patients with ethylene glycol poisoning. As shown in Fig. 107–2, a minor pathway for the elimination of glyoxylic acid involves its conversion to α-hydroxy-β-ketoadipate by α-ketoglutarate:glyoxylate carboligase, a thiamine and magnesium-requiring enzyme. There are no data to support an increase in α-hydroxy-β-ketoadipate formation following thiamine administration in ethylene glycol–poisoned animals or humans. However, animal models of primary hyperoxaluria show increases in urinary oxalate during thiamine deficiency, suggesting at least a potential importance of this pathway.[27,72] Because therapy is benign and inexpensive, it is prudent to administer standard doses of thiamine to patients with suspected or confirmed ethylene glycol poisoning.

Routine thiamine administration should also be considered in patients with congestive heart failure and long-term use of diuretics. Diuretics enhance renal thiamine elimination.[64] In one randomized trial, 200 mg of daily intravenous thiamine was able to increase cardiac ejection fraction by 22% at 7 weeks.[66] Unfortunately, although ejection fraction was not measured, another small study was unable to show a statistical benefit in a variety of clinical parameters.[68]

ADVERSE EVENTS

Very few complications are associated with the parenteral administration of thiamine. The older literature emphasized intramuscular administration because of numerous reports of anaphylactoid reactions associated with intravenous thiamine delivery.[21,55,61,70,83] It is generally believed that these reactions resulted from responses to the vehicle (chlorbutanol) or its contaminants rather than thiamine itself. Despite the availability of purer, aqueous preparations of thiamine, rare adverse reports still occur.[4,45,53,69] Although the intramuscular route is theoretically comparably efficacious in a healthy individual, many patients requiring thiamine may have diminished muscle mass or a coagulopathy, exacerbating the potential for pain and unpredictable absorption. The safety of thiamine use was evaluated in a large case series in which nearly 1000 patients received parenteral doses of up to 500 mg of thiamine without significant complications.[86] This study suggests that if anaphylaxis to thiamine exists, its occurrence is exceedingly rare, permitting the safe intravenous administration of thiamine to most patients.

PREGNANCY CATEGORY

Thiamine hydrochloride is listed in pregnancy category A and is also considered safe for use in lactating mothers.

AVAILABILITY

Multiple manufacturers formulate thiamine hydrochloride for intravenous or intramuscular administration. Typical concentrations are either 50 or 100 mg/mL. Although more concentrated solutions are available, their use is usually reserved for preparation of total parenteral nutrition solutions.

CHAPTER 78
ETHANOL WITHDRAWAL

Jeffrey A. Gold • Lewis S. Nelson

Alcohol withdrawal represents a major cause of morbidity in the alcoholic population and a substantial resource burden on certain medical centers and communities. Complicating management is that there is no diagnostic test for this clinical syndrome, and the diagnosis is established on the basis of the patient history and clinical findings. The impact on patient outcome and resource utilization can be enhanced through early recognition of risk factors and insight into the expected clinical course of these patients. This will allow for empiric initiation of therapy and targeted management. The underlying pathophysiology provides insight into the potential complications associated with alcohol withdrawal and the choice of therapy. It is important to seek alternative diagnoses and inciting factors for withdrawal, which may indeed be the same entity.

HISTORY AND EPIDEMIOLOGY

The medical problems associated with alcoholism and alcohol withdrawal were first described by Pliny the Elder in the 1st century B.C. In his work *Naturalis Historia*, the alcoholic and alcohol withdrawal were described as follows: "…drunkenness brings pallor and sagging cheeks, sore eyes, and trembling hands that spill a full cup, of which the immediate punishment is a haunted sleep and unrestful nights. …"[80] Initial treatments as described by Osler were focused on supportive care, including confinement to bed, cold baths to reduce fever, and judicious use of potassium bromide, chloral hydrate, hyoscine, and possibly opium.[79]

Some of the initial large series of alcohol related complications in the early 20th century describe the alcohol withdrawal syndrome (AWS) as a major public health concern. At Bellevue Hospital in New York City, Jolliffe described 7000–10,000 admissions per year for alcohol-related problems from 1902–1935, with an estimated rate of 2.5–5 admissions per 1000 New York City residents.[54] Moore et al.[75] described similar numbers of admissions to Boston City Hospital, with up to 10% of alcoholics admitted with evidence of delirium tremens (DTs). The mortality at the beginning of their study among patients with DTs was 52% (1912), and DTs was the leading cause of death among admitted alcoholics. Over the ensuing 20 years, the mortality rate declined to approximately 10%–12%, a decrease believed to be secondary to improved supportive care and nursing.[75]

Though alcoholics were widely recognized to have a high incidence of delirium and psychomotor agitation, the etiology of these signs and symptoms was controversial and attributed to ethanol use, ethanol abstinence, or coexisting psychological disorders. Isbell and colleagues, in 1955, proved that abstinence from alcohol was the cause of this syndrome when they subjected nine male prisoners to chronic alcohol ingestion for a period of 6–12 weeks followed by 2 weeks of abstinence.[52] While they were ingesting alcohol daily none of these prisoners developed signs and symptoms of DTs but during the abstinence phase six of the nine men developed tremor, elevations in blood pressure and heart rate, diaphoresis, and varying degrees of either auditory or visual hallucinations, consistent with the diagnosis of DTs.[52] In addition, two of the nine abstinent men developed

convulsions, further linking alcohol abstinence to seizures. However, it should be noted that the high rate of development of DTs (67%) in this study is atypical and does not represent the true prevalence found in later epidemiologic studies.[13]

Currently, alcoholism and alcohol withdrawal syndromes still represent a major problem in both the inpatient and outpatient setting. In a 10-year epidemiologic study, the prevalence of self-reported symptoms of alcohol withdrawal, including morning tremors and sweating, in the general population was quite low, with only 1%–3% of men describing one or more symptoms consistent with alcohol withdrawal; rates were even lower among women.[13] However, when the population in this study was enriched by those at risk for alcoholism, with at risk being defined as convicted for driving under the influence, nearly 19% met self-reported *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) criteria for alcohol withdrawal. The prevalence was even higher among persons admitted for detoxification, with nearly 80% experiencing one or more withdrawal symptoms.[13]

Similar results have been obtained in the inpatient setting. Alcohol-related complications accounted for 21% of all medical ICU admissions in an inner city hospital, with alcohol withdrawal being the most common alcohol-related diagnosis.[72] In other studies, 8% of all general hospital admissions, 16% of all postsurgical patients, and 31% of all trauma patients developed AWS.[33,90] The development of AWS in postsurgical and trauma patients can increase the mortality in this population nearly 3-fold.[87,89] Furthermore, alcohol was involved in nearly 86% of homicides, 37% of assaults, and 25%–35% of nonfatal motor vehicle crashes.[15]

PATHOPHYSIOLOGY

Numerous studies over the past 2 decades have provided valuable insight into the mechanism of alcohol withdrawal, allowing for better understanding of both the clinical spectrum of the disorder and potential therapeutic interventions. Alcohol withdrawal is a neurologic disorder with a continuum of progressively worsening symptoms caused by the effects of chronic ethanol use on the central nervous system, and often exacerbated by the clinical manifestations of alcoholism which include nutritional depletion, impaired immunity, anemia, cirrhosis and head trauma.

The effects of chronic alcohol consumption on neurotransmitter function best explain the clinical findings. Persistent stimulation of the inhibitory γ-aminobutyric acid (GABA) receptor-chloride channel complex by ethanol leads to downregulation of GABA receptor–chloride channel complex.[12,57] This allows the alcohol user to maintain a relatively normal level of consciousness despite the presence of high and sedating concentrations of ethanol in the brain. A continued escalation of the steady-state ethanol concentration is required to achieve euphoria termed tolerance, which results in progressive desensitization of the GABA receptor–chloride channel complex.[28] The exact mechanism by which this adaptive change occurs is incompletely defined, but involves substitution of an α_4 for an α_1 receptor subunit on the $GABA_A$ receptor (Chap. 14).[14,66] A converse series of events occurs at the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor. Binding by ethanol to the glycine binding site of this receptor inhibits the NMDA function, resulting in compensatory upregulation of these excitatory receptors.[42,50] Thus, withdrawal of alcohol is associated with both a decrease in GABAergic activity and an increase glutamatergic activity.[42] This phenomenon of a concomitant increased excitation and loss of inhibition results in the clinical manifestations of autonomic excitability and psychomotor agitation.

Repeated episodes of alcohol withdrawal may lead to poorly understood permanent alterations in neurotransmitters and their receptors. In rats, repeated episodes of alcohol withdrawal leads to persistent and progressive EEG abnormalities, with further episodes of withdrawal becoming increasingly resistant to benzodiazepines. Both clinical observation and in vitro data suggest that repeated episodes of alcohol withdrawal lead to permanent dysregulation of GABA receptors. This understanding may be an explanation for the "kindling phenomena," which is the clinical observation of increasing severity of alcohol withdrawal among individual subjects, and the development of benzodiazepine-resistant alcohol withdrawal.[11,37,104]

CLINICAL SYNDROMES

Alcohol withdrawal is defined in the DSM-IV as the cessation of substantial or prolonged alcohol use resulting, within a period of a few hours to several days, in the development of two or more of the clinical findings listed in Table 78–1.[32] Additionally, these symptoms must have no other organic etiology. Alcohol withdrawal syndromes can be classified both by timing (early vs. late) and severity (complicated vs. uncomplicated). However, there are no adequate or fully accepted criteria by which to define these categories. Furthermore, the clinical course of AWS can vary widely among patients, and progression of individual patients through these different stages is extremely variable. In fact, some substantial alcohol users experience no withdrawal syndromes following the cessation of alcohol consumption. Recognizing these limitations, this conceptual framework still proves helpful in the clinical management of patients with alcohol withdrawal.

■ EARLY UNCOMPLICATED WITHDRAWAL

Alcohol withdrawal begins as early as 6 hours after the cessation of drinking. Early withdrawal is characterized by autonomic hyperactivity including tachycardia, tremor, hypertension, and psychomotor agitation.[97] Although these symptoms are uncomfortable, they are

---

TABLE 78–1. DSM-IV Criteria for Alcohol Withdrawal[32]

A. Cessation of (or reduction in) alcohol use that has been heavy and prolonged.

B. Two (or more) of the following, developing within several hours to a few days after criterion A:

 1. Autonomic hyperactivity (eg, sweating or pulse rate greater than 100)
 2. Increased hand tremor
 3. Insomnia
 4. Nausea or vomiting
 5. Transient visual, tactile, or auditory hallucinations or illusions
 6. Psychomotor agitation
 7. Anxiety
 8. Grand mal seizures

C. The symptoms in criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

---

not generally dangerous. Most patients who ultimately develop severe manifestations of AWS initially develop these findings, but this is not universal. Early in this "stage" of AWS, the symptoms are still readily amenable to treatment with ethanol, as is done daily by most chronic alcohol users.

■ ALCOHOLIC HALLUCINOSIS

Nearly 25% of patients with AWS will develop hallucinations, which are generally auditory and persecutory, and a subset of these patients will develop alcoholic hallucinosis, a syndrome of persistent hallucinations.[96,98] Although classically these persistent hallucinations are tactile or visual, other types of hallucinations are described. Tactile hallucinations include formication, or the sensation of ants crawling on the skin, which can result in repeated itching and excoriations. However, as opposed to DTs, alcoholic hallucinosis is associated with a clear sensorium. The presence of alcoholic hallucinosis is neither a positive nor a negative predictor of the subsequent development of DTs.[50]

■ ALCOHOL WITHDRAWAL SEIZURES

Approximately 10% of patients with AWS develop alcohol withdrawal seizures, or "rum fits." For many patients, a generalized alcohol withdrawal seizure may be the first manifestation of the AWS.[97] Approximately 40% of patients with alcohol withdrawal seizures have isolated seizures and 3% develop status epilepticus.[95,97] Alcohol withdrawal seizures may occur in the absence of other signs of alcohol withdrawal and are characteristically brief, generalized, tonic–clonic events with a short post-ictal period. Occasionally a flurry of seizures may occur over a short time period.[95] Regardless, rapid termination and normal post-ictal mental status belie the seriousness of an alcohol withdrawal seizure. For approximately one-third of patients with DTs, the sentinel event is an isolated alcohol withdrawal seizure. Alcohol withdrawal seizures occurring in the presence of an elevated ethanol concentration may be a poor prognostic indicator for the development of a more severe AWS because the relative protection against withdrawal of an elevated ethanol concentration will be lost as the concentration drops.[94] Finally, clinicians should be cognizant that anticonvulsants are prescribed for many alcoholics because they have a preexisting seizure disorder, often related to repetitive brain trauma.[35] Conversely, the use of anticonvulsants does not unequivocally indicate the presence of a preexisting seizure disorder because of the difficulty in differentiating these seizures from those of alcohol withdrawal.

■ DELIRIUM TREMENS

Delirium tremens is the most serious complication of the AWS, and generally occurs between 48 and 96 hours after the cessation of drinking.[97] Many of the clinical manifestations of DTs are similar to those of uncomplicated early alcohol withdrawal, differing only in severity, and include tremors, autonomic instability (hypertension and tachycardia), and psychomotor agitation. However, unlike AWS, DTs as defined in DSM-IV, is associated with either (1) disturbance of consciousness (such as reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention, delirium, confusion, and frank psychosis, or (2) a change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.[32] Unlike the early manifestations of alcohol withdrawal, which typically last for 3–5 days, DT can last for up to 2 weeks (Table 78–2).[97]

TABLE 78–2. Diagnostic Criteria for Substance Withdrawal Delirium[32]

A. Disturbance of consciousness (ie, reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.

B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.

C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.

D. There is evidence from the history, physical examination, or laboratory findings that the symptoms in criteria A and B developed during, or shortly after a withdrawal syndrome.

Note: This diagnosis should be made instead of a diagnosis of substance withdrawal only when the cognitive symptoms are in excess of those usually associated with the withdrawal syndrome and when the symptoms are sufficiently severe to warrant independent clinical attention.

RISK FACTORS FOR THE DEVELOPMENT OF ALCOHOL WITHDRAWAL

Factors determining whether an individual will develop AWS are not well identified. The strongest predictor for the development of AWS is a history of prior episodes of AWS/DTs and/or a family history.[31,62] The influence of family history on the development of AWS suggests a strong role for genetic factors. A growing number of studies have identified numerous polymorphisms associated with the development of AWS/DTs. These include genes involved in dopamine transmission, glutamate signaling, cannabinoid receptors and neuropeptide Y.[38,42,59,61,93] However, these findings must be interpreted with caution. First, whether or not they represent a predisposition to greater ethanol consumption because of an enhanced mesolimbic reward system, or some other underlying pathophysiologic effect, is unclear. In addition, they may be reflective of protective genetic alterations, as is noted with the GRK5 polymorphism of the β-adrenergic receptor.[67] Second, many of the studies do not systematically divide between AWS, withdrawal seizures, and DTs, all of which may be regulated by different pathways. Finally, almost uniformly these studies are small (less than 200 subjects) and are racially homogenous, making it imperative that they be replicated on a larger scale and in different racial groups.[59] Larger and more varied patient cohorts that include both women and nonwhite ethnic groups are required before any definitive conclusions can be drawn. Racial predisposition to the development or severity of AWS is not definitive, but the experience at our institution suggests that African American patients may be at lower risk of developing severe DTs than Caucasians.[17]

Because of the subjective nature of many of these findings, we discourage the use of pure clinical descriptors, such as DTs, tremors, rum fits, and the like, to classify the severity of alcohol withdrawal in any given patient. Furthermore, the necessity of having a standardized means of classification has enormous implications for epidemiologic, genetic, and treatment studies. One of the more commonly used means for accurately assessing alcohol withdrawal is the Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar) score (Fig. 78–1).[91] This scoring system contains 10 clinical categories and requires less than 5 minutes to complete. Scoring systems are not only essential for symptom-triggered therapy, but provide a basis for comparative analysis of clinical trials in ethanol withdrawal. Greater use of

CIWA-Ar or a comparable validated scale will be essential for interpretation of both genetic and treatment trials in the future. The majority of scoring systems are validated only for patients with mild AWS who are in detoxification or rehabilitation environments and their direct applicability to patients with severe AWS is unclear.

■ CLINICAL AND BIOCHEMICAL PREDICTORS

Alcohol concentrations, homocysteine concentrations, and liver enzymes are often associated with the development of AWS in the results of some but not all studies.[8,94] Because many studies are based on small numbers of often highly selected subjects, their applicability to larger populations is extremely poor.

Numerous attempts have been made to develop biochemical predictors for the presence and/or severity of alcohol withdrawal. Although consistent abnormalities in readily obtained laboratory values are observed in patients with AWS (eg, aminotransferases, magnesium, erythrocyte parameters such as mean corpuscular volume), their role in predicting the severity of AWS is poorly described. In one study, an alanine aminotransferase (ALT) greater than 50 Units/L (odds ratio [OR] 9.0; 3.5–24), a serum chloride concentration less than 96 mEq/L (OR 61.5; 54.4–69.6), and a serum potassium concentration less than 3.6 mEq/L (OR 5.7; 2–16.4) were all associated with the development of alcohol withdrawal in patients admitted to a detoxification center.[102] However, the low specificity of these derangements makes it difficult to assess their predictive value, especially when accounting for other clinical characteristics such as prior history and admission CIWA-Ar score. In addition, there is a negative association between the presence of severe alcohol withdrawal and histopathologic cirrhosis, further clouding the usefulness of routine laboratory testing for prognostication.[3]

Other investigators have focused on admission ethanol concentration as a predictor for the severity of alcohol withdrawal in at risk subjects. In one study, an admission blood ethanol concentration of greater than 150 mg/dL had a 100% sensitivity and a 57% specificity for the need for treatment of alcohol withdrawal.[99] At a different treatment facility, an ethanol concentration of greater than 150 mg/dL had an 81% positive predictive value for the need to use more than a single dose of chlordiazepoxide for the treatment of AWS.[99] In addition, admission blood ethanol concentrations in patients with alcohol withdrawal seizures were 2-fold higher than in those without seizures, irrespective of whether or not they had a history of prior withdrawal seizures.[99] However, these results should be interpreted with caution, as other studies yield conflicting results. In one study, an admission ethanol concentration less than 100 mg/dL was associated with an increased risk of recurrent alcohol withdrawal seizures, and in another study, admission ethanol concentrations failed to predict the development of DTs.[21,81] There are many potential explanations for these disparate results, including differences in patient population, differences in cohort size, and the late onset of DTs, at a time when ethanol concentrations would be extremely low or nonexistent.[21]

More recently, investigators have looked at the prognostic usefulness of serum homocysteine concentrations. Numerous reports document hyperhomocysteinemia in patients with alcoholism, presumably caused by a deficiency of dietary folic acid.[25] Furthermore, homocysteine and its metabolites can act as excitatory neurotransmitters at the NMDA receptor and cause seizures and excitatory neuronal death.[69] In one study, serum homocysteine concentrations were predictive of alcohol withdrawal seizures. However, in this study, there was strong correlation ($r^2 = 0.7666$; $P < 0.001$) between admission blood ethanol concentrations and homocysteine concentrations, raising doubts as to whether this holds any advantage over blood ethanol concentrations.[8] Additionally, among men admitted for alcohol detoxification, those

Patient:_____ Date:_____ Time:_____ (24 hour clock, midnight = 00:00)

Pulse or heart rate, taken for one minute:_____ Blood pressure:_____

NAUSEA AND VOMITING: Ask "Do you feel sick to your stomach? Have you vomited?" Observation.
0   No nausea and no vomiting
1   Mild nausea with no vomiting
2
3
4   Intermittent nausea with dry heaves
5
6
7   Constant nausea, frequent dry heaves and vomiting

TREMOR: Arms extended and fingers spread apart. Observation.
0   No tremor
1   Not visible, but can be felt fingertip to fingertip
2
3
4   Moderate, with patient's arms extended
5
6
7   Severe, even with arms not extended

PAROXYSMAL SWEATS: Observation.
0   No sweat visible
1   Barely perceptible sweating, palms moist
2
3
4   Beads of sweat obvious on forehead
5
6
7   Drenching sweats

ANXIETY: Ask "Do you feel nervous?" Observation.
0   No anxiety, at ease
1   Mild anxious
2
3
4   Moderately anxious, or guarded, so anxiety is inferred
5
6
7   Equivalent to acute panic states as seen in severe delirium or acute schizophrenic reactions

AGITATION: Observation.
0   Normal activity
1   Somewhat more than normal activity
2
3
4   Moderately fidgety and restless
5
6
7   Paces back and forth during most of the interview, or constantly thrashes about

TACTILE DISTURBANCES: Ask "Have you any itching, pins and needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?" Observation.
0   none
1   Very mild itching, pins and needles, burning or numbness
2   Mild itching, pins and needles, burning or numbness
3   Moderate itching, pins and needles, burning numbness
4   Moderately severe hallucinations
5   Severe hallucinations
6   Extremely severe hallucinations
7   Continuous hallucinations

AUDITORY DISTURBANCES: Ask " Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?" Observation.
0   Not present
1   Very mild harshness or ability to frighten
2   Mild harshness or ability to frighten
3   Moderate harshness or ability to frighten
4   Moderately severe hallucinations
5   Severe hallucinations
6   Extremely severe hallucinations
7   Continuous hallucinations

VISUAL DISTURBANCES: Ask "Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?" Observation.
0   Not present
1   Very mild sensitivity
2   Mild sensitivity
3   Moderate sensitivity
4   Moderately severe hallucinations
5   Severe hallucinations
6   Extremely severe hallucinations
7   Continuous hallucinations

HEADACHE, FULLNESS IN HEAD: Ask "Does your head feel different? Does it feel like there is a band around your head?" Do not rate for dizziness or lightheadedness. Otherwise, rate severity.
0   No present
1   Very mild
2   Mild
3   Moderate
4   Moderately severe
5   Severe
6   Very severe
7   Extremely severe

ORIENTATION AND CLOUDING OF SENSORIUM: Ask "What day is this? Where are you? Who am I?"
0   Oriented and can do serial additions
1   Cannot do serial additions or is uncertain about date
2   Disoriented for date by no more than 2 calendar days
3   Disoriented for date by more than 2 calendar days
4   Disoriented for place/or person

with a history of alcohol withdrawal seizures but no recent seizure had a significantly higher serum prolactin concentrations when compared to those without a prior alcohol withdrawal seizure ($P = 0.042$).[46] The robustness of an elevated prolactin or homocysteine concentration appears to be improved when combined, outperforming either individually and an elevated blood alcohol concentration in predicting the risk of alcohol withdrawal seizures.[47] However, additional study is needed before any definitive conclusions can be made.

In a recent study of 35 fatalities with an in-hospital diagnosis of DTs, restraint use and hyperthermia were both predictive of death.[58] Because this is likely a marker for undertreatment with appropriate doses of benzodiazepines (see next section), it highlights the need for aggressive early management.

MANAGEMENT

■ ALCOHOL WITHDRAWAL SEIZURES

Alcohol withdrawal seizures are perhaps the most rigorously studied complication of AWS. Although alcohol withdrawal seizures are generally self-limited, benzodiazepines are preferred for patients with persistent or recurrent alcohol withdrawal seizures. In a randomized, placebo-controlled trial of 229 subjects with alcohol withdrawal seizures, 2 mg of intramuscular lorazepam reduced the risk of recurrent seizure from 24% to 3% ($P < 0.001$) at 6 hours, and the need for hospital admission from 42% to 29% ($P = 0.0222$).[30] However, whether this interrupts the natural history of progression to DTs is not known. There is no role for phenytoin in either treatment or prevention of alcohol withdrawal seizures. In multiple trials, phenytoin was ineffective in preventing recurrence of alcohol withdrawal seizure.[1,18,82] The most likely explanation for the failure of phenytoin is its inability to regulate GABA or NMDA receptors, the principle mediators of the development of seizures in alcohol withdrawal. One exception to this lack of usefulness occurs in the alcoholic patient with a nonalcohol withdrawal-mediated seizure, or a history of underlying seizure disorders.

■ ALCOHOL WITHDRAWAL

In the early stages of alcohol withdrawal, many patients are able to self-medicate with additional alcohol consumption. Among those who seek medical attention, many patients with AWS can be safely managed as outpatients. Outpatient management has significant cost savings with little effect on treatment outcome when the patient is sufficiently stable to tolerate this option.[43] In one study, patients who exhibited a current lack of intoxication, no history of either DTs or alcohol withdrawal seizures, no comorbid psychiatric or medical disorders, and a CIWA-Ar score of less than 8 were safely managed as outpatients.[2] Patients not meeting these criteria were referred to inpatient detoxification centers or medical units, depending on the severity of withdrawal and other comorbid conditions.

For all patients with AWS, the initial stages of therapy remain the same, and should include a thorough assessment to identify coexisting medical, psychiatric, or toxicologic disorders. In particular, an assessment for central nervous system trauma and infection should include the appropriate use of computed tomography and lumbar puncture. Patients with altered cognition or an elevated body temperature should receive antibiotics as appropriate, pending the results of a lumbar puncture. In concert with this approach, adequate supportive care should be instituted, with attention to identifying treatable causes of abnormal vital signs and clinical findings.

Chronic alcohol consumption leads to severe vitamin and nutritional deficiencies and electrolytes disturbances that should be corrected.[25,49]

Specifically, parenteral thiamine should be given to all patients to prevent the development of Wernicke encephalopathy. It is generally suggested that thiamine should be given prior to the administration of dextrose to prevent precipitation of Wernicke encephalopathy.[73,100] Although there is little evidence to support this approach, the administration of thiamine (see Antidote in Depth A25: Thiamine Hydrochloride) and dextrose together is a reasonable practice. Because there is typically a high incidence of intravascular volume depletion among alcoholics, all patients should receive adequate volume resuscitation. Of 39 deaths between 1915 and 1936 attributed to DTs in which volume status was recorded, all subjects were volume depleted.[75] Finally, for patients with AWS, particularly if severe, prevention of nosocomial complications is paramount for reducing hospital stay. Currently, in addition to adequate volume replacement, we recommend that all patients be kept with the head of the bed elevated to prevent pulmonary aspiration, and that deep vein thrombosis prophylaxis be given if the patient is bed bound for an extended period.

The association of severe alcohol withdrawal with severe psychomotor agitation led to early use of sedative-hypnotics. One of the first randomized trials compared chlorpromazine to paraldehyde. In both study arms there was a 0% mortality, suggesting equivalency of the two treatments.[34] Over the ensuing years, numerous trials documented similar efficacy between paraldehyde, benzodiazepines, and antipsychotics.[16,34,92] However, in a landmark study, 547 patients were randomized to 1 of 4 drugs (chlordiazepoxide, chlorpromazine, hydroxyzine, and thiamine) or to placebo for the treatment of alcohol withdrawal.[55] Patients receiving chlordiazepoxide had the lowest incidence of both DTs and alcohol withdrawal seizures, establishing benzodiazepines as a first-line agent for treatment of AWS. Of note, use of chlorpromazine, an antipsychotic, was associated with a significant increase in the incidence of seizures in both humans[55] and animal models.[10]

Since this study, numerous trials have compared different routes of administration among various sedative-hypnotics, both to each other and to placebo. Because of the historical use noted above, chlordiazepoxide remains widely used in outpatient and inpatient detoxification clinics. Oral benzodiazepine administration is generally effective in patients with early or mild AWS, although initial rapid titration with an intravenous regimen may be more efficient. Benzodiazepines administered intravenously have a rapid onset of action, and have long displaced paraldehyde as the sedative-hypnotic of choice for acute control. Among the benzodiazepines, diazepam offers the most rapid time to peak clinical effects, which limits oversedation that may occur following the administration of drugs with slower onset to the peak drug effect, such as lorazepam. Because of the delayed peak clinical effect of lorazepam of approximately 10–20 minutes, several doses may be administered in rapid succession with little clinical effect, followed by the appearance of oversedation from the cumulative doses. Midazolam may be administered intramuscularly if intravenous access is not available, but intramuscular injection significantly delays the time to both onset and peak clinical effect. Although no significant differences are observed between benzodiazepines and barbiturates in terms of mortality or the duration of delirium, the improved pharmacokinetic profile and ease of administration favor benzodiazepines as the preferred initial agent (see A24: Benzodiazepines).[2,63]

Other pharmacokinetic factors and experience confirm that diazepam is preferred for initial intravenous use in patients with moderate to severe AWS. Diazepam has a long half-life [43 ± 13 hours] and has active metabolites (desmethyldiazepam and oxazepam). The prolonged half-life (48–72 hours) of desmethyldiazepam further extends the effective duration of action of the initial dose of diazepam.[107] A retrospective review reported that the use of a single benzodiazepine rather than multiple benzodiazepines was a marker for treatment success

in surgical patients experiencing alcohol withdrawal during surgical admission.[77] These data suggest that it is more important to rapidly sedate the patient with adequate doses of a single benzodiazepine than to use multiple benzodiazepines in hopes of finding an effective regimen. Finally, it should be noted that in patients with advanced liver disease, the use of diazepam may result in a very prolonged period of sedation because of impaired clearance of the parent compound and its metabolites. Consequently, in these patients, a benzodiazepine without active metabolites, such as lorazepam, may be a better drug.

The initial management of patients with AWS/DTs should include rapid titration with intravenous benzodiazepine to achieve sedation. The goal of therapy is to have the patient sedated but breathing spontaneously, with normal vital signs. Although normalization of vital signs is not a mandatory therapeutic endpoint, abnormal vital signs despite adequate sedation should prompt a search for comorbidities. In many patients, complete sedation with diazepam may allow for autotitration; that is, as the AWS resolves, the blood concentrations of diazepam and desmethyldiazepam decrease, allowing gradual recovery. In practicality, most patients need periodic redosing with diazepam to maintain adequate sedation. This is particularly important in patients with AWS with an elevated blood alcohol concentration.

Multiple studies now suggest that if additional doses are required, they should be administered based on symptoms ("symptom triggered"), as opposed to a fixed dosing schedule. In two randomized controlled trials, administration of benzodiazepine in a symptom-triggered fashion reduced both the total amount of benzodiazepine and the duration of treatment.[26,86] In these trials, benzodiazepines were administered every hour as long as the CIWA-Ar score remained greater than 8–10. In both trials, symptom-triggered therapy resulted in a 4- to 6-fold reduction in the duration of therapy and a 4- to 5-fold reduction in the total amount of benzodiazepine administered, with no increase in withdrawal seizures or adverse events.[26,86] Symptom-triggered doses in patients with moderate or severe AWS should be diazepam 10–20 mg IV or lorazepam 2–4 mg.[26,86] For less-symptomatic patients, oral chlordiazepoxide 50–100 mg should be administered. However, it is important to note that the decision to treat in the symptom-triggered group was made based on CIWA-Ar score (usually >8), which demonstrates the usefulness of standardized scoring and evaluation tools. It should also be noted that in both of these trials, patients had very mild withdrawal symptoms, with mean CIWA-Ar scores of 9–11. While experience suggests that this same regimen is also effective in patients with serious withdrawal and/or DTs it has not been validated in this population. Furthermore, it must be emphasized that protocolized use of the CIWA-Ar score is dependent on a significant history of recent heavy drinking and a communicative subject. A prospective analysis of complex medical/surgical patients enrolled in a CIWA-Ar protocol suggested more than 50% patients failed to meet these criteria, leading to unnecessary treatment.[44]

▬ RESISTANT ALCOHOL WITHDRAWAL AND DELIRIUM TREMENS

There is a subgroup of patients with AWS who require very large doses of diazepam, or another comparable drug to achieve initial sedation.[40,68,78,105] This same group often has exceedingly high benzodiazepine requirements to maintain this level of sedation. Subjects with resistant AWS and DTs may have benzodiazepine requirements that exceed 2600 mg of diazepam within the first 24 hours, and generally require admission to an intensive care or stepdown unit.[105] Patients admitted to the Bellevue hospital medical ICU for resistant alcohol withdrawal had very high diazepam requirements, with a mean of 234 mg (range: 10–1490 mg) required in the first 24 hours, and individual

doses of diazepam that often exceeded 100 mg, to control their agitation. At Bellevue, these patients comprise approximately 5% of all ICU admissions, with nearly 40% of patients requiring mechanical ventilation and a mean ICU length of stay of 5.7 days.[36]

The approach to the management of resistant AWS depends on several factors, including the availability of an intensive care unit bed. In the ICU, despite the perception of failure of high benzodiazepine requirements, we favor administration of benzodiazepines in a symptom-triggered fashion. This approach was confirmed in a study of patients who developed AWS postoperatively in the ICU.[88] In this study, a symptom-triggered strategy resulted in a shorter length of stay and a lower incidence of mechanical ventilation than did continuous infusion of midazolam.[88] Patients who receive this therapy generally respond to bolus doses of diazepam, which results in a brief period of sedation followed by recrudescence of their AWS. However, the dose range and drug required to achieve this may be dramatically different than what is observed in subjects with nonresistant AWS. In a recent study, use of escalating bolus doses of diazepam, up to 200 mg as an individual dose, combined with phenobarbital in subjects with continued benzodiazepine resistance (defined as the requirement for bolus doses more frequently than every hour), reduced the need for mechanical ventilation by nearly 50%.[36] In non-ICU settings, the ability to administer frequent intravenous doses of diazepam is limited, and the use of intravenous infusions with secondary sedative agents may be more practical.

In instances of extreme benzodiazepine resistance, patients often receive a second GABAergic drug because of "failure" of benzodiazepine therapy. Phenobarbital, given in combination with a benzodiazepine, in intravenous doses of up to 260 mg, is a reasonable choice.[36] Caution is required to avoid stacking doses of phenobarbital, as the onset of clinical effect takes approximately 20–40 minutes.[45,53] Alternatively, propofol in standard doses may be administered. Although propofol has a rapid onset, it is difficult to titrate, and high dose or long-term use is associated with profound metabolic consequences.[22,23,74] However, in a recent observational study, propofol was safely administered to 21 subjects intubated for severe benzodiazepine resistant DTs.[36] The main drawback to the use of these drugs is their narrow therapeutic–toxic index, with the potential for profound respiratory depression. This is especially true for propofol, which should generally only be used in the setting of mechanical ventilation. Both of these agents can act synergistically with benzodiazepines to enhance GABA-induced chloride channel opening. In addition, propofol uniquely antagonizes NMDA receptors, thus reducing the excitatory component of AWS.[27,41,51]

▬ ETHANOL

Ethanol consumption is a common and effective means by which alcoholics can self-medicate to treat and/or prevent mild alcohol withdrawal. Consequently, some hospitals still administer ethanol for either prophylaxis and/or treatment of AWS. In one survey, 72% of 122 hospitals surveyed had administered either IV or oral ethanol for these indications.[9] Despite its widespread use, little randomized controlled data support its use. In one trial, 39 trauma patients without liver or CNS disease were successfully treated with 10% ethanol infusion for treatment of presumed AWS.[24] Conversely, IV ethanol was no more effective than flunitrazepam in one trial and inferior to diazepam in another in the prevention of AWS in postoperative surgical patients.[31,101] Although the authors did not report any adverse effects in these trials, the necessity for frequent blood alcohol monitoring, unpredictable elimination kinetics, potential for significant hepatic complications, the postulated adverse effects of ethanol on wound healing, and the difficulty in safely administering this therapy make it inappropriate to recommend this regimen.[29,48,73]

■ ADRENERGIC ANTAGONISTS

Numerous studies have investigated the use of sympatholytics to control the autonomic symptoms of alcohol withdrawal. Both β-adrenergic antagonists and clonidine reduced blood pressure and heart rate in randomized, placebo-controlled trials.[4,64,106] However, the inability of these xenobiotics to address the underlying pathophysiologic mechanism of AWS, and subsequently control the neurologic manifestations, makes them suboptimal as sole therapeutic xenobiotics. There are additional concerns that by altering the physiologic parameters that serve as classic markers for AWS severity, there is a risk of underadministering necessary amounts of benzodiazepines.[106] This was observed in a randomized controlled trial of the central α-agonist lofexidine.[56] Finally, while animal evidence suggests a potential role for dexmedetomidine for AWS, there are only scattered case reports documenting its use in humans.[84,85] Consequently, we do not recommend using these drugs for the treatment of AWS until it becomes clear that other standard therapies have failed.

■ MAGNESIUM

The theoretical benefits of magnesium supplementation are based both on the high prevalence of magnesium deficiency in alcoholics and its usefulness in preventing seizures in other disorders, including eclampsia.[5,49] Furthermore, magnesium deficiency has many clinical similarities to AWS, clouding the differential diagnosis. Numerous studies have evaluated the efficacy of magnesium supplementation. However, in a randomized, placebo-controlled trial, intravenous magnesium sulfate had no effect on either severity of alcohol withdrawal or incidence of withdrawal seizures.[103] Consequently, aside from repletion of electrolyte abnormalities, there is no indication for routine administration of magnesium for the treatment of AWS.

■ ANTICONVULSANTS

Carbamazepine has been used in multiple trials for treatment of mild AWS, more commonly in Europe where an intravenous preparation is available. In animal studies, carbamazepine increases both the central nervous system GABA concentrations and the seizure threshold in alcohol withdrawal models.[20] In humans, carbamazepine is superior to placebo and equally efficacious as benzodiazepines for treatment of mild to moderate AWS in both inpatients and outpatients.[7,70,71] Similar data have been obtained with valproic acid, which appears to have a benzodiazepine-sparing effect in patients with mild withdrawal.[83] In contrast, a recent randomized, placebo-controlled study of the newer anticonvulsant oxcarbazepine showed no difference between this xenobiotic and placebo in inpatient detoxification.[60] Consequently, while this class of drugs may be reasonably recommended as adjuncts, they should not be used as monotherapy for treatment of established AWS and DT.

NEWER XENOBIOTICS AND FUTURE DIRECTIONS

There is a constant search for newer xenobiotics to treat alcohol withdrawal, especially for agents that target NMDA receptors. In animal studies, NMDA antagonists have shown benefit in preventing AWS seizure, neurologic damage, and alcohol craving.[6,76] In humans, one NMDA receptor inhibitor, acamprosate, has undergone significant study in the prevention of relapse following alcohol detoxification.[19,39] Its effects on AWS are less clear, although in one study of patients capable of outpatient detoxification, it had no adverse effects on CIWA-Ar scores.[19] More recently, antiglutamanergic lamotrigine and topiramate

were compared both to placebo and to diazepam for treatment of mild AWS.[65] All three demonstrated varying degrees of superiority compared to placebo, with no difference when compared to diazepam. However, the role of these xenobiotics in more severe withdrawal as either primary therapy or as adjuncts for use in combination with GABAergic agents remains unclear.

SUMMARY

Alcohol withdrawal is a complex physiologic process involving both enhanced neuronal excitation and reduced inhibition resulting in neuroexcitation. The manifestations of greatest concern are neurologic and include altered mental status and seizure, but the autonomic excess may be clinically consequential. Treatment includes supportive care and sedation with benzodiazepines in escalating doses. When benzodiazepines cannot produce adequate sedation, agents such as phenobarbital or propofol should be added.

CHAPTER 79

DISULFIRAM AND DISULFIRAM-LIKE REACTIONS

Edwin K. Kuffner
Disulfiram

Disulfiram continues to be prescribed as part of alcohol treatment programs and is being more widely studied for other drugs of abuse. Disulfiram toxicity associated with acute overdose, chronic therapy, and from disulfiram–ethanol reactions continues to be reported worldwide. Most of the adverse effects are from case reports and case series which are difficult to interpret because of complications and comorbidities associated with alcohol use and alcoholism, the potential effects of polypharmacy, use of other drugs of abuse, and difficulty in relating specific adverse effects to disulfiram, alcohol or a disulfiram–ethanol reaction. Although serious and life-threatening effects associated with disulfiram are rare, clinicians and toxicologists must remain vigilant in diagnosing and appropriately managing patients with disulfiram associated toxicity.

HISTORY AND EPIDEMIOLOGY

For over 200 years disulfiram (tetraethylthiuram disulfide) and related chemicals have been used in the rubber industry as catalytic accelerators for the vulcanization (stabilization) of rubber by the addition of sulfur.[117] In the early 1900s, workers exposed to disulfiram were observed to develop adverse reactions when exposed to ethanol. Williams, an American physician, suggested that disulfiram might be a useful adjunct in the treatment of alcoholism.[127] In the 1940s, two Danish physicians, Hald and Jacobsen, became ill after consuming alcohol while using disulfiram as an antihelmintic.[42] Subsequently, disulfiram was approved by the FDA for the the treatment for alcoholism in 1951. Although data supporting the benefit of using disulfiram in a comprehensive alcohol treatment program have been questioned, other pharmacologic therapies such as naltrexone and acamprosate have been approved for the treatment of alcohol dependence, and the potential benefits of disulfiram therapy continue to be evaluated in clinical trials disulfiram is still widely prescribed today.[38,47,70,95,115] Although the use of disulfiram for treating alcoholism is decreasing, its use in the management of addictions to other drugs of abuse such as cocaine is increasing.[92] Specific epidemiologic information about the three different forms of disulfiram toxicity is difficult to elucidate, even from an analysis of the American Association of Poison Control Centers (AAPCC) (Chap. 135).

Data from the AAPCC from 2003 to 2007 confirms that each year US poison centers are notified of between three and four hundred disulfiram exposures. Major adverse outcomes are rare. Since 1982 only 14 deaths associated with disulfiram have been reported to the AAPCC, most reported to involve a disulfiram-ethanol reaction.

Unlike many xenobiotics reported to the AAPCC, the majority of the disulfiram exposures were in adults. Serious adverse effects reported in the literature associated with both therapeutic use of disulfiram and with disulfiram overdose continue to be reported mostly in the form of case reports and case series. As such, these reports are difficult to interpret because of complications and comorbidities associated with alcohol use and alcoholism, the potential effects of polypharmacy, and the difficulty in relating the adverse effect to disulfiram, alcohol or a disulfiram–ethanol reaction.

PHARMACOLOGY AND PHARMACOKINETICS OF DISULFIRAM

Disulfiram does not produce central nervous system effects that alter an alcoholic's drinking behavior. The effectiveness of disulfiram in discouraging alcohol consumption is aversive in nature, as it is dependent on the patient's fear of developing a disulfiram–ethanol reaction. Therapeutic doses of disulfiram, used as part of a comprehensive alcohol treatment program, typically range from 125 to 500 mg/day.

■ ABSORPTION

Disulfiram is highly lipid soluble and very insoluble in water. Following ingestion, disulfiram is either absorbed as the parent compound or rapidly converted to diethyldithiocarbamic acid (diethyldithiocarbamate) in the acid environment of the stomach.[13] Diethyldithiocarbamic acid is also very unstable in this acid environment and either rapidly undergoes absorption and spontaneous decomposition to carbon disulfide and diethylamine, or chelates copper, forming a bis(diethyldithiocarbamate)-copper complex. The bis(diethyldithiocarbamate)-copper complex is more stable than diethyldithiocarbamic acid and also can be absorbed as it passes through the upper gastrointestinal tract. In fact, most disulfiram is absorbed from the small intestine as this bis(diethyldithiocarbamate)-copper complex. Approximately 70%–90% of an ingested therapeutic dose of disulfiram is absorbed. The bioavailability of disulfiram varies with different preparations. In one study, the mean serum disulfiram concentration in humans following a 250-mg dose was reported to be 0.38 ± 0.03 μg/mL.[29] Peak serum concentrations of disulfiram and its metabolites are achieved 8–10 hours following a 250-mg dose.[29]

■ DISTRIBUTION

Approximately 96% of disulfiram itself and approximately 80% of disulfiram metabolites are protein bound.[50] Following absorption, disulfiram and its metabolites are uniformly distributed throughout tissues. A specific volume of distribution for disulfiram is not recognized.

■ METABOLISM

Since absorbed disulfiram is rapidly converted to diethyldithiocarbamic acid by erythrocyte glutathione reductase and endogenous thiols, it may be difficult to detect parent drug in the bloodstream. Diethyldithiocarbamic acid in the blood also reversibly chelates copper, forming a bis(diethyldithiocarbamate)-copper complex. Diethyldithiocarbamic acid is metabolized by a number of different pathways, including glucuronidation, methylation, nonenzymatic degradation, and oxidation. Nonenzymatic degradation of diethyldithiocarbamic
Disulfiram

FIGURE 79–1. Disulfiram metabolism occurs in the liver and in the erythrocyte. The most consequential metabolites are diethyldithiocarbamate and carbon disulfide.

FIGURE 79–2. The site of action of disulfiram. The irreversible inactivation of aldehyde dehydrogenase results in an increased acetaldehyde concentration after ethanol is administered.

acid produces diethylamine and carbon disulfide. Carbon disulfide can be further oxidized to carbonyl sulfide, which, in turn, can be further oxidized to carbon dioxide. Phase II methylation of diethyldithiocarbamic acid, which is mediated by an *S*-methyltransferase, produces diethyl-dithiomethylcarbamic acid. Diethyldithiomethylcarbamic acid can be oxidized to diethylthiomethylcarbamic acid. Diethylthiomethylcarbamic acid is further oxidized to sulfoxide and sulfone metabolites and undergoes demethylation to form diethylthiocarbamic acid. Although diethyldithiocarbamic acid can be converted back to disulfiram, and carbon disulfide and diethylamine can be converted back to diethyldithiocarbamic acid, these reactions are not clinically significant[27] (Fig. 79–1). Significant interindividual variability exists in the metabolism of disulfiram resulting in varying concentrations of the different metabolites.[29]

■ ELIMINATION

Following a 250-mg dose, the half-lives of disulfiram, diethyldithiocarbamate, and carbon disulfide are 7.3 ± 1.5 hours, 15.5 ± 4.5 hours, and 8.9 ± 1.4 hours, respectively.[22] Approximately 20% of disulfiram is excreted unchanged in the feces and another 20% or more is excreted by the lungs as carbon disulfide. The majority of disulfiram is excreted in the urine as the glucuronidated metabolite of diethyldithiocarbamic acid.[50] At 48 hours after administration of a single 250-mg dose, there is a negligible amount of disulfiram and metabolites detectable in the serum.[29,48]

DISULFIRAM–ETHANOL REACTION

■ PHARMACOLOGY AND PHARMACOKINETICS OF DISULFIRAM–ETHANOL REACTION

Understanding the metabolism of ethanol is critical to understanding the mechanism of action of disulfiram as it relates to the disulfiram–ethanol reaction (Fig. 79–2). Disulfiram and its metabolites impair both cytosolic aldehyde dehydrogenase 1 (ALDH 1) and mitochondrial aldehyde dehydrogenase 2 (ALDH 2). A few days of treatment with disulfiram can reduce baseline aldehyde dehydrogenase activity
by 50%. Although aldehyde dehydrogenase is present throughout the body, inhibition of hepatic mitochondrial aldehyde dehydrogenase is most important in the disulfiram–ethanol reaction. This inhibition by disulfiram of ALDH 2 leads to a rise of acetaldehyde concentrations 5–10 times above baseline.

The exact mechanism by which disulfiram and its metabolites inhibit ALDH 1 and ALDH 2 is still unclear. Disulfiram may inactivate aldehyde dehydrogenase by oxidizing sulfhydryl groups and causing internal sulfur-sulfur bonds, or by competing for nicotinamide adenine dinucleotide.[99] The metabolites of disulfiram, including diethylthiomethylcarbamic acid and its sulfoxide and sulfone metabolites, may also inhibit aldehyde dehydrogenase.[42,50] Different metabolites possibly inactivate different isoenzymes of aldehyde dehydrogenase. Diethylthiocarbamic acid is believed to inactivate ALDH 2. Since aldehyde dehydrogenase inhibition is irreversible, new ALDH must be synthesized to metabolize acetaldehyde.[50] This explains why disulfiram has a longer duration of effect than would be predicted based on its half-life.

The duration of the inhibition of aldehyde dehydrogenase by disulfiram is partially dependent on the dose ingested and the route of administration. A 500-mg dose inhibits aldehyde dehydrogenase for up to 4 days, a 1000-mg dose for up to 6 days, and a 1500-mg dose up to 8 days.[42] Disulfiram-ethanol reaction has been reported up to 1–3 weeks following cessation of disulfiram therapy. There are also sustained-release and depot disulfiram preparations, but none are readily available in the United States. A patient reacted to oral ethanol 21 days following the subcutaneous injection of 2 g of disulfiram.[93] Although the severity of the disulfiram–ethanol reaction following subcutaneous disulfiram dosing is reported to be less than that following oral dosing, this has not been proven.

The accumulation of acetaldehyde, which would normally be metabolized rapidly by aldehyde dehydrogenase, is responsible for many of the symptoms produced by the disulfiram–ethanol reaction. In fact, intravenous administration of acetaldehyde to humans produces symptoms similar to those experienced by patients on disulfiram who consume ethanol.[1,122] Acetaldehyde may increase the release of histamine, which may also be responsible for some of the effects of the disulfiram–ethanol reaction.

Disulfiram–ethanol reactions are reported following exposure to disulfiram by the oral and subcutaneous routes, and to ethanol by any route. Disulfiram–ethanol reactions may follow exposure to the ethanol contained in many products other than alcoholic beverages. Table 79–1 lists some common household products containing ethanol.

■ OTHER ENZYMES INHIBITED BY DISULFIRAM

Disulfiram and its metabolites inhibit other enzymes besides ALDH 1 and ALDH 2, especially those that contain sulfhydryl groups and metalloproteins. Importantly, disulfiram inhibits dopamine β-hydroxylase (DBH), an enzyme necessary for norepinephrine synthesis.[39,83] The mechanism for this inhibition may be the chelation of copper by

Adhesives

Alcohols: denatured alcohol, rubbing alcohol

Detergents

Foods: liquor-containing desserts, fermented vinegar, some sauces

Nonprescription xenobiotics: analgesics, antacids, antidiarrheals, cough and cold preparations, topical anesthetics, vitamins

Personal hygiene products: after-shave lotions, colognes, contact lens solutions, deodorants, liquid soaps, mouthwashes, perfumes, shampoos, skin liniments and lotions

Solvents

diethyldithiocarbamate, which is necessary for dopamine β-hydroxylase activity.[103] Inhibition of DBH leads to increased CNS concentrations of dopamine and decreased concentrations of epinephrine and norepinephrine. DBH inhibition may contribute to the therapeutic effects of disulfiram, especially in the management of cocaine addiction and may also explain some of the psychiatric effects following both acute disulfiram overdose and chronic disulfiram therapy. Although it has been theorized that some of the neurologic effects following both acute disulfiram overdose and chronic disulfiram therapy may be related to the metabolite carbon disulfide, this has not been confirmed in a well-controlled trial.[97] Decreased norepinephrine in the presence of acetaldehyde, a potential vasodilator, may also account for the hypotension associated with the disulfiram–ethanol reaction. This decrease is consistent with decreased urinary concentrations of vanillylmandelic acid in humans taking disulfiram.[43] Disulfiram and its metabolites may also inhibit microsomal carboxylesterases and plasma cholinesterases.[70]

DISULFIRAM AND THE CYTOCHROME P450 SYSTEM

Disulfiram and its metabolites are inhibitors of cytochrome P450 (CYP) 2E1.[52] Single doses of disulfiram administered to healthy humans result in 50% inhibition of baseline CYP2E1 activity for at least 3 days, with some inhibition for longer than 1 week.[26,28] Although animal studies suggest that disulfiram alters acetaminophen metabolism, a human study found that disulfiram did not significantly alter the metabolism of a therapeutic dose of acetaminophen, in either healthy patients or in patients with alcoholic liver disease.[94] Disulfiram may be an inducer of CYP2B1 and CYP2A1, but it does not appear to affect CYP2C9, CYP2C19, CYP2D6, or CYP3A4 activity.[36,50,52] The effects of disulfiram on CYP enzymes may be both dose and time dependent.

DISULFIRAM–XENOBIOTIC INTERACTIONS

Disulfiram may decrease the clearance of benzodiazepines (chlordiazepoxide, diazepam, and oxazepam),[68] phenytoin,[86] methylxanthines (theophylline[66] and caffeine[36] some tricyclic antidepressants (desipramine and imipramine)[21] and some monamine oxidase inhibitors (tranylcypromine[8]). Disulfiram increases the prothrombin time (international normalized ratio) in patients taking warfarin.[89,104] Combined therapy of disulfiram with omeprazole can cause catatonia.[41] Isoniazid,[126] metronidazole,[104] and methylphenidate[15] may potentiate the neuropsychiatric effects of disulfiram, producing confusion and psychosis.[104]

Patients taking disulfiram therapeutically may develop hypotension following the administration of anesthetic agents.[25] Disulfiram may also increase serum cocaine concentrations and potentiate the cardiovascular effects of cocaine.[75] There is a theoretical concern that disulfiram may decrease the metabolism of propylene glycol found in many liquid and parenteral drug formulations, but specific cases of toxicity have not been reported. Although animal studies suggest that disulfiram may increase the carcinogenicity of ethylene dibromide, this has not been substantiated in humans.[96,131]

DISULFIRAM AS AN ANTIDOTE

Case reports suggest that disulfiram may be useful for the treatment of nickel dermatitis.[20] However, a small double-blind, placebo-controlled study of patients with hand eczema and nickel allergy did not find a clinically significant difference between those treated with disulfiram and those treated with placebo.[51] The conditions of some patients have worsened with this therapy,[55] and because some patients treated for nickel dermatitis have developed hepatitis this therapy is not generally indicated.

Diethyldithiocarbamate, a disulfiram metabolite, is available as the chelator dithiocarb. Although animal data and human case series suggest that diethyldithiocarbamate may be an effective chelator for the treatment of nickel-carbonyl poisoning, no well-controlled human trial has evaluated this therapy.[116] Because disulfiram increases nickel absorption in humans, it is prudent to use disulfiram or diethyldithiocarbamate only for the treatment of nickel-carbonyl poisoning and not for the treatment of elemental or inorganic nickel poisoning. Although animal studies suggest that diethyldithiocarbamate may be effective for nickel-carbonyl poisoning there are no well-controlled human studies[10,93] (see Chap. 97).

CLINICAL MANIFESTATIONS

Data from clinical trails as well as clinical use suggest that there is considerable variation in the development and severity of disulfiram–ethanol reaction.[12,19,70] Symptoms of the disulfiram–ethanol reaction often begin within 15 minutes peak within 30 minutes to 1 hour, and then gradually subside over the next few hours.

Signs and symptoms of a disulfiram–ethanol reaction include nonallergic facial and generalized body warmth and flushing, conjunctival injection, pruritus, urticaria, diaphoresis, lightheadedness, vertigo, headache, nausea, vomiting, and abdominal pain. Cardiac effects include palpitations, chest pain, and dyspnea. Tachycardia and hypotension, including orthostatic hypotension, are common. Rare complications include altered mental status, electrocardiographic abnormalities, shock,[82] dysrhythmias, myocardial ischemia,[79] hypertension,[124,132] bronchospasm,[132] myoclonus,[118] and methemoglobinemia.[114] Esophageal rupture and intracranial hemorrhage secondary to profound vomiting may occur.[31] Deaths attributed to the disulfiram–ethanol reaction occur but are rare.[2,49,82] Many of the historical deaths were associated with doses of disulfiram in excess of current recommended doses.

DISULFIRAM–ETHANOL LIKE REACTIONS

The term *disulfiram like reaction* is commonly used to describe a presentation similar to the typical disulfiram–ethanol reaction when the patient has not been exposed to both disulfiram and ethanol. Most *disulfiram like* reactions involve an exposure to ethanol.[35,56,64,85]

Ingestion of ethanol following ingestion of various *Coprinus* species of mushrooms can cause symptoms of a disulfiram–ethanol reaction (Chap. 117).[102,111]

TABLE 79–2. Xenobiotics Reported to Cause a Disulfiram-like Reaction with Ethanol[6,14,44,56,57,81,85,95,105,111,121,131]

Antimicrobials

    Cephalosporins, especially those that contain a methylthiotetrazole (MTT) side chain, such as cefotetan, cefoperazone, cefamandole, and cefmenoxime.

    Metronidazole

    Moxalactam

    Trimethoprim-sulfamethoxazole

    Possible reactions with chloramphenicol, furazolidone, griseofulvin, nitro-furantoin, procarbazine quinacrine, sulfonamides

Calcium carbimide (citrated)

Carbon disulfide

Carbon tetrachloride

Chloral hydrate

Dimethylformamide

Mushrooms

    Coprinus mushrooms including *C. atramentarius, C. insignis, C. variegatus,* and *C. quadrifidus, Boletus luridus, Clitocybe clavipes, Polyporus sulphureus, Pholiota squarosa, Tricholoma aurantum, Verpa bohemica*

Nitrefazole

Phentolamine

Sulfonylurea oral hypoglycemics

    Chlorpropamide

    Tolbutamide

Tacrolimus

Thiram analogs (fungicides)

    Copper, mercuric, and sodium diethyldithiocarbamate

    Zinc and ferric dimethyldithiocarbamate

    Zinc and disodium ethylenebis [dithiocarbamate]

Thiuram analogs:

    Tetraethylthiuram monosulfide and disulfide (disulfiram)

    Tetramethylthiuram disulfide (thiram)

Tolazoline

Trichloroethylene

Many xenobiotics in combination with ethanol have been reported to produce symptoms of the disulfiram–ethanol reaction (Table 79–2). Unfortunately, the potential for disulfiram-like reactions with individual xenobiotics has rarely been studied systematically.[123] Alcohols other than ethanol and organic solvents, including mineral spirits, can also cause symptoms of a disulfiram–ethanol reaction.[109]

MANAGEMENT OF DISULFIRAM–ETHANOL REACTIONS

For most patients experiencing suspected disulfiram–ethanol reactions, it is frequently useful to confirm the presence of ethanol, either with an exhaled ethanol concentration or by obtaining a blood ethanol concentration. Because only small amounts of ethanol can precipitate a disulfiram–ethanol reaction, some patients, especially those with small ingestions or dermal exposures, may still manifest reactions in the absence of detectable ethanol concentrations at the time of evaluation. Elevated acetaldehyde concentrations in the blood will occur during a disulfiram–ethanol reaction, but acetaldehyde concentrations are not readily available, and thus are not clinically useful in managing most patients.

Symptomatic and supportive care is the mainstay of treatment. Gastrointestinal decontamination aimed at removing ethanol is unlikely to have any clinically significant effect on limiting the severity or duration of the disulfiram–ethanol reaction, because even small amounts of ethanol can cause toxicity in the presence of disulfiram. Additionally, because nausea and vomiting are common, patients often experience spontaneous gastric emptying. Antiemetics may improve nausea and vomiting, and histamine (H_1) receptor antagonists, such as diphenhydramine, may lessen cutaneous flushing.[113] Most patients with hypotension respond to intravenous crystalloid administration. Symptomatic hypotension refractory to these measures rarely occurs. If hypotension is refractory to crystalloid administration, a vasopressor should be administered. There is a theoretical benefit to administering a direct-acting vasopressor such as norepinephrine, because disulfiram inhibits dopamine β-hydroxylase, an enzyme necessary for norepinephrine synthesis. Indirect-acting vasopressors, such as dopamine, that require functioning dopamine β-hydroxylase to create a releasable pool of norepinephrine, may be less effective in the setting of disulfiram toxicity. Patients with cardiovascular instability should have an electrocardiogram performed.[62] Most patients with a typical disulfiram–ethanol reaction who have normal vital signs can be safely discharged following resolution of symptoms. More prolonged observation is essential for patients with persistent symptoms, ECG abnormalities, or any potentially life-threatening effect.

Fomepizole, an inhibitor of alcohol dehydrogenase, prevents the metabolism of ethanol to acetaldehyde.[9] Theoretically, by preventing the production of acetaldehyde, fomepizole could limit the effects of the disulfiram–ethanol reaction. A patient on disulfiram experiencing a disulfiram–ethanol reaction was given fomepizole experimentally, with an almost immediate decrease in the serum acetaldehyde concentration, and a rapid clinical improvement.[65] Fomepizole normalized blood acetaldehyde concentrations and relieved the symptoms of the disulfiram–ethanol reaction in four volunteers given calcium carbimide and ethanol.[65] Fomepizole should therefore be considered for patients with life-threatening signs or symptoms of a disulfiram–ethanol reaction who are unresponsive to standard treatment (see Antidotes in Depth A31: Fomepizole).

CLINICAL MANIFESTATIONS

■ ACUTE DISULFIRAM OVERDOSE

Acute overdose of disulfiram is uncommon and typically does not cause life-threatening toxicity. Most patients will develop symptoms within the first 12 hours following ingestion, with resolution of symptoms within 24 hours of ingestion.

Nausea, vomiting, and abdominal pain are common. A spectrum of central nervous system depression—from drowsiness to coma—may occur.[79] Metabolic acidosis is rare.[69] Dysarthria and movement disorders, including myoclonus, ataxia, dystonia, and akinesia, occur rarely. The movement disorders may be related to direct effects of carbon disulfide on the basal ganglia.[60,63,69] Sensorimotor neuropathy, subacute weakness, and psychosis are uncommon.[45,54] Hypotonia may be a prominent feature in children.[3,6] Persistent neurologic abnormalities, lasting for weeks to months, are reported in both children and adults, but are rare.[69,78,100,133]

■ CHRONIC DISULFIRAM THERAPY

In published clinical trials disulfiram at therapeutic doses for the treatment of alcoholism appears to be well tolerated.[17,18,24,37] Most of the serious adverse effects associated with disulfiram therapy are derived from case reports involving oral therapy. Toxicity associated with chronic disulfiram therapy correlates poorly with dose, and there is a wide variability in latency period between the time therapeutic dosing is initiated and when symptoms develop. Side effects associated with chronic disulfiram therapy, unsurprisingly, are obviously reported most commonly in alcoholic patients.

Adverse effects most typically involve the liver, the skin, or the central nervous system. Commonly reported effects include nausea, drowsiness, dizziness, irritability, anxiety, headache, a metallic taste in the mouth, halitosis, and skin odor described as having a sulfur or garlic smell, decreased libido, impotence, and hypertension.[43,71,121]

A spectrum of hepatic effects ranging from asymptomatic minor elevations of aminotransferase activity, to hepatic dysfunction, fulminant hepatic failure, and death are reported.[5] Hepatic effects most frequently occur at recommended doses with exposure durations that are extremely variable.[34] The true incidence of disulfiram-associated hepatic effects is unclear. Asymptomatic elevations in aminotransferase concentrations associated with disulfiram therapy have been reported to range from 6% to 30% in alcoholics.[40,119,129] The true incidence likely varies and is dependent on the frequency of sampling. The incidence of hepatic failure or death associated with disulfiram therapy is estimated at 1 in 25,000–30,000 patients treated per year[94] or 1 patient per 1.3 million daily doses distributed.[7] The mechanism of disulfiram-associated hepatotoxicity is poorly understood and may be caused by an immunologic or hypersensitivity reaction, by direct hepatotoxicity related to a metabolite, and possibly related to TNF-α.[22,67] Histologic patterns of toxicity are predominantly hepatocellular, involving eosinophilic leucocyte infiltration and centrilobular disappearance of hepatocytes due to necrosis or apotosis.[7] Although it is reported that disulfiram-associated hepatotoxicity may be exacerbated by concurrent alcohol consumption and cirrhosis, nonalcoholic patients taking disulfiram as a treatment for nickel dermatitis and patients without biopsy-confirmed cirrhosis have also developed hepatotoxicity.[7,61,63] Although elevated aminotransferase concentrations has been suggested by some as a relative contraindication to initiating disulfiram therapy this has not been confirmed.[7,108] Aminotransferase concentration has not been shown to be different in alcoholics treated with disulfiram who had confirmed hepatitis compared to seronegative patients.[72] Although hepatic effects have most commonly been reported with oral dosage forms they have also been reported with implantable disulfiram.[76]

Dermatoses associated with disulfiram therapy include exfoliative dermatitis, contact dermatitis, urticaria, pruritus, acne, and yellow palms.[107,128] Localized skin reactions at the site of disulfiram implants as well as generalized reactions may occur.[53,120] Healthcare workers handling disulfiram medications may also develop dermatoses.[73] Interestingly, thiram and its analogs, which are found in rubber, are also potent skin sensitizers.[89] Some patients with rubber sensitivity develop localized and generalized dermatitis following ingestion of disulfiram, whereas other patients can be treated with disulfiram without dermatologic complications.[87,125] Disulfiram can also cause exacerbations of nickel and cobalt dermatitis.[55,77] Disulfiram may exacerbate nickel dermatitis because diethyldithiocarbamate complexes with nickel and increases its absorption.[46]

Reported neuropsychiatric side effects include headache, dizziness, confusion,[98] memory impairment,[71] ataxia, parkinsonian and extrapyramidal symptoms,[63] seizures,[23] optic neuropathy,[88] coma, peripheral neuropathy, psychosis including mania,[4,16] depression, catatonia,[32] punding,[30] and organic brain syndrome.[58,106] Confusion, memory impairment, peripheral neuropathy, and psychiatric diagnoses are common in alcoholic patients who are not taking disulfiram. Alcohol-induced and disulfiram-induced peripheral neuropathies are difficult to distinguish clinically. Disulfiram-induced peripheral neuropathy usually involves motor nerves more than sensory and autonomic nerves, is worse distally, and is usually bilateral. A small prospective study of alcoholics taking therapeutic doses of disulfiram revealed abnormalities of peripheral nerve function.[90] Neurologic symptoms may be related to both dose and duration of therapy, but these issues are not well studied.[28] Although case reports suggest an increased incidence of psychiatric complications, one prospective randomized study did not find an increased incidence of psychiatric complications in alcoholic patients taking disulfiram.[11]

Disulfiram therapy may increase serum cholesterol concentration.[74] Although patients with occupational exposures to carbon disulfide, a metabolite of disulfiram, have an increased risk of atherosclerosis and ischemic heart disease, this has not been proven for patients taking disulfiram.[117] One case report suggests that disulfiram may cause thrombocytopenia.[67] Disulfiram is not believed to be carcinogenic. Disulfiram is not routinely indicated for pregnant patients and is currently labeled as FDA pregnancy category C. Although case reports suggest potential teratogenic effects there are no adequate and well-controlled studies in pregnant women.[101]

DIAGNOSTIC TESTING

Serum disulfiram concentrations are not useful when managing most patients with suspected disulfiram toxicity following an acute overdose, chronic therapy, or a disulfiram–ethanol reaction. When interpreting a serum disulfiram concentration, it is important to note that because of rapid metabolism, only a small proportion of ingested disulfiram may appear in the blood as the parent compound.[50] Metabolites of disulfiram, including diethyldithiomethylcarbamic acid and diethylthiomethylcarbamic acid, can also be measured in the serum. Other markers of ingestion of disulfiram include carbon disulfide on the breath and diethylamine in the urine.[33] The activity of hepatic mitochondrial aldehyde dehydrogenase can be determined by liver biopsy, but this is impractical and dangerous. Leukocyte aldehyde dehydrogenase activity correlates most closely with hepatic mitochondrial aldehyde dehydrogenase activity. Decreased erythrocyte ALDH 1 activity and leukocyte ALDH 2 activity are markers of disulfiram exposure, although neither enzyme assay is commonly available.

■ CHRONIC DISULFIRAM THERAPY

Monitoring for evidence of drug-induced liver injury is recommended during the course of therapy. Unfortunately, for disulfiram specifically and for most other potentially hepatotoxic medications limited data are available on which to base monitoring recommendations.[110] Two common strategies employed for detecting and preventing severe hepatotoxicity include periodic monitoring of biomarkers including alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase, and total bilirubin as well as clinical monitoring for signs or symptoms of hepatic injury.[129,130] Given the lack of data to inform the most clinically effective and cost effective approach, clinicians should consider employing both strategies.

When monitoring biomarkers in patients on chronic disulfiram therapy, the most effective frequency or duration of testing or intervals between tests is unclear. Biomarker monitoring before initiation of disulfiram to establish a baseline and during the course of therapy is recommended.

Because isolated aminotransferase elevations, without other evidence of impaired hepatic function such as elevated total bilirubin or international normalized ratio (INR), are poor predictors of the development of hepatic dysfunction and hepatic failure, there is poor agreement on when disulfiram therapy should be modified or discontinued based on the finding of mildly elevated aminotransferase concentration.

There is much greater agreement that the development of an aminotransferase concentration greater than 3 times the upper limit of the reference range in combination with evidence of impaired hepatic synthetic function such as jaundice, elevated total bilirubin greater than 2 times the upper limit of the reference range or INR greater than 1.5 is suggestive of more severe drug-induced liver injury. In such situations mortality may be 16% or higher and should necessitate discontinuing disulfiram.[7,110]

As a method of determining compliance with chronic disulfiram therapy, some authors have advocated using ethanol patch testing to produce cutaneous vasodilation. Studies demonstrate that patch testing is not a reliable measure of compliance with disulfiram therapy. Measuring leukocyte aldehyde dehydrogenase activity, or serum concentrations of disulfiram and/or its metabolites, are better measures of compliance with disulfiram therapy.

MANAGEMENT OF DISULFIRAM TOXICITY

■ ACUTE DISULFIRAM OVERDOSE

Symptomatic and supportive care is the mainstay of treatment. There is no antidote for disulfiram toxicity. No studies have specifically addressed gastrointestinal decontamination in the setting of an acute disulfiram overdose. Unless otherwise contraindicated, activated charcoal, 1 g/kg of body weight, should be administered. It would be unusual for a patient with isolated disulfiram ingestion to require either orogastric lavage or whole-bowel irrigation. Emesis is not indicated, especially because some emetics contain ethanol, which could precipitate a disulfiram–ethanol reaction.

■ CHRONIC DISULFIRAM TOXICITY

There is indirect evidence that continued use of disulfiram in the face of elevated aminotransferase activity may increase the risk of developing life-threatening hepatotoxicity. Based on research with other medications, most patients on disulfiram who develop mild increased aminotransferase activity will likely adapt and their aminotransferases will normalize with continued disulfiram therapy.[110] Adaptation refers to the liver's ability to adjust to the presence of, and ongoing exposure to, medications such as disulfiram, such that serious hepatic injury or dysfunction does not develop.[84] Since isolated aminotransferase elevations, without other evidence of impaired hepatic function such as elevated total bilirubin or international normalized ratio (INR), are poor predictors of the development of hepatic dysfunction and hepatic failure, there is poor agreement on when disulfiram therapy should be modified or discontinued based on the finding of mildly elevated aminotransferase activity in otherwise asymptomatic patients. If the physician and patient determine that the risk benefit analysis favors continuing disulfiram therapy, enhanced periodic monitoring of aminotransferases and total bilirubin as well as vigilant clinical monitoring for signs and symptoms of hepatic injury such as anorexia, nausea, vomiting, abdominal pain, generalized weakness, malaise, fever, pruritus, scleral icterus, or jaundice is recommended.

Hepatotoxicity usually resolves following discontinuation of disulfiram therapy. Supportive care is the mainstay of treatment for disulfiram-associated hepatic failure. In severe cases, liver transplantation has been successfully performed for disulfiram-induced hepatic failure in both children and adults.[80,96]

SUMMARY

Because disulfiram is still used in comprehensive alcohol treatment programs, it is critical to understand the distinction between the different forms of disulfiram toxicity, including toxicity from an acute overdose, from chronic therapy, and from a disulfiram–ethanol reaction. Disulfiram toxicity following an acute overdose is unlikely to be life-threatening unless a massive amount is ingested, an event that is most likely to occur in suicidal adults. Although death is reported following disulfiram–ethanol reactions, most patients do not develop life-threatening toxicity.

Serious adverse effects associated with chronic disulfiram therapy continue to be reported and are associated with both therapeutic use of disulfiram and with disulfiram overdose. Most of the adverse effects are reported from case reports and case series which are difficult to interpret because of the complications and comorbidities associated with alcohol use and alcoholism, the potential effects of polypharmacy, and difficulty in relating the adverse effect to disulfiram, alcohol or a disulfiram–ethanol reaction. Although serious and life-threatening effects are associated with disulfiram the most significant is the disulfiram-associated hepatic failure which appears to be a very rare occurrence.

CHAPTER 80
γ-HYDROXYBUTYRIC ACID

Brenna M. Farmer

γ-Hydroxybutyric Acid [GHB]   γ-Butyrolactone [GBL]   Butanediol
Gamma-hydroxybutryic acid, or GHB, is an abused xenobiotic and a neurotransmitter and neuromodulator that is produced in the brain. It has also been synthesized and used and abused in this form. It has been used experimentally to treat absence seizures in animals,[63] as an adjunct to general anesthesia, as a sleep agent, as an anabolic nutritional supplement, and to treat alcohol dependence and alcohol withdrawal.[30,45,51,73] It is classified as a Schedule I drug due to its popularity as a drug of abuse and its association with drug facilitated sexual assault, and also as a Schedule III drug for the treatment of narcolepsy.[22] Two precursors of GHB, γ-butyrolactone (GBL) and 1,4-butanediol (1,4-BD)[64] have many industrial uses but are also used as recreational drugs and as drugs to achieve chemical submission (as "date rape" drugs). These two precursors exert their effects through conversion to GHB.[8,52] Numerous other analogs of GHB have industrial and commercial uses (see Table 80–1) and may result in GHB intoxication.

HISTORY AND EPIDEMIOLOGY

GHB was discovered in 1960 while searching for an analog for γ-aminobutyric acid (GABA).[33] Due to its CNS depressive and amnestic properties, GHB was used initially as an anesthetic adjunct, especially in Europe but never gained favor in the United States for this indication. During the 1970s, an FDA-investigational new drug protocol was submitted to test the use of GHB as a treatment for sleep disturbances. In the 1980s and 1990s, body builders popularized GHB as an anabolic dietary supplement due to its release of growth hormone. Its euphoric effects were recognized at this time, and it rapidly gained favor as a "club drug." Because it can cause coma and profound amnesia, GHB has been used in drug-facilitated sexual assault, and in 1990 the FDA banned all use of nonprescription GHB due to this concern.[61]

Following the FDA ban, the analogs GBL and 1,4-BD were quickly substituted for GHB in dietary supplements. After the Samantha Reid and Hillory J. Farias Date-Rape Prevention Act of 1999 was passed in 2000 the DEA classified GHB and its analogs as Schedule I substances claiming that GHB was a hazard to public safety.[19,61] Also in 2000, a new drug application was submitted to the FDA for GHB—under the generic name sodium oxybate and the trade name Xyrem®—to reduce the incidence of cataplexy and improve the symptoms of daytime sleepiness in patients with narcolepsy.[77] This latter indication was approved in 2002 and given a Schedule III designation by the DEA,[76] which was expanded, in 2005, to include the treatment of excessive daytime sleepiness in patients with narcolepsy.

In 2007, during an epidemic of toxicity from toy beads, marketed under the names Bindeez®or Aquadots®, 1,4-BD was identified in the sticky surface material that allowed the beads to reversibly adhere to one another. Multiple cases of toxicity were reported, largely in England and Australia.[26,56]

National statistics demonstrated a trend of escalating GHB abuse and poisoning throughout the 1990s. However, a decline has been seen in exposures reported to poison control centers and the Drug Abuse Warning Network in recent years. In 2002, there were 1386 exposures with GHB and its analogs and precursors reported to the American Association of Poison Control Centers (AAPCC)–Toxic Exposure Surveillance System, representing more than a 2-fold increase from approximately 600 GHB cases reported in 1996. Among these, 1181 exposures (85%) required treatment in a healthcare facility and resulted in 272 major outcomes and 3 deaths (see Chap. 135).[74] More recently there has been a further decline in the number of reported exposures to GHB and its analogs. From the 2006 AAPCC report, 485 cases mentioned exposure to GHB and its analogs. In 297 of those cases, GHB and or its analogs were listed as the single agent of exposure. Of the cases reported, 232 were treated in healthcare facilities with 145 of those cases resulting in "moderate" or "severe" findings according to the National Poison Center Database. One death was associated with confirmed GBL exposure when it was ingested with ethanol.[7] This trend in reduced use/abuse is also consistent with the Drug Abuse Warning Network's (DAWN) 2005 estimates which were 1861 emergency department (ED) visits for GHB exposures while their 2004 estimate was 2340 ED visits.[15]

The apparent trend of decreased GHB exposures in the United States after 2000 contrasts starkly with the increased use reported in some European countries (Denmark, Sweden, and Norway) and Australia.[11,14,32] In Melbourne, Australia, a recent retrospective study showed a 4% increase per month in the number of ambulance calls related to GHB and its analogs from March 2001 to October 2005.[11]

PHARMACOLOGY

GHB is both a precursor and degradation product of GABA.[64] It has a dual pharmacologic profile, with the neuropharmacology of endogenous GHB being distinct and divergent from that of exogenously administered GHB. The principal difference between their profiles is that the activity of endogenous GHB appears to be mediated by the GHB receptor, whereas the activity of exogenously administered GHB is most likely mediated by intrinsic activity at the $GABA_B$ receptor.

■ ENDOGENEOUS GHB

GHB is formed from GABA by the enzymes GABA transaminase and succinic semialdehyde reductase[41] (see Fig. 80–1). GHB is also endogeneously transformed from GBL by lactonases and from 1,4-BD by alcohol and aldehyde dehydrogenases. Endogenous GHB acts as a putative neurotransmitter found in highest concentrations in the hippocampus, basal ganglia, hypothalamus, striatum, and substantia nigra.[41,43,71] It has subcellular systems for synthesis, vesicular uptake, and storage in presynaptic terminals. It is released in a Ca^{2+}-dependent manner following depolarization of neurons.

After release, GHB binds to GHB-specific receptors that modulate other neurotransmitter systems.

Endogenous GHB acts predominantly on the GHB receptor, which is a G protein–linked receptor located presynaptically.[12,41,62] The GHB receptor is located in the synaptosomal membranes of neuronal cells most highly concentrated in the pons and hippocampus followed by the cerebral cortex and caudate. The GHB receptor has no affinity for typical $GABA_A$ or $GABA_B$ agonists such as GABA and baclofen,

respectively. Localized application of GHB can produce a response that mimics the action of endogenous GHB released by nerve stimulation.[4,46]

GHB activity is terminated by active uptake from the synaptic cleft for metabolism by specific cytosolic and mitochondrial enzymes.

GHB receptors are highly associated with dopaminergic neurons and increase the concentration of dopamine by stimulating tyrosine hydroxylase to synthesize dopamine.[41,65,67] GHB is also a neuromodulator of dopamine, acetylcholine, endogenous opioids, and glutamate.[41] It either increases (concentrations below 1 mM) or decreases (at higher concentrations) the release of dopamine throughout the mesolimbic system.[10] In contrast, GHB increases dopamine concentrations in the striatum and cortex in a dose-dependent manner by stimulating tyrosine hydroxylase to synthesize dopamine.[41,42,65] GHB also increases the turnover of serotonin in the brain by stimulating both serotonin synthesis and breakdown.[25,29] Furthermore, GHB decreases acetylcholine in the brainstem and corpus striatum, as well as in the hippocampus (via GABA$_B$ receptors).[47,65] GBL, but not GHB itself, increases total brain acetylcholine concentrations by decreasing firing of cholinergic neurons.[24,34,58]

Through an unclear mechanism, GHB increases the release of growth hormone by promoting slow wave sleep without effecting total sleep time and GHB release is enhanced.[69,72] Although GHB has no effect on total sleep time, it decreases latency to slow wave sleep while also decreasing the time spent in stage 1 and stage 2 of the sleep cycle.[35]

■ EXOGENEOUS GHB

Exogeneous GHB, which produces supraphysiologic GHB concentrations, acts predominantly on the GABA$_B$ receptor which is found throughout the cerebral cortex, cerebellum, and thalamus.[23,28,55,75] Presynaptically and postsynaptically, these receptors signal the adenylate cyclase system to activate calcium channels and G protein coupled inwardly rectifying potassium channels.[5] Through these GABA$_B$ receptor signaling pathways, both dopamine and acetylcholine pathways are altered leading to decreased dopamine release and decreased acetylcholine concentrations.[10,47] These effects of GHB are potentiated by baclofen, a GABA$_B$ receptor agonist. Further discussion of these receptors and pathways is found in Chapter 13.

■ GHB ANALOGS

GBL, like GHB, exists in the mammalian brain.[13] Its pharmacologic properties are only evident after conversion to its active metabolite, GHB. Like GBL, 1,4-BD occurs naturally in the brain and exerts its pharmacologic and toxicologic properties only when converted to GHB by alcohol dehydrogenase.[53]

Table 80–1 lists other GHB analogs known to result in similar toxicity and lists synonyms for GHB, GBL, and 1,4-BD that are often found on the labels of commercial and illicit products.

PHARMACOKINETICS AND TOXICOKINETICS

The endogeneous production and metabolism of GHB is shown in Figure 80–1. Exogeneous GHB is typically ingested in its sodium salt form. Oral bioavailability of exogeneous GHB is approximately 60% in rats.[36,38] It is rapidly absorbed from the GI tract in 15–45 minutes. GHB displays two-compartment distribution in animals with an initial volume of distribution of 0.4 L/kg and final volume of distribution 0.6 L/kg.[16,36–38] It is lipid soluble and crosses the blood–brain barrier rapidly. It does not bind significantly to any plasma proteins.[49]

GHB is metabolized mainly by succinic semialdehyde reductase (also known as GHB dehydrogenase) to succinic semialdehyde, which is subsequently metabolized to succinate and enters the tricarboxylic acid cycle (see Fig. 80–1). GHB is also metabolized directly to succinate via beta oxidation in the liver.[51] GHB is subject to first-pass metabolism by the cytochrome P450 system.[36] In adult volunteers, the elimination half-life is 20–53 minutes. Less than 5% of GHB is excreted unchanged in the urine.[49]

Initial clinical effects of ingested GHB occur in 15–20 minutes and peak in 30–60 minutes.[6] The clinical manifestations of GHB follow a steep dose–response curve. Doses of 20–30 mg/kg create euphoria, memory loss, and drowsiness while doses of 40–60 mg/kg result in coma.[20,43] Doses of 25 mg/kg given to naïve healthy subjects result in mean serum GHB concentration of 39.4 + 25.2 μg/mL (range 4.7–76.3 μg/mL).[6]

GBL undergoes conversion to GHB by a lactonase.[53,54] In comparison to GHB, GBL is more rapidly absorbed from the gastrointestinal tract and has a longer duration of action, both of which result from higher lipid solubility. 1,4-BD exerts its effects after conversion to GHB by alcohol dehydrogenase (ADH).[8,52] Co-ingestion with ethanol can prolong the onset of clinical effects because of competitive inhibition of ADH.[48,57]

In HIV patients taking protease inhibitors, GHB first-pass metabolism is altered such that low doses of GHB can produce toxic manifestations. This results from the interactions of the protease inhibitors on the cytochrome P450 system.[1,27]

■ CLINICAL MANIFESTATIONS

The clinical manifestations of GHB are mainly due to its effects on the CNS. Vital sign changes include bradycardia, hypotension, bradypnea, and hypothermia. Pupils may be miotic and poorly responsive to light. Acute toxicity typically results in CNS depression/coma, respiratory depression, salivation, vomiting, and sometimes myoclonus.[16,40] Of these findings, the most concerning is respiratory depression, as death has resulted from apnea.[9,39,78] Salivation and vomiting can complicate the respiratory depression leading to pulmonary aspiration in an unconscious patient. Case series also report aggressive and combative behavior, which may become more prominent in the setting of assessing the gag reflex or trying to endotracheally intubate the unconscious patient.[16,79] Motor manifestations can be confusing. Although GHB induces seizure activity (EEG changes and convulsions) in animal models, this has never been demonstrated in humans. More commonly GHB induces myoclonus that can be confused with convulsions.[18] The sedative effects of GHB are synergistic with ethanol and other sedative-hypnotics or CNS depressants. When 1,4-BD is used simultaneously with ethanol, the effects of the 1,4-BD are prolonged as ethanol competitively inhibits alcohol dehydrogenase thus preventing the conversion of 1,4-BD to GHB.

Other findings reported in patients taking prescribed therapeutic doses for narcolepsy include confusion, abnormal thought processes, and depression.[77] The most common adverse effects reported in these patients using prescribed GHB include nausea, dizziness, headache, vomiting, and urinary incontinence.[77]

Electrocardiographic findings include sinus bradycardia and prominent U waves which may be related to the sinus bradycardia. Other standard laboratory tests are typically normal.[9]

Recovery from overdose occurs rapidly, typically in less than 6–8 hours, and patients often extubate themselves following rapid improvement of their level of consciousness. No sequelae should be expected if hypoxia or aspiration did not occur.

Frequent GHB users can develop both tolerance and dependence to GHB.[21,61] Such patients typically use GHB or one of its analogs every

2–4 hours over a prolonged period of time, with cumulative daily doses in the range of 10 grams or more.[44] In rats receiving doses of GHB every 3 hours for up to 6 days tolerance was observed.[2] Although the exact mechanism is unknown, tolerance may be the result of the induction of GHB metabolism and a decrease in CNS sensitivity.[70]

DIAGNOSTIC TESTING

Routine "screens" for drugs of abuse do not typically include analysis for GHB. Specific testing for GHB and its related substances usually is not requested unless there is suspicion of its use associated with drug-facilitated sexual assault. However, urine and serum testing can also be performed if needed for forensic purposes. Gas chromatography-mass spectrometry (GC/MS) is the test of choice for both urine and serum. GHB can be detected in the urine up to 12 hours after use.[6] Interpretation of these tests must include cutoff concentrations as GHB, GBL, and 1,4-BD also occur naturally. These cutoff concentrations must be able to distinguish endogenous production and therapeutic use (as in patients using prescribed GHB for narcolepsy) from abuse or misuse. Attempts to relate concentrations to clinical effects in any individual might not be valid, however, when used chronically and when tolerance develops. Due to rapid metabolism and elimination, concentrations return to baseline shortly after drug naïve patients become clinically normal. Endogeneous GHB urine concentrations are usually less than 5–10 μg/mL while endogeneous GHB serum concentrations are usually less than 5 μg/mL.[6] In patients receiving a 25 mg/kg dose of GHB, plasma GHB concentrations ranged from 4.7 μg/mL to 76.3 μg/mL 20–45 minutes after administration and urine concentrations from below the detection limit to 840 μg/mL. In general, loss of consciousness occurs when serum concentrations reach 50 μg/mL, and deep coma when concentrations rise above 260 μg/mL.[59]

Screening for GHB may also routinely be performed when specific genetic or metabolic disorders are of concern. In particular, elevated GHB concentrations on a urinary organic acid screen in a child may indicate a succinic semialdehyde dehydrogenase deficiency. These children have developmental delay, seizures, hypotonia and elevated GHB concentrations in the blood, urine, and CSF.[50] One case report reveals a child with a serum GHB concentration of 775 μg/mL, significantly higher than most patients with exogenous GHB poisoning.[31]

Other routine tests in patients with depressed levels of consciousness include a rapid evaluation of blood glucose, an ethanol concentration as clinically indicated, and an ECG. When intentional overdose or self-harm is suspected, a determination of serum acetaminophen concentration is also indicated. Other studies should be obtained based on the clinical condition of the patient.

MANAGEMENT

Supportive care is the mainstay of therapy for GHB toxicity. All patients presenting to the hospital should have their airway, breathing, and circulation assessed initially. Patients with GHB toxicity may require airway protection in the presence of profound coma and respiratory depression or apnea. However, many become combative during the intubation process. Supportive care with a nasal airway may suffice in the snoring patient who has an appropriate gag and respiratory function. The need for endotracheal intubation is a bedside clinical decision and should be based on the patient's ability to oxygenate and ventilate, especially when diagnosis is known or highly suspected as recovery is expected shortly. Atropine may be given as needed for severe bradycardia. However, in most instances, the bradycardia does not need to be treated in otherwise healthy patients. An IV catheter

should be established and intravenous fluids infused as necessary for hypotension. Patients should be warmed if they are hypothermic.

There is no role for gastric decontamination in patients with GHB toxicity as GHB is rapidly absorbed from the gastrointestinal tract. The increased risk of vomiting and aspiration also limits any beneficial role of gastric decontamination. If a co-ingestant is present, appropriate decontamination methods may be employed if there are no contraindications to their use.

Other therapies such as dextrose and thiamine should be administered as clinically indicated. Some proposed antidotes include physostigmine, naloxone, and flumazenil. All of these antidotes lack a pharmacologic basis for use and may place the patient at increased risk as other drugs of abuse commonly used with GHB may interact with these medications. An animal model did not support the use of physostigmine in GHB intoxication,[3] nor did a systematic literature review.[68] Naloxone can be administered to the patient with respiratory and CNS depression in the setting of unknown or presumed overdose. In GHB-toxic patients, naloxone administration is largely unsuccessful at improving clinical status.[39]

Those patients whose symptoms resolve may be discharged from the hospital following appropriate psychosocial evaluation for abuse and dependency. All patients who do not follow the expected course of resolution of their clinical manifestations (in approximately 6 hours) should be admitted to the hospital and investigated for other potential etiologies.

GHB WITHDRAWAL

Patients who use GHB or its analogs daily in large quantities can develop dependence.[21] Such patients are prone to withdrawal if they abruptly cease or decrease their daily dose. In patients prescribed GHB for narcolepsy, withdrawal rarely develops when the GHB is used as prescribed as the recommended doses are low and given only at night.[66,77] The majority of patients with GHB withdrawal are body builders.

GHB withdrawal is similar to ethanol and benzodiazepine withdrawal. It can be severe and potentially life threatening. The onset of withdrawal typically occurs 1–6 hours after last use. Men appear to be more commonly affected than women.[44] Manifestations of withdrawal include tachycardia, hypertension, tremors, agitation, dysphoria, nausea/vomiting, auditory and visual hallucinations, and seizures.[17,21,44,66]

For acute withdrawal symptoms, benzodiazepines and supportive care are the mainstays of therapy.[44,66] Rapid cooling, intravenous fluids, and evaluation for other medical or traumatic illnesses should be performed. These patients may require large doses of benzodiazepines to control symptoms. In patients with withdrawal symptoms refractory to benzodiazepines, barbiturates and propofol can be considered.[44,60,66] In these refractory patients, endotracheal intubation may be required (see Chap. 14, Withdrawal Principles).

SUMMARY

GHB is a unique xenobiotic because it occurs naturally as an endogenous neurotransmitter, is a licensed pharmaceutical, as well as a drug of abuse. GHB, GBL, and 1,4-BD result in GHB toxicity through complex neuropharmacological effects. GHB toxicity rarely results in death when patients are treated with supportive care. A life-threatening withdrawal syndrome can occur with cessation or decreased use of the drug and its related analogs. This withdrawal syndrome should be treated in a manner similar to ethanol withdrawal or sedative-hypnotic withdrawal. With appropriate care of both acute intoxication and withdrawal, patients can recover without sequelae, but psychosocial care and referral for management of abuse or dependency is essential.

CHAPTER 81
INHALANTS

Heather Long

Inhalant abuse is defined as the deliberate inhalation of vapors for the purpose of changing one's consciousness or becoming "high." It is also referred to as volatile substance abuse and was first described in 1951.[32] Inhalants are appealing to adolescents because they are inexpensive, readily available, and sold legally. Initially, inhalant abuse was viewed as physically harmless, but reports of "sudden sniffing death" began to appear in the 1960s.[9] Shortly thereafter, evidence surfaced of other significant morbidities, including organic brain syndromes, peripheral neuropathy, and withdrawal.

EPIDEMIOLOGY

The demographics of inhalant abuse differ markedly from those of other traditional substances of abuse. The 2003 National Survey on Drug Use and Health found that more than 2.6 million youths between the ages of 12 and 17 years used inhalants at least once in their lifetime.[122] Inhalants were the most frequently reported illicit xenobiotics used in the past year by 12- and 13-year-old adolescents, and youths aged 12 to 17 years continued to report higher rates of past-year use than did adults aged 18 years and older. The lifetime prevalence of inhalant use peaked among 8th graders at 15.6%. The median age of first use is 13 years.[7] A worrisome trend reported by the 2007 Monitoring the Future Study is that perceived risk of even one-time use of an inhalant has fallen steadily since 2001.[89]

Although long considered to be a problem among boys, there has been a steady increase of inhalant abuse among girls, and their lifetime prevalence now equals that of boys.[11] In the United States, the problem is greatest among children of lower socioeconomic groups, and non-Hispanic white adolescents are the most likely and black adolescents the least likely to use inhalants.[85] Although inhalant use is a problem in both urban and rural communities, its prevalence is higher in rural settings.[116] This may relate to the easier access that teens in urban areas have to other drugs of abuse.

Inhalant abuse includes the practices of sniffing, huffing, and bagging. *Sniffing* entails the inhalation of a volatile substance directly from a container, as occurs with airplane glue or rubber cement. *Huffing* involves pouring a volatile liquid onto fabric, such as a rag or sock, and placing it over the mouth and/or nose while inhaling and is the method used by more than 60% of volatile-substance abusers.[85] *Bagging* refers to instilling a solvent into a plastic or paper bag and rebreathing from the bag several times; spray paint is among the xenobiotics commonly used with this method. A newly reported form of abuse, *"dusting,"* refers to the inhalation of compressed air cleaners containing halogenated hydrocarbons (eg, CRC Dust Off™), marketed for cleaning computers and electronics equipment. Reports of such exposures, including death and ventricular dysrhythmias, doubled in 2005 and tripled in 2006, yet dusting is not perceived to be harmful by users and, surprisingly, many users do not consider it a form of inhalant abuse.[84]

XENOBIOTICS COMMONLY USED

There are myriad xenobiotics abused as inhalants (Table 81–1), most of which are volatile hydrocarbons. Hydrocarbons are organic compounds comprised of carbon and hydrogen atoms and are divided into two basic categories: aliphatic (straight, branched, or cyclic chains) and aromatic. Most of the commercially available hydrocarbon products are mixtures of hydrocarbons; for example, gasoline is a mixture of aliphatic and aromatic hydrocarbons that may consist of more than 1500 compounds. Substituted hydrocarbons contain halogens or other functional groups such as hydroxyl or nitrite that are substituted for hydrogen atoms in the parent structure. Solvents are themselves a heterogeneous group of xenobiotics that are used to dissolve other chemical compounds or provide a vehicle for their delivery.

The most commonly inhaled volatile hydrocarbons are fuels, such as gasoline, and solvents, such as toluene.[116] Other commonly inhaled hydrocarbon-containing products include spray paints, lighter fluid, air fresheners, and glue. The choice of xenobiotic used likely reflects their availability: cases from the 1970s frequently reported abuse of antiperspirants and typewriter correction fluid. Now, abuse of computer and electronics cleaners is on the rise. In most reported cases of inhalant use, the inhalant is identified not by its chemical name (eg, butane, toluene) but rather by its form (eg, lighter fluid, paint thinner). Because exact components may vary between commercial products, this method is inaccurate and imprecise.

Although volatile alkyl nitrites are technically substituted hydrocarbons, they have pharmacologic and behavioral effects, as well as patterns of abuse, that are distinct from the other volatile hydrocarbons. For this reason, researchers usually classify them as a separate category among abused inhalants. Amyl nitrite is the prototypical volatile alkyl nitrite.[7] Amyl nitrite became popular in the 1960s with the appearance of "poppers," small glass capsules containing the chemical in a plastic sheath or gauze. When crushed, the ampules release the amyl nitrite. When nonprescription sales of amyl nitrite were restricted in 1968, sex and drug paraphernalia shops began selling small vials of butyl and isobutyl nitrites marketed as room deodorizers or liquid incense.[7,80] Because of further restrictions on sales of alkyl nitrites, most of these products now contain chemicals that are not technically alkyl nitrites, such as cyclohexyl nitrite.[7]

The most commonly used nonhydrocarbon inhalant is nitrous oxide. Nitrous oxide, or "laughing gas," is used medicinally as an inhalational anesthetic. It is the propellant in supermarket-bought whipped cream canisters, and cartridges of the compressed gas are sold for home use in whipped cream dispensers. These battery-sized metal containers of compressed gas may be used as "whippits," in which the container is punctured using a device known as a "cracker," and the escaping gas is either inhaled directly or collected in a balloon and then rebreathed.

PHARMACOLOGY

Although chemically heterogeneous, inhalants are generally highly lipophilic and gain rapid entrance into the central nervous system (CNS). Little is known about the cellular basis of the effects of inhalants. Evidence to date shows that the most commonly abused hydrocarbons have molecular mechanisms similar to those of other classic CNS depressants with frequently overlapping cellular sites of action. Their effects are probably best represented by the model for ethanol in which multiple different cellular mechanisms explain diverse pharmacologic and toxicologic effects.[7]

■ VOLATILE HYDROCARBONS

The clinical effects of the volatile hydrocarbons are likely mediated through stimulation of inhibitory neurotransmission within the CNS. Like ethanol, toluene, trichloroethane (TCE), and trichloroethylene enhance γ-aminobutyric acid type A (GABA$_A$) receptor–mediated synaptic currents as well as glycine receptor–activated ion function. Stimulation of

TABLE 81–1. Common Inhalants and the Constituent Xenobiotics

Inhalant	Chemical
Glues/adhesives	Toluene, *n*-hexane, benzene, xylene, trichloroethane, trichloroethylene, tetrachloroethylene, ethyl acetate, methylethyl ketone, methyl chloride
Spray paint	Toluene, butane, propane
VCR head cleaner	Ethyl chloride
Computer keyboard duster	Difluoroethane, tetrafluoroethane
Hair spray, deodorants, air fresheners	Butane, propane, fluorocarbons
Cigarette lighter fluid	Butane
Paint thinner	Toluene, methylene chloride, methanol
Gasoline	Aliphatic and aromatic hydrocarbons
Carburetor cleaner	Methanol, methylene chloride, toluene, propane
Dry cleaning agents, spot removers, degreasing agents	Tetrachloroethylene, trichloroethane, trichloroethylene
Typewriter correction fluid	Trichloroethane, trichloroethylene
Nail polish remover	Acetone
Paints, lacquers, varnishes	Trichloroethylene, toluene, *n*-hexane
"Poppers"	Amyl nitrite, isobutyl nitrite
Room deodorizers	Butyl nitrite, isobutyl nitrite, cyclohexyl nitrite
Whipped cream dispensers, "whippits"	Nitrous oxide

these receptors acts to increase chloride permeability, hyperpolarizing the neuronal cell membrane and inhibiting excitability.[13,62,118] Despite very different molecular structures, ethanol, enflurane, chloroform, toluene, and TCE compete for binding sites at α_1 glycine receptors.[12] Like ethanol, toluene, TCE, and benzene all also interfere with glutamate-mediated excitatory neurotransmission by inhibiting *N*-methyl-D-aspartate (NMDA) receptor–mediated currents in a concentration-dependent manner.[6,34,102] Furthermore, repeated toluene exposure increases NMDA receptors, suggesting that chronic exposure can lead to upregulation of NMDA receptors as occurs with alcohol.[6,138]

Toluene is the prototypical volatile hydrocarbon and the best studied. In animal models, differences in pharmacologic action are demonstrated between toluene and other alkylbenzenes, and halogenated hydrocarbons such as TCE, and acetone.[19,34,126] These differences may represent evidence that specific cellular sites for their actions exist. Additionally, these differences may explain the variation in their abuse potential or their clinical effects.[7] Despite these distinctions, there are marked similarities in the behavioral and pharmacologic effects of the volatile hydrocarbons. Moreover, the clinical effects profile shared by the volatile hydrocarbons, subanesthetic concentrations of general anesthetics, ethanol, and benzodiazepines suggests that they share cellular mechanisms. Shared clinical effects include anxiolytic effects,[23] anticonvulsant effects,[140] impaired motor coordination,[92] and evidence of physical dependence on withdrawal.[40,41]

Most research on inhalants has focused on the neural basis of their effects, yet it is the cardiotoxicity that is responsible for the majority

of their lethal effects. In vivo, toluene reversibly inhibits myocardial voltage-activated sodium channels.[35] Similarly, it inhibits muscle sodium channels but with less potency.[48] Ethanol and toluene have opposite effects on potassium channels in vivo; ethanol potentiates the large conductance, calcium-activated potassium channels as well as certain G-protein-coupled inwardly rectifying potassium channels while toluene inhibits them.[37] This inhibition of the sodium channels and the inwardly rectifying potassium channels is postulated to play a role in cardiac dysrhythmias and sudden sniffing death associated with the aromatic and halogenated hydrocarbons. Animal studies show toluene and 1,1,1-trichloroethane produce biphasic dose–response curves for motor activity: low concentrations yield motor excitation while high concentrations produce sedation, motor impairment, and anesthesia.[20,133] Molecular mechanisms underlying both the neural and cardiac effects may optimize the conditions and explain the observed clinical phenomenon described in sudden sniffing deaths (see below).

There are scant data on the pharmacokinetics of the inhalants. Most data are derived from studies on occupational and environmental exposures and have limited applicability to intentional inhalation. More relevant to the understanding of inhalants are the similarities with the inhalational anesthetic agents, many of which are also halogenated hydrocarbons. Factors determining pharmacokinetic and pharmacodynamic effects of a given inhalational anesthetic include its concentration in inspired air; partition coefficient; interaction with other inhaled substances, alcohol, and drugs; the patient's respiratory rate and blood flow; their percent body fat; and individual variation in drug metabolism (Chap. 67).[52]

Partition coefficients measure the relative affinity of a gas for two different substances at equilibrium and are used to predict the rate and extent of uptake of an inhaled substance. The blood:gas partition coefficient is most commonly referenced. The higher the number, the more soluble the substance is in blood. Substances with a low blood:gas partition coefficient, like nitrous oxide, are rapidly taken up by the brain and, conversely, are rapidly eliminated from the brain once exposure is ended (Table 81–2).

In a rodent model of inhalation abuse of toluene and acetone, the rapidity of onset and the depth of CNS depression were dependent on the concentration of the solvent inhaled.[26] There was a parallel relationship between brain concentration and pharmacologic effect during induction (inhalation) and postexposure. Brain and liver concentrations dropped rapidly after exposure; concentration in blood decreased at the slowest rate. Elimination was biphasic: rapid elimination during the first step was a result of tissue redistribution, alveolar ventilation, and metabolic clearance. During the second phase there was a slow decrease in tissue concentrations as a result of the gradual mobilization from adipose tissue with subsequent exhalation or metabolism. Acetone, which is more water soluble than toluene, is less potent and more slow acting than toluene, but is eliminated much more slowly than toluene and has a much longer duration of action.[26] Positron emission tomography (PET) studies using (^{11}C) radiolabeled toluene, butane, and acetone in nonhuman primates showed rapid uptake of radioactivity in striatal and frontal regions of the cortex followed by rapid clearance from the brain.[49] Whole-body PET scans in mice showed excretion through the kidneys and liver.[50]

The inhalants are eliminated unchanged via respiration, undergo hepatic metabolism, or both (see Table 81–2). For some, the percentage that is metabolized versus eliminated unchanged varies with the exposure dose. Nitrous oxide and the aliphatic hydrocarbons are frequently eliminated unchanged in the expired air. The aromatic and halogenated hydrocarbons are metabolized extensively via the cytochrome P450 (CYP) system, particularly CYP2E1, which has a substrate spectrum that includes a number of aliphatic, aromatic, and halogenated hydrocarbons.[17,57,58,141] Extrahepatic expression of CYP2E1 occurs to

TABLE 81–2. Blood:Gas Partition Coefficients, Routes of Elimination, and Important Metabolites of Selected Inhalants

Xenobiotic	Blood:Gas Partition Coefficient (98.6°F/37°C)	Routes of Elimination	Important Metabolites
Acetone	243–300	Largely unchanged via exhalation 95% and urine 5%	None
n-Butane	0.019	Largely unchanged via exhalation	None
Carbon tetrachloride	1.6	50% unchanged via exhalation; 50% hepatic metabolism and urinary excretion	CYP2E1 to trichloromethyl radical, trichloromethyl peroxy radical, phosgene
n-Hexane	2	10%–20% exhaled unchanged; hepatic metabolism and urinary excretion	CYP2E1 to 2-hexanol, 2,5-hexanedione, γ-valerolactone
Methylene chloride	5–10	92% exhaled unchanged; hepatic metabolism and urinary excretion	(1) CYP2E1 to CO and CO_2 (2) Glutathione transferase to CO_2, formaldehyde, and formic acid
Nitrous oxide	0.47	>99% exhaled unchanged	None
Toluene	8–16	<20% exhaled unchanged; >80% hepatic metabolism and urinary excretion	CYP2E1 to benzoic acid, then (1) glycine conjugation to form hippuric acid (68%) (2) glucuronic acid conjugation to benzoyl glucuronide (insignificant pathway except following large exposure to toluene)
1,1,1-Trichloroethane	1–3	91% exhaled unchanged; hepatic metabolism and urinary excretion	CYP2E1 to trichloroethanol, then (1) conjugated with glucuronic acid (urochloralic acid) or (2) further oxidized to trichloracetic acid
Trichloroethylene	9	16% exhaled unchanged; 84% hepatic metabolism and urinary excretion	CYP2E1 to epoxide intermediate (transient); chloral hydrate (transient); trichloroethanol (45%), trichloroacetic acid (TCA) (32%). Urinary TCA peaks 2–3 days postexposure
1,2-dichloro-1,1-difluoroethane	NA	NA	CYP2E1 to 2-chloro-2,2-difluoroethyl glucuronide, 2-2chloro-2,2-difluoroethyl sulfate, chlorodifluoroacetic acid, chlorodifluoroacetaldehyde hydrate, chlorodifluoroacetaldehyde-urea adduct, and inorganic fluoride. No covalently bound metabolites to liver proteins

NA = Not available

a lesser extent but may be of toxicologic significance, particularly in the kidneys and the dopaminergic cells of the substantia nigra.[18,63,129] In humans, there appear to be no significant gender differences in CYP2E1; however, it is polymorphic and, as such, allelic distributions vary among different human populations.[18,114] Moreover, this polymorphism may explain the varying degrees of toxicity exhibited following inhalant abuse.

Reward and reinforcement effects of inhalants are readily demonstrated. While the mechanisms underlying their reinforcement behavior remain poorly studied, activation of the mesolimbic dopamine system is thought to play an important role in this as with more commonly studied drugs of abuse.[50,105]

◼ VOLATILE ALKYL NITRITES

Unlike other volatile hydrocarbons, the volatile alkyl nitrites are not thought to have any direct effects on the CNS. Their effects are mediated through smooth muscle relaxation in the central and peripheral vasculature and they share a common cellular pathway with other nitric oxide (NO) donors similar to nitroglycerin and sodium nitroprusside.[71] A rat model of inhalation of isobutyl nitrite found a half-life of 1.4 minutes with almost 100% biotransformation to isobutyl alcohol. Bioavailability following inhalation was estimated to be 43%.[70]

◼ NITROUS OXIDE

The pharmacokinetics and pharmacodynamics of nitrous oxide (N_2O) abuse are derived from its use as an inhalation anesthetic. Anesthetic uptake or induction, as well as emergence with N_2O, is rapid because of its low solubility in blood, muscle, and fat.[119] There is no appreciable metabolism of N_2O in human tissue. An animal study found N_2O significantly inhibited excitatory NMDA-activated currents and had no effect on GABA-activated currents.[64] N_2O also stimulates dopaminergic neurons, but the significance of this in mediating its anesthetic effects remains unclear.[68,93]

Animal studies suggest the analgesic effects (or more accurately the antinociceptive effects because it refers to animals) of N_2O appear to be mediated through opioid peptide release in the midbrain. These antinociceptive effects can be reversed by the opioid antagonist naloxone.[15] However, in humans the anesthetic effects are not attenuated by naloxone, and the subjective and psychomotor effects of N_2O are not extinguished by even high doses of naloxone.[115,142]

CLINICAL MANIFESTATIONS

Signs and symptoms of inhalant use may be subtle, tend to vary widely among individuals, and generally resolve within several hours of exposure. Following acute exposure, there may be a distinct odor of

the abused inhalant on the patient's breath or clothing. Depending on the inhalant used and the method, there may be discoloration of skin around the nose and mouth. Mucous membrane irritation may cause sneezing, coughing, and tearing. Patients may complain of dyspnea and palpitations. Gastrointestinal complaints include nausea, vomiting, and abdominal pain. After an initial period of euphoria, patients may have residual headache and dizziness.

■ VOLATILE HYDROCARBONS

The CNS is the intended target of the inhalants and is most susceptible to its adverse effects. Initial CNS effects include euphoria and hallucinations, both visual and auditory, as well as headache and dizziness. As toxicity progresses, CNS depression worsens and patients may develop slurred speech, confusion, tremor, and weakness. Transient cranial nerve palsies are reported.[124] Further CNS depression is marked by ataxia, lethargy, seizures, coma, and respiratory depression. These acute encephalopathic effects generally resolve spontaneously and associated neuroimaging abnormalities are not reported.[43]

As can be expected, given the high lipophilicity of most inhalants, toxicity from chronic use is manifested most strikingly in the CNS. Toluene leukoencephalopathy, characterized by dementia, ataxia, eye movement disorders, and anosmia, is the prototypical manifestation of chronic inhalant neurotoxicity. Patients with toluene leukoencephalopathy display characteristic neurobehavioral deficits reflecting white matter involvement: inattention, apathy, and impaired memory and visuospatial skills with relative preservation of language.[43] Autopsy studies reveal white matter degeneration including cerebral and cerebellar atrophy and thinning of the corpus callosum.[72,106] On microscopy, there is diffuse demyelination with relative sparing of the axons. Abundant perivascular macrophages containing coarse or laminar myelin debris found in areas of the greatest myelin loss is a characteristic pathologic feature.[43] This targeting of myelin, which is 70% lipid, may be explained by toluene's lipophilicity.[43] As myelination continues at least through the second decade of life, the typical toluene abuser who begins inhaling during adolescence may be particularly susceptible to its toxic CNS effects.[42] Advances in magnetic resonance imaging (MRI) with gadolinium, which allow enhanced visualization of the cerebral white matter, demonstrate that the extent of white matter injury in the brain directly corresponds to the clinical severity of toluene leukoencephalopathy.[43] It is postulated that reactive oxygen species generated either by toluene or its metabolite benzaldehyde induce lipid peroxidation in the brain.[82,104] Genetic polymorphisms and host susceptibility among chronic abusers are also hypothesized to play a role.[54]

Acute cardiotoxicity associated with hydrocarbon inhalation is manifested most dramatically in "sudden sniffing death." In witnessed cases, sudden death frequently occurred when sniffing was followed by some physical activity. Examples include running or wrestling or a stressful situation like being caught sniffing by parents or police.[9] It is thought that the inhalant "sensitizes the myocardium" by blocking the potassium current (I_{KR}), thereby prolonging repolarization.[95] This produces a substrate for dysrhythmia propagation; the activity or stress then causes a catecholamine surge that initiates the dysrhythmia (Chap. 23).[95] Cardiac dysrhythmias following the inhalation of hydrocarbons were documented with the halogenated inhalational anesthetics in the early 1900s, and this association was subsequently confirmed in both animal and human studies.[44,125]

More typically, the clinical presentation of a patient with hydrocarbon cardiotoxicity may include palpitations, shortness of breath, syncope, and electrocardiographic (ECG) abnormalities, including atrial fibrillation, premature ventricular contractions, QT interval prolongation, and U waves.

Multiple case reports of ventricular fibrillation follow intentional inhalation of other hydrocarbons such as butane fuel,[56,137] Freon (Dupont

trade name for fluorinated hydrocarbons), and Glade Air Freshener (SC Johnson), which contains a mixture of short-chain aliphatic hydrocarbons.[77] Among 44 patients with a history of inhalant abuse, specifically toluene exposure, the QT interval and corrected QT dispersion were significantly greater than in healthy controls. Furthermore, the QT interval and corrected QT dispersion were significantly greater in the 20 toluene abusers with a history of unexplained syncope than in asymptomatic abusers and controls.[2] Although cardiotoxic effects of inhalant abuse are generally acute, dilated cardiomyopathy is reported with chronic abuse of toluene and with trichloroethylene.[86,139] Microscopy reveals evidence of chronic myocarditis with fibrosis.[139]

The primary respiratory toxicity complication of inhalational abuse is hypoxia, which is either caused by rebreathing of exhaled air, as occurs with bagging, or displacement of inspired oxygen with the inhalant, reducing the fraction of inspired oxygen (F_{IO_2}). Direct pulmonary toxicity associated with inhalants is most often a result of inadvertent aspiration of a liquid hydrocarbon (Chap. 106). Aspiration injury is associated with acute lung injury and the acute respiratory distress syndrome, a continuum of lung injury characterized by increased permeability of the alveolar–capillary barrier and the resulting influx of edema into the alveoli, neutrophilic inflammation, and an imbalance of cytokines and other inflammatory mediators.[132] Reports of asphyxiation initially ascribed to inhalant abuse were later found caused by suffocation by a plastic bag, mask, or container pressed firmly to the face, and not specifically by toxicity of the inhaled vapor.[9,29,131]

Irritant effects on the respiratory system are frequently transient, but patients may develop chemical pneumonitis. This syndrome is characterized by tachypnea, fever, tachycardia, crackles, rhonchi, leukocytosis, and radiographic abnormalities, including perihilar densities, bronchovascular markings, increased interstitial markings, infiltrates, and consolidation. Rebreathing of exhaled air, as occurs with bagging, may lead to hypercapnia and hypoxia. Acute eosinophilic pneumonia following abuse of a fabric protector containing 1,1,1-trichloroethane is also reported.[69] Barotrauma presents as pneumothorax, pneumomediastinum, or subcutaneous emphysema.[109]

Hepatotoxicity is associated with exposure to halogenated hydrocarbons, particularly carbon tetrachloride, but also chloroform, trichloroethane, trichloroethylene, and toluene.[81] Intentional inhalation of carbon tetrachloride is rarely reported, but its toxic metabolite, the trichloromethyl radical, created by the cytochrome CYP2E1, can covalently bind to hepatocyte macromolecules and cause lipid peroxidation.[103] The resultant depletion of glutathione and the potentially fatal centrilobular necrosis mimic acetaminophen toxicity and have led to a postulated role for N-acetylcysteine (NAC) and its use is suggested. Animal studies on the efficacy of NAC in preventing carbon tetrachloride–induced hepatoxicity have yielded mixed results.[33,36] There are no clinical trials in humans, but case series suggest a protective role for NAC.[107] Two cases of centrilobular hepatic necrosis following inhalation of trichloroethylene are reported. In a case series of 34 serum-confirmed inhalant deaths, two of the three who died from trichloroethane and trichloroethylene inhalation had cirrhosis of the liver at autopsy. None of the victims of other inhalants had liver cirrhosis.[47] Inhalation of either toluene or one of the many halogenated hydrocarbons is associated with elevated liver enzymes and hepatomegaly that generally return to baseline within 2 weeks of abstinence.[5,61,66,76,94,97]

Most reported renal toxicity is associated with toluene inhalation. Traditionally, prolonged toluene inhalation was said to cause a distal renal tubular acidosis (RTA), resulting in hypokalemia. However, distal RTA is associated classically with a hyperchloremic metabolic acidosis and a normal anion gap, whereas toluene abuse may be associated with an increased anion gap. Production of hippuric acid, a toluene metabolite, plays an

important role in the genesis of the metabolic acidosis.[30] Hippurate excretion, usually expressed as a ratio to creatinine, rises dramatically with toluene inhalation.[87] The excretion of abundant hippurate in the urine unmatched by ammonium mandates an enhanced rate of excretion of sodium and potassium cations. Continued loss of potassium in the urine leads to hypokalemia. Toluene is rapidly metabolized to hippuric acid, and the hippurate anion is swiftly cleared by the kidneys, leaving the hydrogen ion behind. This prevents the rise in the anion gap that would normally occur with an acid anion other than chloride, resulting in a normal anion gap. In some cases, the loss of sodium causes extracellular fluid volume contraction and a fall in the glomerular filtration rate, which may transform the metabolic acidosis with a normal anion gap into one with a high anion gap caused by the accumulation of hippurate and other anions.[30] Through unclear mechanisms, other renal abnormalities occur with toluene inhalation, including hematuria, albuminuria, and pyuria. Glomerulonephritis associated with hydrocarbon inhalation is also reported and is a result of antiglomerular basement membrane antibody-mediated immune complex deposition.[14,128,143]

Toluene-abusing patients may present with profound hypokalemic muscle weakness. In a study of 25 patients admitted to the hospital following inhalant abuse, nine presented with muscle weakness. The mean serum potassium concentration was 1.7 mEq/L and six of these patients also had manifestations of rhabdomyolysis. Four patients were quadriplegic on presentation and of these, two were initially diagnosed erroneously with Guillain-Barré syndrome. The patients had inhaled toluene 6 to 7 hours per day for 4 to 14 days prior to presentation.[120]

Acute dermatologic and upper airway toxicity is associated with the inhalation of fluorinated hydrocarbons. First- and second-degree burns of the face, neck, shoulder and chest are reported in a 12-year-old-girl inhaling difluoroethane from a computer cleaner.[90] Pyrolysis of difluoroethane may yield hydrofluoric acid burns.[45] Vesicular lesions resembling frostbite and massive, potentially life-threatening edema of the oropharyngeal, glottic, epiglottic, and paratracheal structures are also reported.[1,73,84] This is caused by the cooling of the gas associated with its rapid expansion once it is released from its pressurized container. With chronic abuse of volatile hydrocarbons, patients may develop severe drying and cracking around the mouth and nose as a consequence of a defatting dermatitis known as "huffer's eczema." Other manifestations of chronic irritation include recurrent epistaxis, chronic rhinitis, conjunctivitis, halitosis, and ulceration of the nasal and oral mucosa.[87]

Bone mineral density was significantly lower in 25 adolescent chronic glue sniffers compared with that of healthy controls.[39] In a mouse model, chronic exposure to toluene significantly reduced bone mineral density.[4]

Methylene chloride (dichloromethane), most commonly found in paint removers and degreasers, is unique among the halogenated hydrocarbons in that it undergoes metabolism in the liver by CYP2E1 to carbon monoxide.[98] In addition to acute CNS and cardiac manifestations, inhalation of methylene chloride is associated with delayed onset and prolonged duration of signs and symptoms of carbon monoxide (CO) poisoning. The CO metabolite is generated 4 to 8 hours after exposure and its apparent half-life is 13 hours, significantly longer than that of CO following inhalation (Chap. 125).[8,121] Methanol toxicity is reported following intentional inhalation of methanol-containing carburetor cleaners.[46,78,83] Significant findings may include hyperemic discs on funduscopic examination, metabolic acidosis, and CNS and respiratory depression (Chap. 107). Methanol-containing carburetor cleaners may also contain significant amounts of toluene (43.8%), methylene chloride (20.5%), and propane (12.5%). These xenobiotics may potentiate CNS depression and contribute to the toxicity associated with these products.

Chronic inhalation of the solvent n-hexane, a petroleum distillate and a simple aliphatic hydrocarbon found, for example, in rubber cement, can cause a sensorimotor peripheral neuropathy. Toxicity is mediated via a metabolite, 2,5-hexanedione, that interferes with glyceraldehyde-3-phosphate dehydrogenase–dependent axonal transport, resulting in axonal death.[38] Numbness and tingling of the fingers and toes is the most common initial complaint; progressive, ascending loss of motor function with frank quadriparesis may ensue.[31] Sural nerve biopsy shows axonal swelling and axonal loss, with secondary loss of myelin, probably as a result of retraction by axonal swelling, and accumulation of neurofilaments.[74] Nerve conduction studies show marked conduction slowing and conduction block (Chap. 18).[31,74]

Reports of polyneuropathy associated with chronic gasoline inhalation date to the 1960s and describe a symmetric, progressive, sensorimotor neuropathy with occasional superimposed mononeuropathies.[27,67] Initially these deficits were attributed to the presence of tetraethyl lead as an "antiknocking" agent in gasoline, but cases following abuse of unleaded gasoline are also reported.[27,110] n-Hexane is present in gasoline in concentrations of up to 3% and is thought to be the likely mediator of gasoline neuropathy.[134]

Teratogenicity Fetal solvent syndrome (FSS) was first reported in 1979.[127] The authors described a 20-year-old primigravida with a 14-year history of solvent abuse defined as "daily" and "heavy" who gave birth to an infant exhibiting facial dysmorphia, growth retardation, and microcephaly, a constellation of findings that resembles fetal alcohol syndrome (FAS). Since then a number of cases and case series have been reported.[3,60,108,136] A general limitation of these case series is their reliance on self-reporting of substance abuse. In a number of cases included for analysis of teratogenic effects, mothers admit to use during pregnancy of other potential teratogens, including ethanol, cocaine, heroin, and phenobarbital.[3,136] Cases purported to represent inhalant abuse in the absence of other drug abuse, particularly ethanol, are not verified by laboratory testing. A small study of infants born to mothers with a self-reported history of chronic solvent abuse found 16% had major anomalies, 12.5% had facial features resembling FAS, and 3.6% had cleft palate.[108] Craniofacial abnormalities common to both FAS and FSS include small palpebral fissures, thin upper lip, and midfacial hypoplasia. Features of FSS that distinguish it from FAS include micrognathia, low-set ears, abnormal scalp hair pattern, large anterior fontanelle, and downturned corners of the mouth.[127] Hypoplasia of the philtrum and nose are more characteristic of FAS.[100] Compared with matched controls, infants born to mothers who report inhalant abuse are more likely to be premature, have low birth weight, have smaller birth length, and have small head circumference.[3,136] Follow-up studies of these infants show developmental delay when compared with children matched for age, race, sex, and socioeconomic status.[3,60] A rat model of toluene-abuse embryopathy found a significant reduction in the number of neurons within each cortical layer, as well as abnormal neural migration.[53] In animal models of inhalant abuse, exposure to brief, repeated, high concentrations of toluene significantly increases rates of growth restriction, minor malformations, and impaired motor development.[21,65] In another rat model of maternal inhalant abuse, toluene levels in fetal brain tissue, the placenta, and amniotic fluid increased in a concentration-dependent manner.[22]

Withdrawal Observed similarities in the acute effects of inhalants compared with other CNS depressants have suggested similar patterns of tolerance and withdrawal. Rodent models of inhalant abuse with toluene and TCE show evidence of physical dependence that manifests as an increase in handling-induced seizures on cessation of inhalation.[41,135] Additionally, these studies demonstrate cross-tolerance of the benzodiazepine diazepam with the motor-stimulating effects of TCE and, to a lesser degree, with toluene. Inhalant abusers have themselves described tolerance with weekly usage in as little as 3 months.[55] Withdrawal symptoms, including irritability, insomnia, craving, nausea, tremor, and dry mouth lasting 2 to 5 days after last use, are described.[112]

■ VOLATILE ALKYL NITRITES

Methemoglobinemia caused by inhalation of amyl, butyl, and isobutyl nitrites is well reported.[24,79] Nitrites are strong oxidants that may induce hemoglobin oxidation from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. Patients may present with signs and symptoms of methemoglobinemia including shortness of breath, cyanosis, tachycardia, and tachypnea (Chap. 127). Eye pain and transient increased intraocular pressure are reported following use of amyl nitrite.[99]

■ NITROUS OXIDE

Reported deaths associated with abuse of nitrous oxide (N_2O) appear to be caused by secondary effects of N_2O, including asphyxiation and motor vehicle collisions while under the influence, and not to direct toxicity.[123,131] Investigations following deaths associated with N_2O have found many of the dead were discovered with plastic bags over their heads, in an apparent attempt to both prolong the duration of effect and increase the concentration to heighten the effect.[131] Autopsy findings in these cases were consistent with asphyxiation: acute lung injury, cardiac petechiae, and generalized visceral congestion.[123,131] Laboratory simulation of a reported death in which the victim was found with a plastic bag over his head with a belt fastened loosely around his neck and a spent whipped cream canister within the plastic bag showed N_2O displaces oxygen in a closed space.[131] Additionally, N_2O concentrations in this simulation were greater than 60%; at concentrations of nitrous oxide greater than 50%, the normal hypoxic response is diminished.[131] The combined effects of displaced oxygen and a blunted hypoxic drive may increase the risk of asphyxia.

Chronic abuse of N_2O is associated with neurologic toxicity mediated via irreversible oxidation of the cobalt ion of cyanocobalamin (vitamin B_{12}). Oxidation blocks formation of methylcobalamin, a coenzyme in the production of methionine and S-adenosylmethionine, required for methylation of the phospholipids of the myelin sheaths. Additionally, cobalamin oxidation inhibits the conversion of methylmalonyl to succinyl coenzyme A. The resultant accumulation of methylmalonate and propionate can result in synthesis of abnormal fatty acids and their subsequent incorporation into the myelin sheath (Chap. 67).[101] Case reports and small case series in humans following self-reported chronic, heavy abuse of N_2O found development of myeloneuropathy resembling the subacute combined degeneration of the dorsal columns of the spinal cord of classic vitamin B_{12} deficiency.[16,75,130] Presenting signs and symptoms reflect varying involvement of the posterior columns, the corticospinal tracts, and the peripheral nerves. Numbness and tingling of the distal extremities is the most common presenting complaint. Physical examination may reveal diminished sensation to pinprick and light touch, vibratory sensation and proprioception, gait disturbances, the Lhermitte sign (electric shock sensation from the back into the limbs with neck flexion), hyperreflexia, spasticity, urinary and fecal incontinence, and extensor plantar response.[28,101] Among reported patients with N_2O-associated neurotoxicity who had documented levels of vitamin B_{12}, approximately 50% had low serum vitamin B_{12} concentrations.[16,28,75,117,130] In the few patients who underwent Schilling tests, results were normal.[75,130] Nerve conduction studies and electromyography typically revealed a distal, axonal sensorimotor polyneuropathy.[28,75,130]

LABORATORY AND DIAGNOSTIC TESTING

Routine urine toxicology screens are unable to detect inhalants or their metabolites. Although most volatile inhalants can be detected using gas chromatography, the likelihood of detection is limited by the dose, time to sampling, and method of specimen storage. Blood is the preferred

---

TABLE 81–3. Inhalants With Unique Clinical Manifestations	
Inhalant	Clinical Manifestations
Toluene	Hypokalemia; hepatotoxicity; leukoencephalopathy (chronic)
1,1,1-Trichloroethane, trichloroethylene	Hepatotoxicity
Methylene chloride	Carbon monoxide poisoning
Carburetor cleaner	Methanol poisoning
Alkyl nitrites (amyl, butyl, isobutyl)	Methemoglobinemia
n-Hexane	Peripheral neuropathy (chronic)
Nitrous oxide	Myeloneuropathy (chronic)

---

specimen, but urinalysis for metabolites and hippuric acid (for toluene) may extend the time until the limit of detection is reached.[25] Specimens should be stored at a temperature between 23°F (−5°C) and 39.2°F (4°C).[25] Testing is not readily available at most institutions and the need to send the specimen to a reference laboratory limits the clinical utility in most situations. A thorough history and physical examination and careful questioning of the patient's friends and family are probably more helpful in cases of suspected inhalant abuse.

Depending on the patient's signs and symptoms, additional diagnostic testing may be indicated, including an ECG, chest radiograph, serum electrolytes, liver enzymes, and serum pH. Inhalation of some agents presents unique diagnostic considerations (Table 81–3). Routine laboratory testing, including cerebrospinal fluid analysis, is unremarkable in patients with inhalant-induced leukoencephalopathy. A computed tomography (CT) scan of the head is generally normal until late in the disease, when diffuse hypodensity of white matter becomes evident. T2-weighted MRI with its superior resolution of white matter is the diagnostic study of choice. Standard MRI does not detect initial changes caused by toluene leukoencephalopathy; measurement of N-acetyl aspartate (NAA), a marker of CNS axons, with magnetic resonance spectroscopy (MRS) may assist with earlier detection. A decrease in NAA concentration, usually expressed as the ratio of NAA to creatinine (NAA:Cr), may serve as a marker of axonal damage.[43]

MANAGEMENT

Management begins with assessment and stabilization of the patient's airway, breathing, and circulation (the "ABCs"). The patient should be attached to a pulse oximeter and cardiac monitor. Oxygen should be administered and the patient should be treated with nebulized β agonists if wheezing is present. Early consultation with a regional poison center or medical toxicologist may assist with identification of the xenobiotic and patient management.

Cardiac dysrhythmias associated with inhalant abuse carry a significantly poor prognosis. Sudden death following use is not limited to new users and there appears to be no premonitory signal to the user.[6,9,94] Life-threatening electrolyte abnormalities must be considered early and corrected in the patient presenting with dysrhythmia. Patients with nonperfusing rhythms should be managed following standard management with defibrillation. There are no evidence-based treatment guidelines for the management of inhalant-induced cardiac dysrhythmias, but β-adrenergic antagonists are thought to offer some cardioprotective effects to the sensitized myocardium.[95] Propranolol

and esmolol have both been used successfully in treatment of ventricular dysrhythmias following inhalant abuse.[51,91]

Fluid and electrolyte abnormalities should be sought and corrected early. In the course of management other complications, including methemoglobinemia, elevated carboxyhemoglobin, and methanol toxicity, should be managed with the appropriate antidotal therapy. Patients with respiratory symptoms that persist beyond the initial complaints of gagging and choking should be evaluated for hydrocarbon pneumonitis and treated supportively (Chap. 106).

With abstinence, behavioral and neuroimaging changes associated with toluene-induced leukoencephalopathy may be partially reversible early on; beyond a poorly defined period, changes are irreversible.[43] Cessation of abuse is the most important therapeutic intervention in patients with *n*-hexane–induced neuropathy and N_2O-induced myeloneuropathy; limited anecdotal evidence supports the coadministration of vitamin B_{12} (1000 μg intramuscularly) and methionine (1 g orally) in cases of N_2O-induced myeloneuropathy.[28,111,117]

Agitation, either from acute effects of the inhalant or from withdrawal, is safely managed with a benzodiazepine. In the vast majority of patients, symptoms resolve quickly and hospitalization is not required. The potential toxicity of inhalants should be reinforced and patients should be referred for counseling. Subsets of users, meeting the criteria for inhalant dependence and inhalant-induced psychosis, require inpatient psychiatric care. Pharmacotherapy with carbamazepine or the antipsychotics haloperidol or risperidone appears beneficial to some patients with an inhalant-induced psychotic disorder.[59,88] Case reports describe successful treatment of inhalant dependence with lamotrigine, which inhibits excitatory glutamatergic tone, and with buspirone, an atypical anxiolytic.[96,113] Drug use treatment programs for inhalant abuse are scarce and few providers have special training in this area.[10]

SUMMARY

Inhalants are a heterogeneous group of xenobiotics that include the volatile hydrocarbons, the alkyl nitrates, and nitrous oxide. The incidence of abuse is greatest among adolescents. The central nervous system is the intended target for the inhalant users; early effects include euphoria, hallucinations, headache, and dizziness. Acute cardiotoxicity is manifested most dramatically in "sudden sniffing death." Unique considerations and toxicity are associated with specific agents (see Table 81–3). Diagnosis is largely clinical; further diagnostic testing should be guided by the patient's presenting complaint. Management begins with basic life support and care is generally supportive. Cessation of use is the only known treatment for many manifestations of chronic toxicity.

CHAPTER 82
HALLUCINOGENS

Kavita M. Babu

The term "hallucinogen" describes a diverse group of xenobiotics that alter and distort perception, thought, and mood without clouding the sensorium. Hallucinogens can be categorized by their chemical structures, and further divided into natural and synthetic members of each family. The major structural classes of hallucinogens include the lysergamides, tryptamines (indolealkylamines), amphetamines (phenylethylamines), arylhexamines, cannabinoids, harmine alkaloids, belladonna alkaloids, and the tropane alkaloids. In addition, there are several unique hallucinogens, such as *Salvia divinorum*, nutmeg, kratom, and kava kava. This chapter focuses on lysergamides, tryptamines, phenylethlyamines, and these unique hallucinogens. More on the other classes can be found in Chap. 71 (Monoamine oxidase inhibitors), Chap. 75 (Amphetamines), Chap. 83 (Cannabinoids), and Chap. 85 (Phencyclidine and Ketamine).

HISTORY

The term "hallucination" may be defined as false perception that has no basis in the external environment. The term is derived from the Latin alucinari, "to wander in mind." While the term "psychedelic" has been used for years to refer to the recreational and nonmedical effects of hallucinogens, other terms, like entheogen and entactogen, frequently appear in Internet discussions. Entheogens are "substances which generate the god or spirit within," while entactogens create an awareness of "the touch within."[41] These terms all refer to the same xenobiotics, used with differing intent or in varying settings. Hallucinations differ from illusions, which are distorted perceptions of objects based in reality.

Hallucinogens have been used for thousands of years by many different cultures, largely during religious ceremonies. The ancient Indian holy book, *Rig-Veda*, written over 3500 years ago, describes a sacramental xenobiotic called Soma both as a god and as an intoxicating xenobiotic. Although debated for many years, the source of Soma is now believed to be the juice of the mushroom *Amanita muscaria*.[98,105] The Aztecs used the psilocybin-containing teonanacatl (flesh of the gods), and *Ololiuqui* (morning glory species) in their religious ceremonies. To this day, the Native American Church in the United States uses peyote in religious ceremonies.

Synthetic hallucinogen use is often said to have begun with the discovery of lysergic acid diethylamide, or LSD. The synthesis of LSD resulted from extensive research on the medicinal uses of ergot alkaloids derived from the fungus, *Claviceps purpurea*. From medieval times through recent years, several large-scale epidemics of vasospastic ischemia, gangrene, and hallucinations (collectively called ergotism) have resulted from *C. purpurea* contamination of cereal crops.[136] The hallucinations from *Claviceps* ingestion have been attributed to the ergot alkaloid lysergic acid amide from which LSD was chemically synthesized. *Claviceps purpurea* has been suggested, but subsequently disproved, as the cause of the mass hysteria leading up to the Salem witch trials. Many of these adverse effects after ingestion of *C. purpurea* have been attributed to the serotonergic agonist effects of the ergot alkaloids (see Chap. 51).[38]

In 1938, Albert Hofmann, a Swiss chemist, synthesized LSD-25, the twenty-fifth substance in a series of lysergic acid derivatives being researched as new arousal, or analeptic, agents. These lysergic acid compounds were based on ergot extracts from *C. purpurea*. Five years later, LSD-25 was "tested" when Hofmann had an unintentional exposure in his laboratory, and subsequently developed hallucinations.[62,117] Soon thereafter, Sandoz laboratories began marketing LSD under the trademark Delysid as an adjunct for analytic psychotherapy. In the 1950s, a small number of psychiatrists began using LSD to release the repressed memories of patients, and as an experimental model for schizophrenia.[124] The Central Intelligence Agency reportedly experimented with the use of LSD as a tool for interrogating suspected communists and as a mind-control agent.[23,117]

In the 1960s, the concept of the "fifth freedom" emerged. As individuals explored this "right" to alter their consciousness as they saw fit, LSD (also called acid) became a fashionable recreational drug. In one of the most famous slogans of the 1960s, Dr. Timothy Leary popularized LSD as a way to "Tune in, Turn on, Drop out."[117] By 1966, federal law banned the use of LSD.[91] Initial reports of LSD-induced chromosomal damage appeared in the 1960s.[31,64,75] However, further studies of pregnant women who had taken LSD did not demonstrate an increased risk of abortions nor birth defects.[44,72]

LSD use diminished in the late 1970s and early 1980s, perhaps due to users' concerns regarding potential health risks of brain damage, "bad trips," and flashbacks.[97] In the meantime, there was a rise in the use of the "designer" hallucinogens. Exploiting a loophole in drug enforcement laws, these synthetic tryptamine and amphetamine hallucinogens were chemically similar to, but legally distinct from, their outlawed counterparts.

A resurgence in LSD use was reported among high school teens in the late 1990s, with more prevalent use in suburbs than in cities.[92,106] In 1997, two studies of adolescents showed a lifetime prevalence of LSD use at 13% and 14%.[66,97] In 2000, Drug Enforcement Administration (DEA) agents seized an LSD-production lab and apprehended two men involved in massive production of LSD in Kansas. Their incarceration resulted in a more than 90% decrease in LSD availability nationwide.[126]

All-night dance clubs host "rave parties," at which emerging hallucinogens are popular.[13] While the impact of these parties on the growth of hallucinogens in the United States is unclear, many of the newer hallucinogens have been christened "club drugs" because of this association.[53] The Internet has developed as a vehicle for the rapid and facile sharing of information on the synthesis of emerging drugs, user experiences, and adverse effects. Additionally, the Internet marketplace has made many "herbal" hallucinogens widely available via unregulated web sites.[35]

EPIDEMIOLOGY

The 2006 National Survey on Drug Use and Health (NSDUH) reported the following trends in hallucinogen use: more than 23 million Americans over the age of 12 reported LSD use during their lifetime, 6.6 million had used phencyclidine (PCP), and 12 million reported previous methylenedioxymethamphetamine (MDMA) use. Additionally, 2.3 million people reported prior use of ketamine, while only 700,000 reported use of α-methyltryptamine (AMT), dimethyltryptamine (DMT), or 5-methoxy-dimethyltryptamine (5-MeO-DMT). About 1.8 million people reported use of *S. divinorum* during their lifetime. In the reported results, the 18 to 25 age group was most likely to report use of any of these hallucinogens within the previous year.[119] Table 82–1 presents the structural classifications of hallucinogens.

TABLE 82–1. Structural Classifications of Hallucinogens
Lysergamides
d-Lysergic acid diethylamide (LSD)
Lysergic acid hydroxyethylamide
Ipomoea violacea (Morning glory)
Ololiuqui (South American Morning glory)
Ergine
Argyreia nervosa (Woodrose)
Indolealkylamines/Tryptamines
5-Methoxy-*N,N*-dimethyltryptamine
N,N-Dimethyltryptamine
Psilocin
Psilocybin
Phenylethylamines
Mescaline
MDMA (3,4-methylenedioxymethamphetamine)
2C-B
2C-T-7
Tetrahydrocannabinoids
Marijuana
Hashish
Belladonna alkaloids
Jimsonweed (*Datura stramonium*)
Henbane (*Hyoscyamus niger*)
Deadly nightshade (*Atropa belladonna*)
Brugmansia spp
Miscellaneous
Kava Kava
Ketamine
Kratom
Nutmeg
Phencyclidine (PCP)
Salvia divinorum

■ LYSERGAMIDES

Lysergamides are derivatives of lysergic acid, a substituted tetracyclic amine based on an indole nucleus (Fig. 82–1). Naturally occurring lysergamides are found in several species of morning glory (*Rivea corymbosa, Ipomoea violacea*) and Hawaiian baby woodrose (*Argyreia nervosa*).[58] Morning glory seeds contain multiple alkaloids, including lysergic acid hydroxyethylamide and ergonovine. The morning glory seeds were called ololiuqui in ancient Mexico, where Aztecs and other indigenous populations used them in religious rites.[121] However, in one volunteer study, ololiuqui use caused sedation rather than hallucinations.[63] Both morning glory and Hawaiian baby woodrose seeds can be legally purchased for planting in garden stores, and on the Internet.

The synthetic lysergamide, LSD, is derived from an ergot alkaloid of the fungus, *C. purpurea*. Although four LSD isomers exist, only the d-isomer is active. Lysergic acid diethylamide is a water-soluble, colorless, tasteless, and odorless powder. Currently, LSD is usually sold as liquid-impregnated blotter paper, microdots, tiny tablets, "window pane" gelatin squares, liquid, powder, or tablets.[106] LSD users typically experience heightened awareness of auditory and visual stimuli with size, shape, and color distortions. Auditory and visual hallucinations may occur, as well as synesthesia, a confusion of the senses, where users may report "hearing colors, or seeing sounds".[126] Other more complex perceptual effects may include depersonalization and a sensation of enhanced insight or awareness. A "bad trip" may occur with larger doses of LSD and produce anxiety, bizarre behaviors, and combativeness.[126]

LSD is classified by the DEA as a Schedule I drug, with high abuse potential, lack of established safety even under medical supervision, and no known use in medical treatment.[126]

■ INDOLEALKYLAMINES (TRYPTAMINES)

Indolealkylamines, or tryptamines, represent a class of natural and synthetic compounds that structurally share a substituted monoamine group (Fig. 82–2). Endogenous tryptamines include serotonin and melatonin. Naturally occurring exogenous tryptamines include psilocybin, bufotenine, and DMT. Psilocybin is found in three major genera of mushrooms: *Psilocyba, Panaelous,* and *Conocybe*.[105] Other psychoactive mushrooms include *Amanita muscaria* and *Amanita pantherina*, which contain ibotenic acid, muscimol, and muscazone, which are unrelated to the tryptamines.[58] Hallucinogenic mushrooms
FIGURE 82–1. Hallucinogens of the lysergamide chemical class and their chemical similarity to serotonin.
FIGURE 82–2. Hallucinogens of the indolealkylamine chemical class and their chemical similarity to serotonin.

are discussed in Chap. 117. Psilocybin-containing mushrooms, or "magic mushrooms," grow in the Pacific Northwest and southern United States, usually in cow pastures. The mushroom may be recognized by a green-blue color that it assumes after bruising, but misidentification is common.[11]

N,N-Dimethyltryptamine (DMT) is a potent, short-acting hallucinogen. It is found naturally in the bark of the Yakee plant (*Virola calophylla*), which grows in the Amazon Basin and is used by shamans as a hallucinogenic snuff to "communicate with the spirits."[105] DMT is also found in the hallucinogenic tea, ayahuasca, which is used by indigenous healers in the Amazon Basin. In ayahuasca, DMT-containing plants (e.g., *Psychotria viridis*) are combined with plants containing harmine alkaloids (e.g., *Banisteriopsis caapi*), which inhibit hepatic monoamine oxidases to increase the oral bioavailability of DMT (see Chap. 71).[84]

The use of toads in religious ceremonies and witchcraft dates back thousands of years. All species of the toad genus *Bufo* have parotid glands on their backs that produce a variety of substances, including dopamine, epinephrine, and serotonin.[77] Many of these toads produce bufotenine, a tryptamine, which causes hypertension, but does not cross the blood–brain barrier. Interest in bufotenine grew out of reports of a toad-licking fad in the 1980s, in which individuals would reportedly lick toads for recreational purposes.[76] However, further review suggests that bufotenine is not the hallucinogenic substance found in toad secretions. Instead, 5-MeO-DMT has been identified as the psychoactive substance.[135] 5-MeO-DMT is only found in one species of toad, *Bufo alvarius* (Sonoran Desert toad or Colorado River toad).[76] Although bufotenine is currently classified as a Schedule I drug by the DEA, 5-MeO-DMT is not scheduled.[88,128] Like DMT, 5-MeO-DMT is rapidly metabolized by intestinal monoamine oxidase enzymes; licking or ingesting toad skins would thus have limited potential as a route of recreational use.[21] Methods for extracting and drying *B. alvarius* secretions for smoking and insufflation are available and on the Internet. Death has resulted from wrongful use of *Bufo* secretions for purposes of aphrodisia.[29,55] The toad venom glands also produce cardioactive steroids, called bufodienolides, which may cause digoxin-like cardiac toxicity, and in some species can secrete tetrodotoxin.[86,139]

Two of the more important synthetic tryptamines include N,N-diisopropyl-5-methoxytryptamine (5-MeO-DiPT, Foxy Methoxy) and AMT (or IT-290). Since 2001, law enforcement authorities in more than 10 states have seized large amounts of 5-MeO-DiPT and AMT. These drugs are often sold surreptitiously as MDMA. 5-MeO-DiPT received Schedule I status in 2004.[129] AMT is a monoamine oxidase inhibitor that was sold as an antidepressant in the former Soviet Union.[111] AMT was given Schedule I status by the DEA in September 2004.[129]

■ PHENYLETHYLAMINES (AMPHETAMINES)

Endogenous phenylethylamines include dopamine, norepinephrine, and tyrosine. Exogenous phenylethylamines are known for their ability to stimulate catecholamine release and cause a variety of physiologic and psychiatric effects, including hallucinations. Substitution on the phenylalkylamine structure has important effects on both the hallucinogenic and stimulant potential. The presence of a methyl group in the side chain of the phenylethylamines is associated with a higher degree of hallucinogenic effect (Fig. 82–3).[68] MDMA, amphetamine, and methamphetamine are well-known members of this family and are discussed in detail in Chap. 75.

The best recognized of the naturally occurring phenylethylamines is mescaline. Mescaline is found in peyote (*Lophophora williamsii*), a small blue-green spineless cactus that grows in dry and rocky slopes throughout the southwestern United States and northern Mexico. Peyote buttons are the round, fleshy tops of the cactus that have been sliced off and dried. The legal use of peyote in the United States is restricted to the Native American Church where peyote buttons are used for both religious ceremonies and medical treatment for physical and psychological ailments.[24,27]

Other nonindigenous cactus species containing significant amounts of mescaline include the San Pedro cactus (*Trichocereus pachanoi*) and Peruvian torch cactus (*Trichocereus peruvianus*). These plants can be purchased for ornamental purposes in garden stores and on the Internet.[58]

The synthesis and effects of hundreds of other congeners of amphetamine have been described.[110] The most well-known of these synthetic
FIGURE 82–3. Hallucinogens of the phenylethylamine chemical class.

hallucinogenic amphetamines are 4-bromo-2,5-dimethoxyphenethylamine (2C-B, Nexus, Bromo, Spectrum) and 2,5-dimethoxy-4-N-propylthiopheneethylamine (2C-T-7, Blue Mystic). During the 1980s, 2C-B gained popularity as a legal alternative to MDMA. When 2C-B was given Schedule I status in 1995, 2C-T-7 emerged as another legal designer amphetamine.[9] In March 2004, 2C-T-7 also received Schedule I status.[33]

■ SALVIA DIVINORUM

Salvia divinorum is a perennial herbaceous member of the mint family. While there are more than 500 species of *Salvia*, *S. divinorum* is most recognized for its hallucinogenic properties. The plant is characterized by a height greater than 1 m, large green leaves, hollow square stems, and white flowers with purple calyces.[130] *Salvia divinorum* is native to areas of Oaxaca, Mexico, and grows well in sunny, temperate climates. Plants, leaves, and extracts may be purchased on the Internet, and tips for cultivation of plants are easily accessible.

Since the 16th century, the Mazatec Indians have employed *S. divinorum* as a hallucinogen in religious rites as a means of producing visions.[130] The Mazatecs continue to revere *S. divinorum* as an incarnation of the Virgin Mary, referring to the plant as "ska Maria." Currently, the Controlled Substances Act does not prohibit use of *S. divinorum* or extracts of its psychoactive agent, salvinorin A. Nationwide regulation of this substance exists in Australia, and there is local regulation in some municipalities where *S. divinorum* use among teenagers is rampant.[127] The possession and sale of *S. divinorum* is currently illegal in several states, including California, Delaware, Florida, and Georgia. There continues to be widespread marketing of this hallucinogen on the Internet as a "legal hallucinogen."[36]

■ KRATOM

Kratom, or *Mitragyna speciosa Korth*, is derived from the leaves of a tree native to Asia and Africa.[109] Kratom has dual properties as a stimulant and sedative, and was historically used in Southeast Asia by manual laborers to enhance productivity. Although hallucinogenic effects are uncommon, they have been reported in heavy use.[120] Kratom has been illegal in Thailand since 1946, and Australia since 2005. Kratom is currently legal to possess and use in the United States, where some patients who have chronic pain have adopted it to modulate opiate withdrawal symptoms.

■ NUTMEG

Nutmeg is derived from *Myristica fragrans*, an evergreen tree native to the Spice Islands. The fruits of the tree contain a central kernel called the nutmeg, while the surrounding red aril is used to produce a spice called mace.[96] While nutmeg is commonly available as a cooking spice, it has been used medicinally for centuries as an antidiarrheal and abortifacient.[57] It has also been used to produce euphoria and hallucinations, and is a low-cost and accessible recreational herbal that is frequently abused by adolescents.[34,96,102] There are currently no regulations affecting the recreational use of nutmeg.

■ BELLADONNA ALKALOIDS

The belladonna alkaloids, including the tropane alkaloids atropine, hyoscyamine, and scopolamine, can be isolated from a number of plants. Deadly nightshade (*Atropa belladonna*), a perennial plant, grows throughout the United States, and in areas of Europe and Africa. Belladonna alkaloids can be isolated from both the leaves and berries of this perennial plant. Jimson weed (*Datura stramonium*), also called loco weed, grows throughout warm and moist areas of the world.

This bush contains pods full of small black seeds that are ingested for their hallucinogenic properties. The common name Angel's trumpet is used for plants of the Solanaceae family with large trumpet-shaped white flowers (*Brugmansia* or *Datura*). Given their wide availability, in the wild and over the Internet, these plants are frequently used as hallucinogens by adolescents.[54] Unfortunately, these plants can also produce significant morbidity from anticholinergic toxicity in unwary users. Moonflower, a common name given to several plants, including *Datura inoxia*, was responsible for anticholinergic poisoning of more than a dozen adolescents in one series.[30] Additionally, epidemics of unintentional poisoning have been reported among drug users who received heroin adulterated with scopolamine.[60]

TOXICOKINETICS

LSD is the most studied hallucinogen, and there is extensive information about its pharmacokinetics (Table 82–2). Ingestion is the most common route of exposure, and the gastrointestinal (GI) tract rapidly absorbs LSD. Other routes of administration include intranasal, parenteral, sublingual, smoking, and conjunctival instillation. Plasma protein binding is over 80% and volume of distribution is 0.28 L/kg. It is concentrated within the visual cortex, as well as the limbic and reticular activating systems. It is metabolized in the liver via hydroxylation and glucuronidation, and excreted predominantly as a pharmacologically inactive compound. LSD has an elimination half-life of about 2.5 hours. Only small amounts are eliminated unchanged in the urine.

While LSD use has been reported via intravenous and intramuscular routes, ingestion of blotter paper is the most common route of abuse. The minimum effective oral dose is 25 μg.[69] The onset of effects may occur 30 to 60 minutes after exposure, with a duration of 10 to 12 hours.

Ingestion of 200 to 300 morning glory seeds is required to achieve hallucinogenic effects. Hawaiian baby woodrose seeds contain ergine, and only five to 10 seeds are required to produce hallucinations. After ingestion of woodrose seeds, the effects typically last for 6 to 8 hours, and produce tranquility without marked euphoria.[4]

Peyote buttons are very bitter, and can be eaten whole or dried and crushed into a powder, which is reconstituted as tea.[58] Nausea, vomiting, and diaphoresis often precede the onset of hallucinations, which begin at 1 to 3 hours postingestion, and last for up to 12 hours.[96] Six to 12 peyote buttons, or 270 to 540 mg of mescaline, are commonly required to produce hallucinogenic effects.[104] Ingestion of up to 5 g of psilocybin-containing mushrooms may be required to produce hallucinogenic effects. After ingestion of psilocybe mushrooms, psilocybin is converted to psilocin, the active hallucinogen in the GI tract.[56] The effects of psilocin are similar to LSD, but with a shorter duration of action of about 4 hours.

For recreational purposes, DMT is typically smoked, snorted, or injected. Hallucinogenic effects peak in 5 to 20 minutes, with a duration of 30 to 60 minutes, which earned DMT the nickname the "businessman's trip." 5-MeO-DiPT is most commonly ingested, but may be smoked or insufflated. Effects begin 20 to 30 minutes after ingestion, and include disinhibition and relaxation. There is a dose-dependent response and at higher ranges, and symptoms include mydriasis, euphoria, auditory and visual hallucinations, nausea, diarrhea, and jaw clenching.[90,112] The hallucinogenic effects are reported to last from 3 to 6 hours.[85,112] Other substances may be used to heighten or prolong the hallucinogenic effects of 5-MeO-DiPT. These include sildenafil, γ-hydroxybutyrate, benzodiazepines, and marijuana. AMT is available as a white powder, which may be ingested, smoked, or insufflated. Hallucinations typically occur within 30 minutes, and may last from 12 to 16 hours.[74]

TABLE 82–2. Pharmacology of Selected Hallucinogens

Drug name or Source	Psychoactive Component (if Different)	Typical Oral Dose	Onset	Duration
Bufo species toads	5-MeO-DMT	5–15 mg (smoked)	Immediate (smoked)	5–20 min (smoked)
DMT	–	15–60 mg	5–20 min	30–60 min
"Foxy Methoxy"	5-MeO-DiPT	6–10 mg	20–30 min	3–6 h
Woodrose (*Argyreia nervosa*)	Ergine	5–10 seeds		6–8 h
Jimson weed (*Datura stramonium*)	Atropine, hyoscyamine, scopolamine	10 seeds	20–30 min	2–3 h
Kratom (*Mitragyna speciosa Korth*)	Mitragynine, 7-hydroxy-mitragynine	2–6 g (stimulant); >7 g (sedative)	10–15 min	4–6 h
LSD	Lysergic acid diethylamide	50–100 μg	30–60 min	10–12 h
"Magic mushrooms" (*Psilocybe* species)	Psilocybin, psilocin	5 g mushrooms	30 min–2 h	4 h
Nutmeg (*Myristica fragrans*)	Myristicin, elemicin	20 g	1 h	24 h
Peyote (*Lophophora williamsii*)	Mescaline	6–12 buttons, 270–540 mg mescaline	1–3 h	10–12 h
Salvia divinorum	Salvinorin A	–	30 min (inhaled); 1 h (po)	15–20 min (inhaled); 2 h (po)
2C-B	–	16–30 mg	1 h	6–10 h

Amphetamine, methamphetamine, and MDMA are well absorbed through the GI tract. The elimination half-life ranges from 8 to 30 hours for members of this class, and is dependent on urine pH.[12,32] Amphetamines are weak bases and undergo more rapid elimination in acidic urine.[107] The volume of distribution ranges from 3 to 5 L/kg for amphetamine, 3 to 4 L/kg for methamphetamine, and likely more than 5 L/kg for MDMA.[12,32,73,107] Elimination of other amphetamines occurs through multiple mechanisms including aromatic hydroxylation, aliphatic hydroxylation, and *N*-dealkylation.[73] Tolerance has been demonstrated in chronic amphetamine users.[70]

There is little information about 2C-B and 2C-T-7 in the medical literature. Both drugs may be used via oral, intranasal, and intrarectal routes. Both 2C-B and 2C-T-7 exert their hallucinogenic effects within 1 hour of use, and physiologic and psychologic effects may persist for 6 to 10 hours. Specific toxicokinetic data on 2C-B and 2C-T-7 are not available; however, the toxicokinetics of other phenylethylamines may be similar.

Salvia divinorum may be chewed, smoked, or ingested as tea. Hallucinations occur immediately after exposure to the drug and are typically quite vivid. Synesthesia is reported among Salvia users.[36] Hallucinogenic effects after *S. divinorum* use are typically brief, lasting only 1 to 2 hours. Pharmacokinetic data for *S. divinorum*, and its primary psychoactive, salvinorin A, have been described in one volunteer study.[113] Psychoactive effects were typically experienced 5 to 10 minutes after absorption of salvinorin A via the buccal mucosa, reaching a plateau during the first hour after exposure, and resolving within 2 hours. Vaporization and inhalation of salvinorin A led to more rapid effects at 30 seconds after exposure. These effects would plateau at 5 to 10 minutes, and typically subside after 20 to 30 minutes. In this study, ingestion of *S. divinorum* leaves did not produce the same effects as buccal or inhalational administration, leading to the theory that GI inactivation of salvinorin A occurs after ingestion.[113]

Kratom leaves can be decocted into tea, chewed, or smoked.[65] Kratom leaves contain approximately 0.8% mitragynine by weight, but this can vary by geographic origin of trees, as well as season.[108] Neuropsychiatric effects are dose dependent and occur within 5 to 10 minutes of exposure, with effects lasting 4 to 6 hours.[120] Stimulant effects predominate at doses of 2 to 6 g, while sedation becomes more pronounced at doses above 7 g.

Nutmeg is usually ingested as a paste, or mixed in a beverage; 15 to 20 g are required for clinical effects.[96] This dose is often unpalatable, and a case report of recreational use of encapsulated nutmeg has been described.[102] Clinical effects can begin 1 hour after nutmeg ingestion; nausea and vomiting precede the onset of hallucinations, and effects can persist for more than 24 hours after exposure.[96]

The belladonna alkaloids are most concentrated in the seeds of Jimson weed; each seed contains approximately 0.1 mg of atropine.[115] Ingestion of as few as 10 seeds can produce hallucinations within 20 to 30 minutes; these effects can last for 2 to 3 hours. While the roots and seeds of Angel's trumpet contain the highest alkaloid concentrations, users most often brew the blossom into a tea. Each blossom contains approximately 0.3 mg of atropine and 0.65 mg of scopolamine.[54] The elimination half-lives of atropine and hyoscyamine are 2.5 and 3.5 hours, respectively, while the elimination half-life of scopolamine is considerably longer, at 8 hours.[15]

PHARMACOLOGY

Although the lysergamide, indolealkylamine, and phenylethylamine hallucinogens are structurally distinct, the similarities in their effects on cognition support a common site of action on central serotonin receptors.[3,20,26,61,123] Serotonin modulates many psychological and physiologic processes, including mood, personality, affect, appetite,

motor function, sexual activity, temperature regulation, pain perception, sleep induction, and antidiuretic hormone (ADH) release. There are more than 14 known 5-hydroxytryptamine, [serotonin (5-HT)] receptor subtypes (see Chap. 13); differing affinity for these subtypes occurs based on the structure of the hallucinogen, and may account for the subtle differences between their effects.

The lysergamide, indolealklylamine, and phenylethylamine hallucinogens all bind to the 5-HT$_2$ class of receptors. There is a good correlation between the affinity of both indolealkylamine and phenylethylamine hallucinogens for 5-HT$_2$ receptors in vitro and hallucinogenic potency in humans in vivo.[3,52,95,123] Of the multiple subtypes of 5-HT$_2$ receptors, 5-HT$_{2A}$, receptors are found with highest density in the cerebral cortex, making the 5-HT$_{2A}$ receptor the most likely common site of hallucinogen action.[79] This theory is bolstered by an animal study that shows that a selective 5-HT$_{2A}$ antagonist can inhibit the effects of LSD and a phenylethylamine, 2,5-dimethoxy-4-iodo-amphetamine (DOI). The response to high doses of LSD and DOI suggest that both lysergamides and phenylethylamines are partial agonists at cortical 5-HT$_{2A}$ receptors.[51,79,101]

Although the majority of investigation has focused on the role of serotonin for drug-induced hallucinations, other neurotransmitters are involved. Stimulation of 5-HT$_{2A}$ receptors enhances release of glutamate in the cortical layer V pyramidal cells.[3,8] LSD and other lysergamides stimulate both D$_1$ and D$_2$ dopamine receptors.[7,50,134] In animal models, LSD and phenylethylamine hallucinogens modulate N-methyl-D-aspartate (NMDA) receptor–mediated effects, and may have a protective effect against neurotoxicity secondary to PCP and ketamine.[8,43]

Another theory that incorporates these other neurotransmitters involves the concept of "thalamic filtering."[49] The thalamus receives input and output from the cortex and reticular activating system, and functions to filter relevant sensory input. This theory has been explored as an explanation for organic psychosis and the effects of hallucinogenic drugs. Multiple neurotransmitters, including dopamine, acetylcholine, γ-aminobutyric acid (GABA), and glutamate, exert their actions on the thalamus. Increased excitatory or decreased inhibitory neurotransmitter in this region of the brain may lead to "sensory overload," which manifests itself clinically as symptoms of psychosis.[49] Experimental evidence also demonstrates electroencephalographic (EEG) abnormalities after exposure to hallucinogens, confirming a cortical, rather the ophthalmologic, etiology for hallucinations.[42]

Salvinorin A, the psychoactive component of *S. divinorum*, is one of the most potent natural hallucinogens. The effect of salvinorin A occurs via binding at the κ-opioid receptor, making it structurally and mechanistically unique (Fig. 82–4).[138] The κ-opioid receptor is distinct from the μ-opioid receptor, stimulation of which generally causes
FIGURE 82–4. Structure of salvinorin A.
FIGURE 82–5. Structure of myristicin.

euphoria and analgesia (see Chap. 38). Salvinorin A has not been demonstrated to have any serotonergic activity.[138]

The opioid effects of Kratom have been attributed to mitragynine.[108,137] The most prevalent of the Kratom alkaloids, mitragynine shares a structural similarity with yohimbine.[10] In vitro, mitragynine is active at both supraspinal opioid δ and μ receptors.[122] This μ-receptor activity results in analgesia and efficacy in treating opioid withdrawal symptoms. Additionally, mitragynine activates noradrenergic and serotonergic pathways.[82] Another Kratom alkaloid, 7-hydroxymitragynine, also demonstrates antinociceptive effects and high affinity for opioid receptors.[83] In animal studies, 7-hydroxymitragynine has more analgesic potency than morphine, even after oral administration.[81]

Nutmeg contains a number of purportedly psychoactive compounds, including myristicin, elemicin, and safrole (Fig. 82–5). The psychoactive components of nutmeg include terpenes and alkyl benzyl derivatives (myristicin, elemicin, and safrole).[96]

It has been theorized that the aromatics found in nutmeg are metabolized to amphetaminelike compounds that create hallucinogenic effects.[96] However, this mechanism is unsupported by both theory and animal data.[102] Nutmeg contains myristicin and elemicin, both weak monoamine oxidase inhibitors, as well as other terpene compounds. Myristicin and elemicin both demonstrate serotonergic activity, which may account for nutmeg's clinical effects.[102]

The pharmacology of atropine, a competitive central and peripheral antimuscarinic agent and the most well-studied belladonna alkaloid, is discussed in detail (see Antidotes in Depth A34–Atropine). Like atropine, scopolamine and hyoscyamine are tertiary amines, which can cross the blood–brain barrier. Scopolomaine causes more sedation than atropine, and its transdermal availability has led to its use in motion sickness patches. Hyoscyamine is more potent than atropine; it has traditionally been used as an antispasmodic for GI conditions.

CLINICAL EFFECTS

Physiologic changes accompany and often precede the perceptual changes induced by lysergamides, tryptamines, and phenylethylamines. The physical effects may be caused by direct xenobiotic effect or by a response to the disturbing or enjoyable hallucinogenic experience. Sympathetic effects mediated by the locus coeruleus include mydriasis, tachycardia, hypertension, tachypnea, hyperthermia, and diaphoresis. They may occur shortly after ingestion and often precede the hallucinogenic effects. Other clinical findings that are reported include piloerection, dizziness, hyperactivity, muscle weakness, ataxia, altered mental status, coma, and rhythmic, pupillary dilation and constriction.[71] Nausea and vomiting often precede the psychedelic effects produced by psilocybin and mescaline. Potentially life-threatening complications, such as hyperthermia, coma, respiratory arrest, hypertension, tachycardia, and coagulopathy, were described in a report of eight patients with massive LSD overdoses.[67] Sympathomimetic effects are generally less prominent in LSD ingestion than in phenylethylamine toxicity. Similar sympathetic symptoms have been described after the use of 2C-B and 2C-T-7. Low doses of 2C-B and 2C-T-7 may produce hypertension, tachycardia, and visual hallucinations, while elevated

doses are associated with shifts in color perception, and enhanced auditory and visual stimulation. An analog of 2C-B, called 2C-B-FLY, or BromoDragonFLY, has been implicated in finger amputations secondary to potent peripheral vasospastic activity, and sudden cardiac death.[93] Three deaths are associated with 2C-T-7 use; in one case death may have resulted from seizures or aspiration.[33,39,125]

The psychological effects of hallucinogens seem to represent a complex and elusive interaction between different neurotransmitters, including the serotonergic and dopaminergic systems. Based on this serotonergic mechanism, serotonin syndrome could theoretically occur after the use of any of the lysergamide, indolealkylamine, or phenylethylamine hallucinogens. Animal studies have documented LSD and tryptamine-induced serotonin syndrome.[114,131] Case reports have linked phenylethylamine use to fatal serotonin syndrome in recreational users.[89,133]

Tolerance to the psychological effects of LSD occurs within 2 or 3 days with daily dosing, but rapidly dissipates if the drug is withheld for 2 days. Psychological cross-tolerance among mescaline, psilocybin, and LSD is reported in humans.[14] There is no evidence for physiologic tolerance, physiologic dependence, or a withdrawal syndrome with LSD. Limited tolerance is demonstrated between psilocybin and cannabinoids such as marijuana.[22]

Salvia divinorum use results in vivid hallucinations and synesthesia.[113] Additionally, its use may cause dieresis, nausea, and dysphoria. These aversive effects may limit its long-term recurrent use.[10]

The dual stimulant and sedative properties of Kratom contributed to its traditional use among manual laborers. However, its opioidlike activity has led to a surge in contemporary use as an herbal treatment for opioid withdrawal among patients with chronic pain.[18,19] Anorexia, weight loss, and insomnia have been reported among Kratom addicts. Hyperpigmentation of the cheeks has also been described among chronic users.[120]

Recreational nutmeg use results in the desired effects of euphoria and hallucinations, as well as the adverse effects of nausea, vomiting, dizziness, flushing, tachycardia, and hypotension. Fatalities from nutmeg ingestion have been reported.[116]

The belladonna alkaloids produce classic symptoms of anticholinergic toxicity, including hyperthermia, tachycardia, mydriasis, flushing, anhidrosis, urinary retention, and ileus. The central effects can include restlessness, hallucinations, agitation, delirium, seizures, coma.[30] The psychosis produced by belladonna alkaloids can be profound; in one case, a young man auto-amputated his tongue and penis after ingestion of tea made from Angel's trumpet.[80]

The vast majority of morbidity from hallucinogen use stems from trauma. Hallucinogen users frequently report lacerations and bruises sustained during their "high." Additionally, dysphoric reactions may drive patients to react to stimuli with unpredictable, and occasionally aggressive, behaviors. Many Internet sites regarding hallucinogen use advise readers to take hallucinogens only while under the supervision of a "sitter."[40]

The psychological effects of hallucinogens are dose related and affect changes in arousal, emotion, perception, thought process, and self-image. The response to the xenobiotic is related to the person's mindset, emotions, or expectations at the time of exposure, and can be altered by the group or setting.[1] People experiencing the effects of a hallucinogen are usually fully alert, oriented, and aware that they are under the influence of a xenobiotic. Euphoria, dysphoria, and emotional lability may occur.

Illusions are common, typically involving distortion of body image and alteration in visual perceptions. Hallucinogen users may display acute attention to details with excessive attachment of meaning to ordinary objects and events. Usual thoughts seem novel and profound. Many people report an intensification of their sensory perceptions such

as sound magnification and distortion. Colors often seem brighter with halolike lights around objects. Frequently, hallucinogen users relate a sense of depersonalization and separation from the environment, commonly called an "out-of-body" experience. Synesthesias, or sensory misperceptions, are frequent. Hallucinations may be visual, auditory, tactile, or olfactory.

Acute adverse psychiatric effects of hallucinogens include panic reactions, psychosis, and major depressive dysphoric reactions. Acute panic reactions, the most common adverse effect, present with frightening illusions, tremendous anxiety, apprehension, and a terrifying sense of loss of self-control.[46] These psychiatric effects may cause patients to seek care in the emergency department (ED).

DIFFERENTIAL DIAGNOSIS

Hallucinosis is the abnormal organic mental condition of persistent hallucinations. The major causes of hallucinosis can be divided by etiology into structural, infectious, functional, and toxic-metabolic. The diagnosis of hallucinogen exposure often must be established on the basis of history and physical examination alone. The person who has ingested hallucinogens typically is oriented and will often give a history of xenobiotic use. This stands in stark contrast to patients with xenobiotic-induced delirium, in whom orientation is, by definition, altered.

Xenobiotics such as amphetamine, cocaine, PCP, and anticholinergics produce delirium or psychosis at doses capable of producing hallucinations. Patients with psychiatric or "functional" causes of perceptual changes, such as schizophrenia, typically present with auditory hallucinations. Patients with central anticholinergic toxicity usually present with delirium, combative behavior, and incoherent mumbling, and may be unaware that the hallucinations are xenobiotic induced.[69] The presence of marked hyperthermia, uncontrollable behavior, or extreme agitation should suggest phenylethylamine use, or an alternative exposure, such as cocaine or PCP.

Evaluation for other causes of altered mental status and hallucinations should include early exclusion of hypoglycemia, encephalitis, meningitis, intracerebral hemorrhage, thyrotoxicosis, sepsis, decompensated psychiatric disease, withdrawal, and other toxic exposures. A computed tomography of the head and lumbar puncture are tests required in a patient where the history of hallucinogen exposure is not ascertained and the altered mental status is of unclear origin.

LABORATORY

Routine urine drug-of-abuse immunoassay screens do not detect LSD or other hallucinogens. Although LSD exposure can be detected by radioimmunoassay of the urine, confirmation by high-performance liquid chromatography (HPLC) or gas chromatography is necessary. These tests are rarely used in the clinical setting, but are much more common for forensic matters.[14,37] False-positive urine testing for LSD has been reported after exposure to several medications including fentanyl, sertraline, haloperidol, or verapamil.[47,99]

Depending on their structure, phenylethylamines may cause positive qualitative urine testing by immunoassay for amphetamines. However, amphetamine drug testing is associated with numerous false-positive results, particularly after the use of cold medications that contain ephedrine, pseudoephedrine, or phenylpropanolamine.[118] Gas chromatography-mass spectrometry (GC/MS) testing methods for detection of 5-MeO-DiPT, DMT, AMT, 2C-T-7, and 2CB have been described.[132]

Routine urine drug immunoassay screens do not detect salvinorin A, Kratom, or myrsiticin. HPLC and liquid chromatography-mass

spectrometry (LC/MS) protocols have been applied to the quantitative analysis of salvinorin A and B in plant matter and in ex vivo animal studies. GC/MS identified salvinorin A in urine and saliva obtained after two human volunteers smoked *S. divinorum*.[94] Myristicin concentrations are not widely available, but have been obtained for confirmation of exposure after a fatality.[116]

TREATMENT

Most hallucinogen users rarely seek medical attention because they experience only the desired effect of the xenobiotic. For any hallucinogen user who does present to the ED, initial treatment must begin with attention to airway, breathing, circulation, level of consciousness, and abnormal vital signs. Even if an ingestion of a hallucinogen is suspected, the basic approach for altered mental status should include glucose, thiamine and oxygen therapy as indicated, as well as the vigorous search for other etiologies.

Hallucinogens rarely produce life-threatening toxicity. GI decontamination with activated charcoal may be considered for asymptomatic patients with recent ingestions, but is probably not helpful after clinical symptoms appear, and attempts may lead to further agitation. Sedation with benzodiazepines is usually sufficient to treat hypertension, tachycardia, and hyperthermia. The patient with a dysphoric reaction can be placed in a quiet location with minimal stimuli. A nonjudgmental advocate should attempt to reduce the patient's anxiety, provide reality testing, and remind the individual that a xenobiotic was ingested and the effect will wear off in a couple of hours. Excessive physical restraint (without chemical restraint) should be avoided to prevent hyperthermia and rhabdomyolysis. Benzodiazepines remain the cornerstone of therapy for both autonomic instability and dysphoria, as the sedating effect can diminish both endogenous and exogenous sympathetic effects.[87] Autonomic instability and hyperthermia may be a feature of phenylethylamine use, as well as tryptamine use or massive LSD overdose.[46,67,87] Hyperthermia resulting from agitation or muscle rigidity requires urgent sedation with benzodiazepines and rapid cooling. While central nervous system (CNS) depression is unlikely to be severe enough to require endotracheal intubation in a patient with a pure hallucinogen exposure, intubation and paralysis may be required in the patient with intractable hyperthermia.[16] Seizures may occur with tryptamine or phenylethylamine use, and can be initially treated with benzodiazepines. Seizures may also result from hyponatremia in MDMA users, and would necessitate treatment with 3% hypertonic saline (see Chap. 75).

The treatment of anticholinergic toxicity from the belladonna alkaloids involves several critical components: correction of abnormal vital signs, management of delirium, and rapid intervention for seizures or dysrhythmias. The mainstays of therapy are fluid resuscitation and benzodiazepines; however, physostigmine should be considered as antidotal therapy in cases of belladonna alkaloid poisoning. Conflicting data exist regarding the efficacy of physostigmine in decreasing morbidity and length of hospital stay when compared with benzodiazepines alone.[25,100] Based on the strength of this evidence, physostigmine should be considered in patients with evidence of anticholinergic delirium, or agitation refractory to treatment with benzodiazepines. More information on physostigmine can be found in Antidotes in Depth A12: Physostigmine Salicylate.

Morbidity and mortality typically result from the complications of hyperthermia including rhabdomyolysis and myoglobinuric renal failure, hepatic necrosis, and disseminated intravascular coagulopathy. For the most part, however, hydration, sedation, a quiet environment, and meticulous supportive care will prove adequate to prevent

morbidity or mortality in recreational use or overdose.[28] Treatment of serotonin syndrome from phenylethylamine use is largely supportive, and includes the avoidance of further administration of serotonergic medications. Specific therapy with cyproheptadine may be warranted (see Chap. 72).[17]

The role of antipsychotics in controlling hallucinogen-induced agitation is unclear and should be avoided. Haloperidol, risperidone, and ziprasidone may have utility in controlling the acutely agitated patient. However, haloperidol and risperidone may worsen panic and visual symptoms, and increase the incidence of hallucinogen persisting perception disorder (HPPD; see below).[2] Ziprasidone safety in hallucinogen users has not yet been reported. While further study on these interventions is required, prolonged psychosis may require treatment with long-term antipsychotic therapy.

LONG-TERM EFFECTS

Long-term consequences of LSD use include prolonged psychotic reactions, severe depression, and exacerbation of preexisting psychiatric illness.[59,103] When LSD was initially popularized, some patients were noted to behave in a manner similar to schizophrenia and required admission to psychiatric facilities. In volunteer studies, panic reactions, HPPD, and extended psychoses were noted. When the drug was used for alleviation of anxiety and personality abnormalities, flashbacks and extended psychosis were reported.[45] It is suggested that these individuals had preexisting compensated psychological disturbances.[3,78]

Flashbacks have been reported in up to 15% to 80% of LSD users.[5] Anesthesia, alcohol intake, and medications may precipitate flashbacks.[48] These perceptions can be triggered during times of stress, illness, and exercise, and are often a virtual recurrence of the initial hallucinations. HPPD is a chronic disorder where flashbacks lead to impairment in social or occupational function. According to the Diagnostic and Statistical Manual IV, the diagnosis of HPPD requires the recurrence of perceptual symptoms that were experienced while intoxicated with the hallucinogen that causes functional impairment and is not due to a medical condition.[6] The etiology of HPPD is still unknown, and the reported incidence varies widely. Symptoms are primarily visual, and reality testing is typically intact in HPPD. Common perceptual and visual disturbances in HPPD include geometric forms; false, fleeting perceptions in the peripheral fields; flashes of color; intensified color; and halos around objects.[78] One finding described after LSD use is palinopsia, or "trailing," which refers to the continued visual perception of an object after it has left the field of vision. These visual perceptions have been associated with normal ophthalmologic examinations and abnormal EEG evaluations, suggesting a cortical etiology for the visual symptoms.

SUMMARY

Hallucinogens are a diverse group of xenobiotics that alter and distort perception, thought, and mood without clouding the sensorium. The lysergamide, phenylethylamine, and tryptamine hallucinogens share a serotonergic mechanism of action; however, other neurotransmitters may be responsible for the complex effects of these hallucinogens. Salvinorin A, a novel hallucinogen, exerts its effects via the opioid κ receptor. Acute adverse psychiatric effects of hallucinogens include panic reactions, true hallucinations, psychosis, and major depressive dysphoric reactions. Hallucinogens rarely produce life-threatening problems, but have been known to cause autonomic instability, seizures, and hyperthermia, particularly in overdose. Meticulous

supportive care with attention to abnormal vital signs is often the only therapy required. Long-term consequence of LSD use may include prolonged psychotic reactions, severe depression, exacerbation of preexisting psychiatric illness, and HPPD.

CHAPTER 83
CANNABINOIDS

Michael A. McGuigan

Cannabis is a collective term referring to the bioactive substances from *Cannabis sativa*. The *C. sativa* plant contains a group of more than 60 chemicals (C21 group) called cannabinoids. In this chapter, the term *cannabis* encompasses all cannabis products. The major cannabinoids are cannabinol, cannabidiol, and tetrahydrocannabinol. The principal psychoactive cannabinoid is Δ⁹-tetrahydrocannabinol (THC). Marijuana is the common name for a mixture of dried leaves and flowers of the *C. sativa* plant. Hashish and hashish oil are the pressed resin and the oil expressed from the pressed resin, respectively. The concentration of THC varies from 1% in low-grade marijuana up to 50% in hash oil. Pure THC and a synthetic cannabinoid are available by prescription with the generic names of dronabinol and nabilone, respectively.

HISTORY AND EPIDEMIOLOGY

Cannabis has been used for more than 4000 years. The earliest documentation of the therapeutic use of marijuana is the 4th century BC in China.[82] Cannabis use spread from China to India to North Africa, reaching Europe around AD 500.[70] In colonial North America, cannabis was cultivated as a source of fiber.

Marijuana was used as an intoxicant from the 1850s until the 1930s when the US Federal Bureau of Narcotics began to portray marijuana as a powerful, addicting substance. Despite this, marijuana was listed in the *United States Pharmacopoeia* from 1850 to 1942. In 1970, The Controlled Substances Act classified marijuana as a Schedule I drug.

In all populations, cannabis use by males exceeds use by females. Currently, marijuana is the most commonly used illicit xenobiotic in the United States. A recent study by the Substance Abuse and Mental Health Services Administration[117] reported that in 2006 in the United States, 6.0% (14.8 million persons) ≥12 years used marijuana in the month prior to the survey; this prevalence is unchanged from previous years. The prevalence of past-month users aged 12 to 17 years was 6.7% (down from 8.2% in 2002). The number of first-time users was estimated to be 2.1 million, with 63.3% less than 18 years of age.

In 2004 in Europe, a mean of 20% (range 5%–31%) of people aged 15 to 64 years have used cannabis at least once in their lifetime; the general trend increased from the early 1990s to the early 2000s. Past-year use ranges from 1.7% to 10.4% and past-month use ranges from 0.5% to 6.2%; approximately 25% (range 19%–33%) of those who used at least once in the last month use it daily (~3 million daily users).[29]

In 2004 in Australia, 33.6% of people ≥14 years of age had used cannabis at least once in their life (unchanged from previous years) and 11.3% had used cannabis within the past year (down from a high of 17.9% in 1998).[4]

■ MEDICAL USES

Cannabinoids are proposed for use in the management of many clinical conditions (Table 83–1), but have generally only been approved for the control of chemotherapy-related nausea and vomiting that are resistant

to conventional antiemetics, for breakthrough postoperative nausea and vomiting, and for appetite stimulation in human immunodeficiency virus (HIV) patients with anorexia-cachexia syndrome.[48] The claims of benefit in the other medical conditions in Table 83–1 are not supported by evidence.[6,41,63,131]

PHARMACOLOGY AND PATHOPHYSIOLOGY

Δ⁹-THC (sometimes referred to in the literature as Δ¹-THC) was isolated in 1964. In the 1990s, two specific G protein–coupled cannabinoid-binding receptors were identified: CB1 (or *Cnr1*) and CB2 (or *Cnr2*). Subsequent research identified endogenous cannabinoid receptor ligands (anandamide, palmitoylethanolamide), as well as cannabinoid receptor agonists and antagonists.[30,47,118]

Both receptors inhibit adenylyl cyclase and stimulate potassium channel conductance.[98] CB1 receptors are distributed throughout the brain with high densities in the basal ganglia (particularly the globus pallidus), substantia nigra, cerebellum, hippocampus, and cerebral cortex (particularly the frontal regions). CB1 receptors are located presynaptically and their activation inhibits the release of acetylcholine, L-glutamate, γ-aminobutyric acid, noradrenaline, dopamine, and 5-hydroxytryptamine.[58,64,109] CB2 receptors are located peripherally in immune system tissues (splenic macrophages), B lymphocytes, peripheral nerve terminals, and the vas deferens. CB2 receptors are believed to participate in the regulation of immune responses and inflammatory reactions.

The neuropharmacologic mechanisms by which cannabinoids produce their psychoactive effects have not been fully elucidated.[49,58,98] Nevertheless, activity at the CB1 receptors is believed to be responsible for the clinical effects of cannabinoids,[12,30,58,118] including the regulation of cognition, memory, motor activities, nociception, and nausea and vomiting. Chronic administration of a cannabinoid agonist reduces CB1 receptor density in several regions of the rat brain.[13]

PHARMACOKINETICS AND TOXICOKINETICS

■ ABSORPTION

The pharmacokinetics of cannabinoids have been extensively reviewed.[40] The rate and completeness of absorption of cannabinoids depend on the route of administration and the type of cannabis product.

Inhalation of smoke containing THC results in the onset of psychoactive effects within minutes. From 10% to 35% of available THC is absorbed during smoking and peak serum THC concentrations occur an average of 8 (range: 3–10) minutes after the onset of smoking marijuana. Peak serum concentrations depend on the dose; a marijuana cigarette containing 1.75% THC produces a peak serum THC concentration of approximately 85 ng/mL.[52]

Ingestion of cannabis results in an unpredictable onset of psychoactive effects in 1 to 3 hours. Because of THC's instability in acidic gastric fluid and first-pass hepatic clearance,[95] 5% to 20% of available THC reaches the systemic circulation following ingestion. Peak serum THC concentrations usually occur 2 to 4 hours after ingestion but delays up to 6 hours are described.[35,71] The therapeutic serum THC concentration for the treatment of nausea and vomiting is greater than 10 ng/mL.[20]

Dronabinol has an oral bioavailability of approximately 10% with high interindividual variability.[37,90] THC is detectable in plasma 1.5 to 4.5 hours after ingestion of dronabinol; peak serum concentrations occur 6.5 to 107 hours after ingestion.[36] Nabilone has an oral bioavailability estimated to be greater than 90% and reaches peak serum concentrations 2 hours after ingestion.[108]

TABLE 83–1. Medical Conditions Proposed for Cannabinoid Use

Anorexia-cachexia syndrome secondary to HIV infection[a]

Anxiety

Asthma

Depression

Epilepsy

Glaucoma

Head injury

Insomnia

Migraine headaches

Multiple sclerosis

Muscle spasticity and spasms

Nausea and vomiting (resistant)[a]

Neurologic disorders

Pain

Parkinson disease

Tourette syndrome

[a] FDA approved use.

FIGURE 83–1. Estimated relative time course of THC and its major metabolite based on the route of exposure. THC = Δ^9 tetrahydrocannabinol; THC-COOH = Δ^9 THC carboxylic acid.

DISTRIBUTION

THC has a steady-state volume of distribution of approximately 2.5 to 3.5 L/kg.[40] Cannabinoids are lipid soluble and accumulate in fatty tissue in a biphasic pattern. Initially, THC is distributed to highly vascularized tissues such as the liver, kidneys, heart, and muscle. Following smoking or intravenous administration, the distribution half-life is less than 10 minutes.[52,95] After the initial distribution phase, THC accumulates more slowly in less vascularized tissues and body fat. Repeated administration of Δ^8-THC (an isomer of Δ^9-THC) to rats over 2 weeks resulted in steadily increasing concentrations of Δ^8-THC in body fat and liver, but not in brain tissue. Once administration of Δ^8-THC stopped, the cannabinoids were slowly released from fat stores as adipose tissue turned over.[94]

THC crosses the placenta and enters the breast milk. Concentrations in fetal serum are 10% to 30% of maternal concentrations. Daily marijuana smoking by a nursing mother resulted in concentrations of THC in breast milk that are eightfold higher than concomitant maternal serum concentrations; THC metabolites do not accumulate in breast milk.[100]

METABOLISM

THC is nearly completely metabolized by hepatic microsomal hydroxylation and oxidation by the cytochrome P450 system (primarily CYP2C9 and CYP3A4).[40] The primary metabolite (11-hydroxy-Δ^9-THC or 11-OH-THC) is active and is subsequently oxidized to the inactive 11-nor-Δ^9-THC carboxylic acid metabolite (THC-COOH) and many other metabolites.[1,3,103]

The serum concentrations of THC and its metabolites change over time. Smoking a marijuana cigarette results in peak serum THC concentrations before finishing the cigarette. In six volunteers, peak serum THC concentrations occurred at 8 (range: 6–10) minutes after onset of smoking, of 11-OH-THC at 13 (range: 9–23) minutes, and of THC-COOH at 120 (range: 48–240) minutes (Fig. 83–1).[52] Approximately
1 hour after beginning to smoke a marijuana cigarette, the THC-to-11-OH-THC ratio is 3:1 and the THC-to-THC-COOH ratio is 1:2; at approximately 2 hours the ratios are 2.5:1 and 1:8, respectively; at 3 hours the ratios are 2:1 and 1:16, respectively.[52]

Ingestion of cannabis results in much more variable concentrations and time courses of THC and metabolites (see Fig. 83–1). Nonetheless, at 2 to 3 hours postingestion the ratios are similar to those after smoking: THC-to-11-OH-THC is 2:1 and THC-to-THC-COOH ranges from 1:7 to 1:14.[35,127]

EXCRETION

Reported elimination half-lives of THC and its major metabolites vary considerably. Following intravenous doses of THC, the mean elimination half-life ranges from 1.6 to 57 hours.[40] Elimination half-lives are expected to be similar following inhalation.[40,52] The elimination half-life of 11-OH-THC is 12 to 36 hours and the elimination half-life of THC-COOH ranges from 1 to 6 days.[65,127]

THC and its metabolites are excreted in the urine and the feces. In the 72 hours following ingestion, approximately 15% of a THC dose is excreted in the urine and roughly 50% is excreted in the feces.[1,18,128] Following intravenous administration, approximately 15% of a THC dose is excreted in the urine and only 25% to 35% is excreted in the feces.[127] Inhalation is expected to produce results similar to intravenous administration.[40,52] In 5 days, 80% to 90% of a THC dose is excreted from the body.[45,56]

Cannabinoids were measured in the urine following smoking a marijuana cigarette containing 27 mg of THC (see Fig. 83–1).[78] THC urine concentrations peaked at 2 hours (mean: 21.5 ng/mL; range: 3.2–53.3 ng/mL) after smoking and were undetectable (less than 1.5 ng/mL) in five of the eight subjects by 6 hours after smoking. Urine concentrations of 11-OH-THC peaked at 3 hours (77.3 ± 29.7 ng/mL). The primary urinary metabolite is the glucuronide conjugate of THC-COOH.[130] THC-COOH urine concentrations peak at 4 hours (179.4 ± 146.9 ng/mL),[78] and it has an average urinary excretion half-life of 2 to 3 days (range: 0.9–9.8 days).[40] Both 11-OH-THC and THC-COOH remained detectable in the urine of all eight subjects for the 8 hours of the study.[78]

Following discontinuation of use, metabolites may be detected in the urine of chronic users for several weeks.[28,60] Factors such as age, weight, and frequency of use only partially explained the long excretion period.[28]

CLINICAL MANIFESTATIONS

The clinical effects of THC use, including time of onset and duration of effect, vary with the dose, the route of administration (ingestion is slower in onset than inhalation), the experience of the user, the user's vulnerability to psychoactive effects, and the setting in which the drug is used. The concomitant use of central nervous system depressants such as ethanol, or stimulants such as cocaine, alters the psychological and physiologic effects of cannabis.

■ PSYCHOLOGICAL EFFECTS

Use of cannabis produces variable psychological effects.[38] The variation, which occurs both between and within users, may be a result of drug tolerance, level or phase of clinical effects, physical and social settings, or user expectations or cognitive set. The most commonly self-reported effect is relaxation. Other commonly reported effects are perceptual alterations (heightened sensory awareness, slowing of time), a feeling of well-being (including giddiness or laughter), and increased appetite.[38]

■ PHYSIOLOGIC EFFECTS

Use of cannabis is associated with physiologic effects on cerebral blood flow, the heart, the lungs, and the eyes.

In a controlled, double-blind positron emission tomography study,[79] intravenous THC increased cerebral blood flow, particularly in the frontal cortex, insula, cingulate gyrus, and subcortical regions. These increases in cerebral blood flow occurred 30 to 60 minutes after use and were still elevated at 120 minutes.[80] Similar blood flow changes result from smoking marijuana.[97]

Common acute cardiovascular effects of cannabis use include increases in heart rate and decreases in vascular resistance.[62,114] Cannabis produces dose-dependent increases in heart rate within 15 minutes of starting a marijuana cigarette (from a baseline mean of 66 beats/min to a mean of 89 beats/min) that reach a maximum (mean: 92 beats/min) 10 to 15 minutes after peak plasma THC concentrations. These changes last for 2 to 3 hours.[8] Increases in blood pressure may occur with cannabis use. In a study of six subjects, an increase in blood pressure from a baseline mean of 119/74 mm Hg to a mean of 129/81 mm Hg occurred, but was not statistically significant.[8] In a double-blind, controlled study of men being investigated for angina pectoris, smoking a marijuana cigarette resulted in statistically significant changes in blood pressure from a baseline mean of 123/79 mm Hg to a peak mean of 132/84 mm Hg.[104] In contrast, repeated THC exposures resulted in significant slowing of heart rate (from a mean of 68 beats/min to a low of 62 beats/min) and lowering of blood pressure (from a mean of 116/62 mm Hg to a low of 108/53 mm Hg).[10] Decreased vascular tone may cause postural hypotension accompanied by dizziness and syncope.

Inhalation or ingestion of THC produces a dose-related short-term decrease in airway resistance and an increase in airway conductance in both normal and asthmatic individuals.[120] Smoking marijuana results in an immediate increase in airway conductance, which peaks at 15 minutes and lasts 60 minutes; ingestion of cannabis produces a significant increase in airway conductance at 30 minutes, which peaks at 3 hours and lasts 4 to 6 hours.[121,122,125] The mechanism for this effect is unclear.

The principal ocular effects of cannabis are conjunctival injection and decreased intraocular pressure. Cannabinoids, applied topically to a rabbit eye, resulted in hyperemia of the conjunctival blood vessels 2 hours after application.[86] Regardless of route of administration cannabis causes a fall in intraocular pressure in 60% of users[39] by acting on CB1 receptors in the ciliary body.[102] The mean reduction in intraocular pressure is 25% and lasts 3 to 4 hours.

■ ACUTE TOXICITY

In addition to the physiologic and psychological effects described above, acute toxicity may include decreases in coordination, muscle strength, and hand steadiness. Lethargy, sedation, postural hypotension, inability to concentrate, decreased psychomotor activity, slurred speech, and slow reaction time also may occur.[93,128]

In young children, the acute ingestion of cannabis is potentially life threatening.[61,81] Ingestion of estimated amounts of 250 to 1000 mg of hashish resulted in obtundation in 30 to 75 minutes. Tachycardia (>150 beats/min) was found in one-third of the children. Less commonly reported findings include apnea, cyanosis, bradycardia, hypotonia, and opisthotonus.

■ ACUTE ADVERSE REACTIONS

Cannabis users occasionally may experience distrust, dysphoria, fear, or panic reactions. Transient psychotic episodes are associated with cannabis use. Commonly reported adverse reactions at the prescribed dose of dronabinol or nabilone include postural hypotension, dizziness, sedation, xerostomia, abdominal discomfort, nausea, and vomiting.

One case of acute pancreatitis (serum amylase up to 3200 IU/mL) following a period of heavy cannabis use is reported, but the causal relationship is unclear.[37]

Life-threatening ventricular tachycardia (200 beats/min) has been reported.[105] In six individuals with acute cardiovascular deaths, postmortem whole-blood THC concentrations ranged from 2 to 22 ng/mL (mean: 7.2 ng/mL; median: 5 ng/mL).[5] While the temporal association is clear, causality is less clear because three of the six people had significant preexisting cardiac pathology. The risk of myocardial infarction is increased five times over baseline in the 60 minutes after marijuana use, but subsequently declines rapidly to baseline risk levels.[87] Atrial fibrillation with palpitations, nausea, and dizziness was temporally associated with smoking marijuana in four patients.[31,69,115]

■ CHRONIC USE ADVERSE EFFECTS

Long-term use of cannabis is associated with a number of adverse effects.

Immune System Cannabinoids affect host resistance to infection by modulating the secondary immune response (macrophages, T and B lymphocytes, acute phase and immune cytokines). However, an immune-mediated health risk from using cannabis has not been documented.[67]

Respiratory System Chronic use of marijuana is associated with clinical findings compatible with obstructive lung disease.[125] Smoking marijuana delivers more particulates to the lower respiratory tract than does smoking tobacco,[133] and marijuana smoke contains carcinogens similar to tobacco smoke. Case reports and a hospital-based case-control study suggest that cancers of the respiratory tract (mouth, larynx, sinuses, lung) are associated with daily or near-daily smoking of marijuana, although exposure to tobacco smoke and ethanol may be confounding factors.[19,120,123] A systematic review and a cohort study with 8 years of follow-up demonstrated no association between marijuana smoking and smoking-related cancers,[43,83] and a population-based case-control study found that marijuana use was not associated with an increased risk of developing oral squamous cell carcinoma.[107]

Cardiovascular System Marijuana use may be a risk for individuals with coronary artery disease. An exploratory prospective study of self-reported marijuana use among patients admitted for myocardial infarction found that patients who used marijuana were at significantly increased risk for cardiovascular and noncardiovascular mortality compared with nonusers.[87,90]

Reproductive System Reduced fertility in chronic users is a result of oligospermia, abnormal menstruation, and decreased ovulation.[15]

Cannabis is a class C drug in pregnancy[14] and affects birthweight and length but does not cause fetal malformations. Statistically significant reductions in birthweight (mean: 79 g less than nonusers) and length (mean: 0.5 cm shorter than nonusers) are reported in women who had urine assays positive for cannabis during pregnancy.[134] The results of three other studies are difficult to interpret because marijuana use in pregnancy was poorly documented.[44,47,134] Epidemiologic studies based on self-reporting of cannabis use do not support an association between the use of cannabis during pregnancy and teratogenesis.[68,74,132,134]

The effect of maternal use of cannabis during pregnancy on neurobehavioral development in the offspring has been studied. No detrimental effects are reported in children born to women who smoked marijuana daily (more than 21 cigarettes per week) in rural Jamaica.[26] Tremors and increased startling are reported in infants younger than 1 week of age whose mothers used cannabis during pregnancy.[33] These findings, which persisted beyond 3 days, were not associated with other signs of a withdrawal syndrome. There were no abnormalities in the children of parents who used greater than five cigarettes per week in Ottawa, Canada, at 12, 24, and 36 months of age, but lower scores in verbal and memory domains at 48 months of age are reported.[32,34,45] The results of studies evaluating the effect of in utero exposure to cannabis on postnatal neurobehavioral development are equivocal because of methodologic concerns regarding exposure assessment and control of covariates,[25] including the continued parental use of cannabis during the postnatal and early childhood periods. The role of secondhand exposure to cannabis on postnatal and early childhood development of neurobehavioral problems has not been evaluated.

Endocrine System In experimental animals, cannabis exposure is associated with suppression of gonadal steroids, growth hormone, prolactin, and thyroid hormone; in addition, cannabis alters the activity of the hypothalamic-pituitary-adrenal axis.[15] In human studies, the results are inconsistent, long-term effects have not been convincingly demonstrated, and clinical consequences are undefined.[15]

Neurobehavioral Effects There is a concern that chronic cannabis use results in deficits in cognition and learning that last well after cannabis use has stopped. Neuropsychological tests administered to 10 cannabis-dependent adolescents, eight adolescent noncannabis drug abusers, and nine nondrug users showed significant differences that persisted for the duration of the study (6 weeks of abstinence) between the cannabis group and the other groups in a visual retention test and a memory test.[112] In a study of three experienced marijuana smokers, cannabis impaired arithmetic and recall tasks up to 24 hours after smoking.[46] Adults who used cannabis more than seven times per week had impairments in math skills, verbal expression, and memory retrieval processes; people who used cannabis one to six times per week showed no impairments.[11] After 1 day of abstinence, 65 heavy marijuana users (median: use on 29 of past 30 days) showed greater impairment on neuropsychological tests of attention and executive functions than light marijuana users (median: use on 1 day of past 30 days).[101] The authors were uncertain whether this difference was caused by residual THC in the brain, a withdrawal effect from the drug, or a direct neurotoxic effect of cannabis.

There is little evidence that adverse cognitive effects persist after stopping the use of cannabis[59] or that cannabis use causes psychosocial harm to the user.[77] The hypothesis that there is a causal association between cannabis use and psychosis has not been proven unequivocally.[9]

An "amotivational syndrome" is attributed to cannabis use. The syndrome is a poorly defined complex of characteristics such as apathy, underachievement, and lack of energy.[22,111] The association of the syndrome with cannabis use is based primarily on anecdotal, uncontrolled observations.[49] Anthropologic field studies, evaluations of US college students, and controlled laboratory experiments have failed to identify a causal relationship between cannabis use and the amotivational syndrome.[49] A study evaluating the role of depression in the amotivational syndrome found significantly lower scores on "Need for Achievement" scales in heavy users (median: daily use for 6 years) with depressive symptoms compared with heavy users without depressive symptoms and light users (median: several times per month for 4.5 years) with or without depressive symptoms.[92] These data suggest that symptoms attributed to an amotivational syndrome are caused by depression, not cannabis. Another study found that behavior that could be interpreted as amotivation was inversely related to the perceived size of the reward.[22]

Abuse, Dependence, and Withdrawal The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition,[2] defines marijuana abuse as repeated instances of use under hazardous conditions; repeated, clinically meaningful impairment in social/occupational/educational functioning; or legal problems related to marijuana use. Marijuana dependence is defined as tolerance, compulsive use, impaired control, and continued use despite physical and psychological problems caused or exacerbated by use. In 2006, 4.2 million (1.7%) of the total population aged 12 or older were dependent on or abused marijuana or hashish.[117]

The amount, frequency, and duration of cannabis use required to develop dependence are not well established.[21,119] Much of the support for cannabis dependence is based on the existence of a withdrawal syndrome. In animals repeatedly given cannabis, the administration of a CB1 receptor antagonist produced signs of withdrawal.[73,116] In humans, chronic users experience unpleasant effects when abstaining from cannabis.[16] The time of onset of withdrawal symptoms is not well characterized.[15,116] The most reliably reported effects are irritability-restlessness-nervousness and appetite and sleep disturbances.[116] Other reported acute withdrawal manifestations include tremor, diaphoresis, fever, and nausea. These symptoms and signs are reversed by the oral administration of THC42.[9,42] The duration of withdrawal manifestations, without treatment, is not clearly established.[17,116]

■ CANNABIS AND DRIVING

The perceptual alterations caused by cannabis suggest that its recent use should be associated with automobile crashes. However, neither experimental nor epidemiologic studies have provided definitive answers about the effects cannabis use has on driving ability. The published analytical studies of the relationship between cannabis and driving behavior/motor vehicle crashes have been reviewed.[7] In experimental driving studies, cannabis impairs driving ability but cannabis-using drivers recognize their impairment and compensate for it by driving at slower speeds and increasing following distance. However, the slower reaction time caused by cannabis results in impaired emergency response behavior.

The epidemiologic studies evaluating the association of cannabis use and traffic crashes provide no evidence that cannabis alone increases the risk of causing fatal crashes or serious injuries.[7,96] Studies of 2500 drivers injured in multiple vehicle crashes found that those with blood tests positive for THC had no higher culpability rate than xenobiotic-free drivers.[75,76] A recent study comparing past driving records of subjects entering a drug treatment center with controls found that a self-reported history of cannabis use was associated with a statistically significant increase in adjusted relative risk for all crashes (relative risk 1.49, 95% confidence interval 1.17–1.89) and for "at fault" crashes (relative risk 1.68, 95% confidence interval 1.21–2.34).[23]

The results of studies evaluating the effect of a combination of cannabis and ethanol are contradictory.[7] One study supported potentiation of effects,[124] one could not evaluate the role of xenobiotics other

than ethanol,[129] and one did not support potentiation.[57] Several issues were not addressed in these studies: the contribution of more than one central nervous system depressant, the concentrations of central nervous system depressants, and the effect of dependency or tolerance.

DIAGNOSTIC TESTING

Cannabinoids can be detected in plasma or urine. Enzyme-multiplied immunoassay technique (EMIT) and radioimmunoassay (RIA) are routinely available; gas chromatography-mass spectrometry (GC/MS) is the most specific assay and is used as the reference method.

EMIT is a qualitative urine test that is often used for screening purposes. EMIT identifies the metabolites of THC. In these tests, the concentrations of all metabolites present are additive. For the EMIT II Cannabinoid 20-ng Assay, the cutoff level for distinguishing positive from negative samples is 20 ng/mL. A positive test means that the total concentration of all the metabolites present in the urine was at least 20 ng/mL. A positive urine test for cannabis only indicates the presence of cannabinoids, it does not identify which metabolites are present or in what concentrations. Qualitative urine test results do not indicate or measure intoxication or degree of exposure. The National Institute on Drug Abuse guidelines for urine testing specify test cutoff concentrations of 50 ng/mL for screening and 15 ng/mL for confirmation.

Variables affecting the duration of detection of urinary metabolites include dose, duration of use, acute versus chronic use, route of exposure, and sensitivity of the method. In addition, factors affecting the quantitative values of urine THC and metabolites include urine volume, concentration, and pH. Using GC/MS, metabolites may be detected in the urine up to 7 days following a single marijuana cigarette.[54,55]

The length of time between stopping cannabis use and a negative EMIT urine test (<20 ng/mL) depends on the extent of use. Release of THC from adipose tissue is important in drug testing because chronic users may release cannabinoids in quantities sufficient to result in positive urine tests for several weeks. In addition, vigorous exercise may stimulate the release of cannabinoids from fat depots. In light users being tested daily under observed abstinence, the mean time to the first negative urine test is 8.5 days (range: 3–18 days) and the mean time to the last positive urine is 18.2 days (range: 7–34 days).[28] In heavy users (mean: 9 years of using at least once a day) being tested under the same conditions, the mean time to the first negative urine test result (EMIT assay less than 20 ng/mL) was 19.1 days (range: 3–46 days) and the mean time to the last positive urine sample was 31.5 days (range: 4–77 days).[28]

Standard laboratory analyses identify THC and its metabolites but cannot identify the source of the THC (eg, marijuana, hashish, dronabinol). EMIT will not identify nabilone because it is not THC; however, nabilone can be specifically identified using high-performance liquid chromatography-tandem mass spectrometry.[106]

Immunoassays may give false-negative and false-positive test results (Table 83–2). To help identify evidence tampering, negative urine immunoassays should be accompanied by examining the urine for clarity and measuring urinary specific gravity, pH, temperature, and creatinine.[113,126]

▪ PASSIVE INHALATION

Studies of passive exposure to marijuana smoke and the urinary excretion of cannabinoids have used enclosed spaces with nonsmokers present during and after active smoking.[24,72,89,96,99]

In an unventilated 6.9 × 8.2 × 7.9-foot room (12,225.8 L of air), five adult volunteers were exposed to the sidestream smoke of four or 16 marijuana cigarettes (THC 25 mg/cigarette) smoked simultaneously over 1 hour on each of 6 consecutive days.[24] After being exposed to

TABLE 83–2. Xenobiotics or Conditions Purported to Produce Inaccurate Screening Test Results for THC

False Negative[a]	False Positive
Bleach (NaOCl)	Dronabinol
Citric acid	Efavirenz
Detergent additives	Ethacrynic acid
Dettol[b]	Hemp seed oil
Dilution	NSAIDs
Glutaraldehyde	Promethazine
Lemon juice	Riboflavin
Potassium nitrite (KNO$_2$)	
Salt (NaCl)	
Tetrahydrozoline	
Vinegar (acetic acid)	
Water	

[a] Xenobiotics producing false-negative urine tests are usually added to a urine sample, not ingested.

[b] Dettol is an antiseptic containing isopropyl alcohol (8%–11%), pine oil (8.4%), and chloroxylenol (4.8%).

four marijuana cigarettes, four of the volunteers had at least one positive urine by EMIT assay (cutoff: 20 ng/mL) at some unspecified time during the 6 study days; exposure to 16 marijuana cigarettes resulted in positive EMIT assays only after the second day's exposure.

In a car (1650 L of air), three adult volunteers were exposed to the smoke from 12 marijuana cigarettes smoked by two people over 30 minutes.[89] EMIT analyses of urine samples from one passive inhaler were positive at time 0–4 hours and on days 2 and 3; a second passive inhaler had one positive urine test at time 4 to 24 hours after exposure.

Three adult volunteers in a 10 × 10 × 8-foot unventilated room (21,600 L of air) were exposed to the sidestream smoke of four marijuana cigarettes (THC 27 mg/cigarette) smoked simultaneously over 1 hour.[91] The concentrations of cannabinoids in urine samples taken 20 to 24 hours after exposure were less than 6 ng/mL when analyzed using RIA methodology.

Another study used an unventilated room (total volume of 27,950 L) containing three desks and a filing cabinet.[72] Over 10 to 34 minutes, each of six volunteers smoked a marijuana cigarette (THC 17.1 mg/cigarette) and left the room. Four nonsmoking adult males were in the study room for 3 hours from the start of smoking. The door was opened and closed 18 times during the study. The maximum urine cannabinoid concentration (measured by RIA) in the nonsmokers was 6.8 ng/mL at 6 hours after the start of smoking.

Another study used a closed 8 × 8 × 10-foot room (15,500 L of air) with each of four subjects smoking two marijuana cigarettes containing 2.5% THC on one occasion and 2.8% THC on a second occasion.[99] On each occasion, two nonsmoking subjects were in the room for 1 hour from the onset of smoking. None of the nonsmokers' urine samples (from 0–24 hours) from either exposure period tested positive on an EMIT assay with a cutoff of 20 ng/mL. An identical experiment in a closed car (approximately 3500 L of air) resulted in one of 23 urine specimens testing positive at 6 hours.

Therefore, passive inhalation of marijuana smoke is unlikely to result in positive urine test results unless the exposure has been extreme.

■ SALIVA

Saliva samples may be used to establish the presence of cannabinoids and time of cannabis consumption. Cannabinoids (THC, THC-COOH, 11-OH-THC) in saliva may be from the smoke of the marijuana or hashish, or from a preliminary metabolism in the mouth.[110] Saliva THC concentrations above 10 ng/mL are consistent with recent use and correlate with subjective intoxication and heart rate changes.[84]

■ HAIR

Hair sample analysis is not useful in identifying THC or its metabolites. Only small quantities of non-nitrogen-containing substances, such as cannabinoids, are found in hair pigments.[27,66,85]

■ SWEAT

The analysis of perspiration to test for cannabinoids is a recent development. Perspiration deposits drug metabolites on the skin and these are renewed even after the skin is washed. Detection threshold is reported to be 10 ng/mL but forensic confirmation by alternative means is required.[66]

ESTIMATING TIME OF EXPOSURE

A measurable serum concentration of THC is consistent with recent exposure and intoxication but there is poor correlation between serum THC concentrations and degree of intoxication.[50]

The ratio of THC to THC-COOH has been used to estimate time of smoking marijuana. Similar concentrations of each indicate cannabis use within 20 to 40 minutes and imply intoxication. In naïve users, a concentration of THC-COOH that is greater than THC indicates that use probably occurred more than 30 minutes ago. Serum THC-COOH concentrations greater than 40 ng/mL suggest chronic cannabis use.[88] The high background concentrations of THC-COOH in habitual users make estimations of time of exposure unreliable in this population.

Serum concentrations of THC and THC-COOH were used in a logarithmic equation to predict the time since smoking a marijuana cigarette.[78] The ratio provided acceptable results up to 3 hours after smoking (predicted time of exposure averaged 27 minutes longer than actual exposure time), but more than 3 hours after smoking the predicted exposure time was overestimated by 3 hours. Mean overestimations of predicted exposure time of 2.5 to 4.2 hours for smoking and of 1.6 hours for ingestions are reported when serum samples are taken more than 4 hours after exposure.[53]

Chronic use or oral administration of cannabis increases the concentration of 11-OH-THC relative to the concentrations of THC or THC-COOH. In these cases, estimating time of exposure based on relative concentrations is problematic.[51] In four subjects, ingestion of cannabis produced total serum metabolite concentrations less than 20 times the serum THC concentration for 3 hours after ingestion, suggesting that a ratio of this magnitude is consistent with recent oral consumption.[71]

MANAGEMENT

Gastrointestinal decontamination is not recommended for patients who ingest cannabis products, nabilone, or dronabinol because clinical toxicity is rarely serious and responds to supportive care. In addition, a patient with a significantly altered mental status, such as somnolence, agitation, or anxiety, has risks associated with gastrointestinal decontamination that outweigh the potential benefits of the intervention.

Agitation, anxiety, or transient psychotic episodes should be treated with quiet reassurance and benzodiazepines (lorazepam 1–2 mg intramuscularly or diazepam 5–10 mg intravenously) or antipsychotics (haloperidol, ziprasidone) as needed. There are no specific antidotes for cannabis. Coingestants, such as cocaine or ethanol, should be identified and their effects anticipated and treated as indicated.

SUMMARY

Cannabis is a commonly used and widely available xenobiotic. Common manifestations of acute cannabis toxicity include relaxation, perceptual alterations, sedation, tachycardia, postural hypotension, inability to concentrate, slurred speech, and slow reaction times. Feelings of distrust, fear, or panic may occur. Obtundation, apnea, bradycardia, hypotonia, and opisthotonus are reported in young children following ingestion of cannabis. THC or its metabolites can be identified in blood or urine, but treatment is not guided by drug concentrations. Treatment of an overdose, a high degree of toxicity, or an acute adverse reaction is symptomatic and supportive.

CHAPTER 84
NICOTINE

Sari Soghoian
MW = 162 daltons

Nicotine

Nicotine is a highly addictive plant-derived alkaloid with stimulant properties, and the most widely used addictive xenobiotic in the world. It is related to coniine—the important alkaloid in poison hemlock—and to lobeline, which is found in *Lobalia inflata*, or Indian tobacco. Most nicotine is derived from members of the genus *Nicotiana*, collectively known as the tobacco plant, in the family Solanaceae. The most important species in human use today is *Nicotiana tabacum.*

The primary source of nicotine exposure is cigarette smoking, and there are over 3000 components to tobacco smoke. The health burden of cigarette smoking and use of other tobacco products is staggering. Epidemic tobacco abuse increases rates of chronic obstructive pulmonary disease (COPD), cardiovascular disease, pulmonary infections, macular degeneration, and cancers, and causes over five million deaths worldwide per year. Nicotine per se may not be the crucial factor in each of these health issues caused by tobacco products.

There are direct health effects of chronic nicotine exposure. Even in low doses, nicotine causes vasoconstriction and other cardiovascular effects related to catecholamine release, and promotes angiogenesis, neuroteratogenicity, and possibly some cancers.[41] Neither these nor the long-term effects of cigarette smoking and tobacco dependency are discussed further in this chapter. Instead, this chapter is concerned with the sources, effects, and management of acute toxicity referable to nicotinic receptor stimulation and cholinergic activation.

HISTORY AND EPIDEMIOLOGY

The tobacco plant is native to the Americas, and its use most likely predates the Mayan empire. In 1492 Christopher Columbus and his crew were given tobacco by the Arawaks, but threw it away not knowing any use for it. Ramon Pane, a monk who accompanied Columbus on his second voyage to America, is credited with introducing tobacco to Europe.[64]

Nicotine was isolated from tobacco in 1828. The principle source of nicotine today is still tobacco products including cigarettes, cigars, pipe tobacco, chewing tobacco, and snuff. Smoking cessation products containing nicotine are increasingly available and include gums, transdermal patches, lozenges, inhaler sprays, and pills. Exposure to tobacco plants during their harvest remains an important source of occupational nicotine toxicity known as green tobacco sickness. Nicotine insecticides are no longer in widespread use in the United States, but are used in other countries and can still be purchased from some online retailers. The neonicotinoids are the only major new class of insecticide developed in the past quarter century, and despite decreased affinity for mammalian compared to invertebrate nicotinic receptors they may still cause significant toxicity in humans. The nicotine receptor partial agonists, used to aid smoking cessation, are a new class of drug that mimics the physiologic effects of nicotine.

SOURCES AND USES OF NICOTINE

■ CIGARETTES

The amount of nicotine contained in a single cigarette is highly variable, and ranges from less than 10 mg in a "low nicotine" cigarette to 30 mg in some European cigarettes (Table 84–1). Since most nicotine is either lost in the sidestream (secondhand smoke) or left in the filter, the absorbed nicotine yield from a smoked cigarette is much less than this, on the order of 0.05 to 3 mg/cigarette.[25] Nicotine yield is determined by burning cigarettes on a smoke machine in a standardized manner. The amount of nicotine absorbed by a particular individual from a single smoked cigarette is highly variable among smokers, and depends on soufflé or "puff" rate, volume, the depth and duration of inhalation, and the size of the residual.[44]

The potential for nicotine toxicity from smoking is limited since peak effects by this route will occur within seconds and tend to limit further intake of drug. Most reports of acute nicotine toxicity referable to cigarette exposure are associated with cigarette and cigarette butt ingestion, usually by young children.[51,57,62]

■ CHEW

Smokeless or chewing tobacco is still widely used[18] despite a clear association with periodontal disease and dental cavities, and up to 48 times the risk of oropharyngeal cancers compared with people who do not use tobacco products.[19] The nicotine content of six major US brands of moist smokeless tobacco (dip) ranged from 3.37 to 11.04 mg/g in one study.[49] Because nicotine is a weak base, smokeless tobacco is buffered to facilitate buccal absorption. The pH of marketed products ranged from 5.24 to 8.35 in one survey.[49] Acute nicotine toxicity from smokeless tobacco is rarely reported in adults, however, a 14-month-old boy had muscle fasciculations and lethargy after ingesting material out of his father's spittoon but recovered within 24 hours with supportive care.[29]

■ GUM

Nicotine gum has been available without a prescription as an aide to smoking cessation in the United States since 1996. It is sold in 2-mg and 4-mg strengths. It is buffered to an alkaline pH to facilitate buccal absorption. The gum is supposed to be chewed until mouth and throat tingling and a peppery taste develops, signaling nicotine release. Approximately 53% to 72% of the nicotine in the gum is absorbed. The gum is then "parked" in the cheek until the sensation subsides, at which time it may be chewed again to release more drug.[52] If used correctly, serum nicotine concentrations rise gradually to a concentration slightly lower than normally achieved by cigarette smoking.[52] If the gum is swallowed whole, serum nicotine concentrations rise even more slowly since the acidic environment of the stomach delays absorption.[7] Conversely, if the gum is chewed vigorously and saliva is swallowed then nicotine concentrations may rise rapidly and adverse reactions may occur.[63]

■ TRANSDERMAL PATCHES

Nicotine patches have been US Food and Drug Administration (FDA) approved for purchase without prescription in the United States since 1996. Most nicotine transdermal delivery systems are designed to deliver 7, 14, or 21 mg of nicotine over 24 hours. Since many patch

TABLE 84–1. Sources of Nicotine		
Source	Content (mg)	Delivered[a] (mg)
1 whole cigarette	10–30	0.05–3
1 cigarette butt	5–7	–
1 cigar	15–40	0.2–1
1 g snuff (wet)	12–16	2–3.5
1 g chewing tobacco	6–8	2–4
1 piece nicotine gum	2 or 4	1–2
1 nicotine patch	8.3–114	5–22 over 16 or 24 h
1 nicotine lozenge	2 or 4	2–4
1 nicotine nasal spray	0.5	0.2–0.4

[a] Delivered by intended use of standard dose.

users have difficulty sleeping, vivid dreams, or nightmares if they wear the patch overnight, systems designed for application for only 16 hours are now made. The patch reservoirs contain an estimated 36 to 114 mg of nicotine per patch.[53] For most children and many adults this exceeds the estimated LD_{50} for nicotine in humans of 1 mg/kg. With proper use only 7 to 21 mg is released into the skin[30] and absorbed. If the patch is punctured by biting or tearing, then delivery of the full content is possible, and severe toxicity may occur.

■ SPRAY/INHALER

A nicotine spray has been available since 1996 to aide efforts at smoking cessation. The most commonly reported adverse effects during initiation of therapy are due to local irritation and include rhinorrhea, lacrimation, sneezing, and nasal and throat irritation.[33] One spray delivers 0.5 mg of nicotine with the recommended dose of two sprays every 30 to 60 minutes as needed. The absorption is about 50% of the delivered dose and may be diminished or delayed by rhinitis or by α-adrenergic agonist decongestants.[40] No report of acute nicotine toxicity from nicotine inhalers has been published to date.

■ LOZENGES

Nicotine lozenges containing 2 and 4 mg of nicotine are available for purchase without prescription in the Unites States. The potential for rapid absorption of nicotine as a bolus dose from chewing the lozenge is a theoretical concern. No case of acute nicotine toxicity from nicotine lozenge misuse is published to date.

■ PLANTS/LEAVES

Green tobacco sickness is an occupational illness that affects workers who have direct contact with tobacco plants during cultivation and harvest. Residual moisture or dewdrops on tobacco leaves may contain as much as 9 mg of nicotine per 100 mL.[28] Sweat wrung out of the shirts worn by workers during tobacco harvest in one study contained up to 98 mg/mL of nicotine.[28] Green tobacco sickness is prevalent with an estimated 8.8% to 42% of tobacco harvesters affected each season.[2–4] Since farm workers are a medically underserved population in the United States, and many at-risk workers are undocumented immigrants, it is most likely underreported. Other risk factors for green tobacco sickness include younger age, working in wet tobacco, and a relative lack of work experience.[2,4,46,50] These factors may all be related

to a lack of nicotine tolerance, although other aspects may be important for the development of toxicity. The use of rain suits or other barrier protection is the only protective factor consistently noted to be useful across multiple studies.[3,45,50]

■ SALTS (PESTICIDES)

Nicotine in the form of tobacco extracts was first reported as effective for pest control in 1690. In 1886 a mixture of tobacco and soapsuds was advocated for aphid control, but it was not until 1912 that the first commercial nicotine insecticides were developed. Crop dusting with nicotine sulfate began in 1917, though at the time this was mostly accomplished by horse-drawn carriage.[56]

The most widely known application of 40% nicotine sulfate, BlackLeaf 40, was discontinued in 1992. Nicotine is still available as a restricted-use pesticide for aphids and thrips, and a 14% preparation of nicotine is still marketed as a greenhouse smoke fumigator.[54] Since nicotine pesticides are highly concentrated, ingestion of even small amounts may produce serious toxicity including catastrophic brain injury[60] and death.[38]

■ NEONICOTINOIDS

The neonicotinoids are a new class of insecticides that have the theoretical advantage of decreased mammalian toxicity because of a lower affinity for the vertebrate, compared to the insect, nicotinic receptors.[65] Examples (and their year of patent) include the heterocyclics nithiazine (1977), imidacloprid (1985), thiacloprid (1985), and thiamethoxam (1989); and the acyclics nitenpyram (1988), acetamiprid (1989), clothianidin (1989), and dinotefuran (1994). Experience with human poisoning from neonicotinoid exposure is limited, and only a handful of case reports have been published to date.

■ NICOTINE RECEPTOR PARTIAL AGONISTS (VARENICLINE, CYTOSINE)

Nicotine receptor partial agonists have been developed to aide in smoking cessation by reducing smoking satisfaction (agonist antagonism effect) while helping to maintain moderate amounts of central dopamine release (partial agonist effect). Cytosine is a plant-derived insecticide with a chemical structure similar to nicotine that has been used in Eastern and Central Europe since the 1960s under the trade name Tabex® (Sopharma Pharmaceuticals) as a smoking cessation drug.[24] Despite widespread use it has not been well studied for its safety, efficacy, pharmacokinetics, and pharmacodynamics in humans.[24]

Varenicline (marketed as Chantix® in the United States, Champix® in Europe) is a xenobiotic developed by Pfizer Inc. as an analog of cytosine. It was FDA approved as a prescription-only aide to smoking cessation in 2006. Several randomized controlled trials have demonstrated efficacy in controlling nicotine cravings and evidence suggests that varenicline increases the probability of successful abstinence from smoking.[14] No reports of toxic manifestations (or lack thereof) after varenicline overdose have been published to date, but postmarketing experience suggests that there is an association with increased rates of suicide with therapeutic use.

PHARMACOLOGY/PHARMACOKINETICS

The pharmacologic characteristics of nicotine are listed in Table 84–2. Nicotine is well absorbed from mucosal surfaces, skin, the intestines, and the respiratory tract. Since nicotine is a weak base, more is nonionized—and will cross biologic membranes more easily—in an

TABLE 84–2. Pharmacologic Characteristics of Nicotine

Absorption	Lungs, oral mucosa, skin, intestinal tract; increased in more alkaline environment
Volume of distribution	Approximately 1 L/kg
Protein binding	5%–20%
Metabolism	80%–90% hepatic; remainder in lung, kidney; principal (inactive) metabolite is cotinine
Half-life	Nicotine: 1–4 h, decreases with repeated exposure; cotinine: 19–20 h
Elimination	2%–35% excreted unchanged in urine

alkaline environment. Cigar and pipe tobacco are air cured to achieve a pH of 8.5, and snuff, chewing tobacco, and nicotine gum are buffered in order to facilitate buccal absorption. Nicotine from cigarette smoke is carried on inhaled tar particles into the lungs where a large alveolar surface area allows rapid absorption into the pulmonary circulation.

Once absorbed, nicotine reaches the arterial circulation and diffuses almost immediately into the central nervous system (CNS). Nicotine readily crosses the placental barrier and is secreted in breast milk. Metabolism occurs primarily in the liver, and in the kidney and lung to a much lesser extent. About 70% of circulating nicotine is metabolized to cotinine, and much smaller amounts to nornicotine, nicotine-1-N-oxide, nicotine glucuronide, and 2'-hydroxynicotine. Hepatic transformation of nicotine is achieved by P450 cytochrome oxidases, aldehyde oxidase, flavin monooxygenase, and by glycosylation. Although multiple P450 enzymes are most likely involved, CYP2D6 and CYP2A6 are known to contribute to nicotine metabolism.

Renal excretion of unchanged nicotine accounts for 2% to 35% of total nicotine elimination,[13] and is pH dependent. Nicotine is reabsorbed in the proximal tubule where pH is relatively high. Acidification of the urine enhances elimination. The half-life of nicotine is 1 to 4 hours and decreases with repeated nicotine exposure as in habitual cigarette smoking. The elimination half-life of nicotine after transdermal patch removal is longer than that noted with nicotine exposure by other routes,[35] but this is most likely because a dermal reservoir of drug is established during patch use, from which absorption continues after removal. Cotinine and *trans*-3'-hydroxycotinine are eliminated in the urine as glucuronide esters independent of urine pH. The elimination half-life of cotinine is closer to 20 hours and urinary cotinine is therefore a more easily detected marker of nicotine exposure.

Serum concentrations of nicotine and cotinine are influenced most strongly by individual variations in clearance.[9,10] Nicotine metabolism is inducible and nicotine-dependent individuals metabolize the drug more rapidly than naïve ones.[32] Nicotine metabolism may also be linked to race and gender. Asians and African Americans metabolize nicotine more slowly than whites, and have prolonged cotinine clearance in the urine.[10,42,55] Women metabolize nicotine faster than men. This is further accelerated by oral contraceptive use and pregnancy, and is most likely mediated by an influence of estrogen on CYP2A6 activity.[32]

Cigarette smoking modulates the bioavailability and effectiveness of numerous medications through effects on drug absorption, metabolism, or pharmacodynamics. Cigarette smoking induces CYP1A2 and accelerates the metabolism of caffeine, clozapine, olanzapine, tacrine, theophylline, and erlotinib.[31,34] This effect may not involve nicotine, however, since nicotine administered intravenously does not affect theophylline metabolism.[7] Smokers also have diminished effectiveness of opioids, benzodiazepines, β-adrenergic antagonists, and nifedipine,[17]

and are more likely to fail antacid and H_2-blocker therapy for peptic ulcer disease.[7] These interactions have not been clearly linked to an effect of nicotine per se, however.

The LD_{50} of nicotine has been estimated at 0.5 to 1 mg/kg in adults,[27,29,43] but severe toxicity has been reported with ingestion of less than 2 mg in a child[47,63] and this dose is sufficient to produce mild symptoms in an adult. Children under 6 years of age who ingest one or more cigarettes, or three or more cigarette butts, generally develop symptoms of nicotine toxicity.[63] A retrospective review of 10 children with cigarette ingestions found that the four patients with symptoms requiring medical evaluation and treatment had ingested at least two whole cigarettes.[43] The acute oral LD_{50} of imidacloprid in rats is 475 mg/kg, and the dermal LD_{50} is greater than 5 g/kg.[65]

Acute tolerance to nicotine develops in smokers who take in small doses of nicotine regularly throughout the day. Sensitization to the effects of nicotine is restored with overnight abstinence.[5,32] Tolerance may also develop in tobacco workers with regular exposure to tobacco plant leaves. The phenomenon of acute tolerance, however, along with considerable genetic variability in nicotine metabolism, implies a range of susceptibility to drug effect.

PATHOPHYSIOLOGY

Nicotine mimics the effects of acetylcholine release by binding to postsynaptic nicotinic receptors (nAchr) in the brain, spinal cord, autonomic ganglia, adrenal medulla, neuromuscular junctions, and chemoreceptors of the carotid and aortic bodies (Chap. 13). When nicotine binds to its receptor, the ion channel opens, allowing an influx of cations, mostly sodium and calcium. Voltage-gated calcium channels are then activated, leading to further influx of calcium and a variety of downstream effects including depolarization.

The clinical effects of nAchr stimulation are dose dependent. Low doses of nicotine and related compounds stimulate nicotinic receptors centrally and in autonomic and somatic motor nerve fibers. Prolonged stimulation at the receptor ultimately leads to receptor blockade (Chap. 68). Activation of nAchr in the CNS directly stimulates neurotransmitter release. At doses generally produced by cigarette smoking there is stimulation of the reticular activating system and an alerting pattern on electroencephalogram.[71] Release of dopamine most likely mediates the reinforcing effects of nicotine, and occurs in the mesolimbic area, the corpus striatum, the prefrontal cortex, and in the nucleus accumbens. Nicotine also stimulates glutaminergic activation and γ-aminobutyric acid (GABA)ergic inhibition of dopaminergic neurons in the ventral tegmental area of the midbrain.[6] These pathways are thought to be important neuromodulatory pathways for drug-induced reward and addiction. Norepinephrine, acetylcholine, GABA, serotonin, glutamate, and endorphins are also released by nicotine, and are associated with cognitive and mood enhancement as well as appetite suppression, increased basal energy expenditures, and anxiety reduction.[6]

At very high doses nicotine induces seizures. Nicotine-induced seizures can be blocked in mice by the nicotine-receptor antagonists mecamylamine, methyllycaconitine citrate (MLA), and hexamethonium.[20] Given to mice in slightly higher doses, however, these nicotine-receptor antagonists are themselves epileptogenic. The specific mechanisms by which nicotine produces seizures are unknown. A disinhibition model has been proposed, in which desensitization or antagonism of central nicotinic cholinergic neurons blocks excitatory input to GABAergic neurons, and a reduction of inhibitory GABAergic input to pyramidal cells then results in increased excitability and seizures.[1,15,23,26] An alternative hypothesis is that synchronous depolarization from activation of α7*-subtype nicotinic receptors promotes kindling-induced seizures.[23]

CLINICAL MANIFESTATIONS

Nicotine is most rapidly absorbed in the lungs, and in decreasing order via the buccal mucosa, gastrointestinal tract, and skin. Time to onset of symptoms is within 5 to 60 seconds after inhalation of nicotine-containing smoke. Symptoms of nicotine toxicity are manifest within 15 to 30 minutes of chewing nicotine gum, but usually begin much sooner. Symptom onset is within 30 to 90 minutes after ingestion of tobacco products.

Exposure to nicotine in low doses comparable to cigarette smoking produces fine tremor, cutaneous vasoconstriction, increased gastrointestinal motility, nausea, and increases in heart rate, respiratory rate, and blood pressure. Low-dose nicotine also increases mental alertness and produces euphoria. Nicotine is rapidly metabolized, and patients who develop only mild symptoms are expected to recover quickly. An important exception to this rule is patients with symptoms of nicotine toxicity after transdermal nicotine patch application, since a reservoir of drug may persist in the skin after patch removal and can serve as a source of ongoing absorption.

Early symptoms of severe nicotine poisoning are referable to nicotinic cholinergic excess: increased salivation, nausea, vomiting, diaphoresis, and diarrhea may all occur within minutes of systemic absorption. Vomiting is the most common finding, and occurs in more than 50% of cases. Vasoconstriction may manifest with pallor and hypertension. Tachycardia may also occur. Neurologic signs and symptoms include headache, dizziness, ataxia, confusion, and perceptual distortions. Severe poisoning may include cardiac dysrhythmias, seizures, and muscle fasciculations early in the course of illness. Bradycardia, hypotension, coma, and neuromuscular blockade with respiratory failure from muscular paralysis may develop later on (Table 84–3). Nicotine is an irritant and ingestion of nicotine, including use of nicotine gum, may cause burning and pain in the mouth, and constriction of the throat muscles. Similarly, application of nicotine patches generally results in dermal irritation, which may be severe.

Data from poison centers in the United States suggests that most children with cigarette ingestions have a benign course. A series of 233 consecutive reports to poison centers of children under 6 years old who ingested cigarettes or butts found that 18% of patients developed symptoms, mostly vomiting (39%).[62] Twelve percent of the patients in this series were managed in an emergency department (ED), and none of them were admitted. Another series of 146 cases of cigarette ingestion by children less than 6 years old reported symptoms in 33.3% of the sample, again mostly vomiting (87%).[6] Follow-up was available for 90 patients, and all had recovered within 12 hours. The relative rarity of life-threatening symptoms after cigarette ingestion may be a result of auto-decontamination from vomiting, or because of limited exposure given the exploratory nature of most ingestions in children.

Cases of more severe toxicity from cigarette ingestion have been reported.[12,63] Severe toxicity including apnea and seizures is also reported in a 20-month-old child who had access to nicotine gum.[61] A retrospective review of nicotine exposures among children reported to one poison center in North America found that four out of five children aged 20 months to 9 years developed severe agitation after exposure to nicotine gum, and two of these patients developed tachycardia or hypotension.[63] The greater likelihood of becoming symptomatic after exposure to gum compared with tobacco products in this review was attributed to the rapid release of nicotine from the gum, rather than an absolute increase in dose. Atrial fibrillation is reported in adults who chew nicotine gum.[16,59]

Several reports have documented acute nicotine toxicity related to nicotine patch misuse. Toxicity from concurrent use of multiple patches as a means of attempted suicide is reported.[37,69] Children have developed symptoms after exploratory self-application of one or more patches to the skin,[66,68] and after biting, chewing, or swallowing all or part of a patch.[68] In a prospective case series of 36 exposures in children younger than 16 years, half were dermal and half oral exposures. Fourteen children (39%) developed symptoms (gastrointestinal distress, weakness, and dizziness), 10 children were evaluated in an ED and two were admitted for observation and supportive care.[68] Toxicity may also develop in people who continue to smoke cigarettes after beginning therapy with the nicotine patch.[67]

Acute nicotine toxicity including vomiting, bradycardia, and severe agitation was reported in an 8-year-old boy after application of a homemade remedy for eczema. The paste was made from a mixture of tobacco leaves, lime juice, and freeze-dried coffee after a recipe published in a book from Bangladesh and written in Bengali. The patient made a full recovery after 4 days with supportive care.[22] Severe poisoning after use of tobacco extract enema is also reported.[27] Tobacco extract and

TABLE 84–3. Signs and Symptoms of Acute Nicotine Poisoning

	Gastrointestinal	Respiratory	Cardiovascular	Neurologic
Early (0.25–1 h)	Nausea Vomiting Salivation Abdominal pain	Bronchorrhea Hyperpnea	Hypertension Tachycardia Pallor	Agitation Anxiety Dizziness Blurred vision Headache Hyperactivity Confusion Tremors Fasciculations Seizures
Late (0.5–4 h)	Diarrhea	Hypoventilation Apnea	Bradycardia Hypotension Dysrhythmias Shock	Lethargy Weakness Paralysis

tobacco smoke enemas were used in the pre-Columbian Americas by many tribes for both medicinal and spiritual purposes. They are still recommended by naturopaths and folk healers as a remedy for constipation, urinary retention, pinworm, and "hysterical convulsions."[36] Exposure to fresh tobacco leaves may produce green tobacco sickness. This syndrome has been likened to seasickness, and is characterized by dizziness, headache, nausea, weakness, vomiting, diarrhea, abdominal cramps, and chills. Signs of autonomic instability may be present in severe cases. Symptom onset is 3 to 17 hours after exposure and the duration of illness may be several days.[45]

Two suicide deaths are reported after ingestion of the neonicotinoid pesticide imidacloprid.[58] In both cases imidacloprid was implicated by postmortem liquid chromatography-mass spectrometry (LC/MS) analysis and no information was available regarding dosage or manner of death. Two other published case reports of intentional imidacloprid ingestions describe a more benign clinical course. In one of these cases symptoms included an initial period of drowsiness, disorientation, and dizziness that resolved within 12 to 15 hours, with subsequent development of fever and vomiting. Oral, esophageal, and gastric erosions were demonstrated by endoscopy.[70] Some of the clinical manifestations noted in this case may have been related to the solvent *N*-methyl pyrrolidone. Another patient who ingested a 17.8% imidacloprid solution also had initial altered level of consciousness followed by fever, bradycardia, and recurrent vomiting.[21] Both patients recovered with supportive care.

DIAGNOSTIC TESTING

Determination of serum or urinary concentrations of nicotine or its metabolites is unlikely to be helpful in the management of the acutely poisoned patient. The presence of measurable concentrations of nicotine or cotinine may reflect coincidental or chronic active or passive exposure, and does not necessarily imply acute intoxication. Cigarette smokers typically maintain serum nicotine concentrations around 30 to 50 ng/mL during the day, but may achieve concentrations as high as 100 ng/mL.[48]

Since urinary cotinine has a longer detection window, the absence of cotinine in the urine is often used to document abstinence from tobacco products. Conversely, urinary cotinine concentrations are used to document exposure to nicotine-containing products, including exposure to secondhand smoke, and to guide dosage adjustments in nicotine replacement therapy.[6,39,48]

MANAGEMENT

Most patients with unintentional or low-dose nicotine exposures will not require medical evaluation. Patients who ingest one or more cigarettes, three or more cigarette butts, any amount of nicotine or a neonicotinoid insecticide, or who have protracted vomiting or develop symptoms other than vomiting should be referred to an ED without delay. Patients with mild or no symptoms after exposure to low doses of nicotine can be observed for several hours and safely discharged home if no complicating circumstances are present such as significant comorbid cardiovascular illness, intent to self-harm, or the presence of clinical symptoms.

Vomiting is common and may limit absorption in some patients with nicotine toxicity. Induction of emesis with syrup of ipecac should be avoided since it is unlikely to be of added benefit and has the potential for harm. Orogastric lavage may be considered in patients who present immediately after large ingestions of nicotine-containing products. Activated charcoal adsorbs nicotine and can reduce absorption, but the risks of pulmonary aspiration from activated charcoal

administration to patients with active vomiting seizing or a depressed level of consciousness outweigh the potential benefit.

Patients with dermal exposure to wet tobacco leaves or pesticides should be undressed completely, and the skin washed thoroughly with soap and copious amounts of water. Personal protective gear should be worn by medical staff charged with handling both clothes and patients prior to decontamination. Symptomatic patients should have any nicotine patches removed immediately and the skin washed with soap and water.

There is no specific antidote for nicotine toxicity. Treatment of acute nicotine toxicity is supportive. The first priority is to ensure airway protection and respiratory support. Seizures may be treated with a benzodiazepine. Hypotension should be treated with fluid boluses and an infusion 0.9% NaCl initially. Patients who fail to respond to volume infusion may require treatment with a vasopressor such as norepinephrine. Dysrhythmias should be treated according to standard protocols. Nicotine elimination is enhanced in acidic urine[8] but the potential risks outweigh the benefits of this elimination strategy.

SUMMARY

The primary source of nicotine is *Nicotiana* species and nicotine toxicity may occur after exposure to the fresh or dried leaves. An increasing number of nicotine-containing products are available today as alternate sources of drug that are intended to facilitate smoking cessation. Nicotine and the neonicotinoids are important pesticides that may also cause significant toxicity in humans. Nicotine is well absorbed after ingestion, inhalation, and dermal exposure. It is rapidly distributed to the brain, where it activates nicotinic acetylcholinergic receptors, stimulates the reticular activating system, and facilitates neurotransmitter release. Metabolism is via the hepatic cytochrome oxidase system, to inactive metabolites that are then slowly excreted in urine. The half-life of nicotine in the body is 1 to 4 hours, with more rapid clearance in individuals chronically exposed to the drug. Clinical manifestations of nicotine toxicity are those of nicotinic cholinergic excess, and most commonly include agitation and vomiting. Severe intoxication may cause seizures, cardiac dysrhythmias, hypotension, and neuromuscular blockade with respiratory failure from muscular paralysis. The clinical course in these cases is typically biphasic, with initial stimulation followed by inhibition. There are no antidotes for nicotine, and acute toxicity should be managed with symptom-directed, supportive care.

CHAPTER 85
PHENCYCLIDINE AND KETAMINE

Ruben E. Olmedo
Phencyclidine (PCP)
Ketamine
Dextromethorphan

Phencyclidine (PCP) and ketamine are dissociative anesthetics that are abused for their psychoactive effects, with ketamine having one-tenth the potency. PCP's popularity peaked during the 1970s. Ketamine gained popularity in the 1990s along with γ-hydroxybutyrate (GHB) and hallucinogenic amphetamines, which remain popular in night-clubs and "raves." Both xenobiotics affect the central nervous system (CNS), producing psychiatric and medical complications during an "out of body experience" and alteration in sensory perception. As a class of their own, they carry out these effects via inhibition of the N-methyl-D-aspartate (NMDA) receptor. The opioid, dextromethorphan, causes similar dissociative effects in high doses and has become popular among today's youth as it is easily obtained in cough suppressants. An understanding of the pharmacology and pathophysiology of PCP and ketamine is valuable in the diagnosis, management, and treatment of patients with toxicity from these agents.

HISTORY AND EPIDEMIOLOGY

PCP was discovered in 1926, but it was not developed as a general anesthetic until the 1950s. At the time, the Parke Davis drug company was searching for an ideal intravenous (IV) anesthetic that would rapidly achieve analgesia and anesthesia with minimal cardiovascular and respiratory depression.[36] It was marketed under the name Sernyl because it rendered an apparent state of serenity when administered to laboratory monkeys. Its surgical use began in 1963, but PCP was rapidly discontinued when a 10% to 30% incidence of postoperative psychoses and dysphoria was documented over the subsequent 2-year period.[81] By 1967 the use of PCP was limited exclusively to veterinary medicine as a tranquilizer marketed under the name Sernylan.

Simultaneously, in the 1960s, PCP was developing as a San Francisco street drug called "the PeaCe Pill."[66] Numerous street names have been given to phencyclidine: on the West Coast it was called "angel dust," PCP, "crystal," "crystal joints" (CJs); Chicago called it "THC" or "TAC"; the East Coast opted for "the sheets," "Hog," or "elephant tranquilizer."[121] Ironically, PCP was initially unpopular with drug users because of its dysphoric effects and unpredictable oral absorption.[157] With time, however, its use spread in a similar geographic pattern to that of marijuana and lysergic acid diethylamide (LSD), from the coastal United States to the Midwest region.[66]

Phencyclidine abuse became widespread during the 1970s.[25,182] The relatively easy and inexpensive synthesis coupled with the common masking of PCP as LSD, mescaline, psilocybin, cocaine, amphetamine, and/or "synthetic THC" (tetrahydrocannabinol) added to its allure and consumption.[121] By the late 1970s PCP abuse had reached epidemic proportions.[7] The Drug Abuse Warning Network (DAWN) reported that the number of PCP-related emergencies and deaths more than doubled in the 2 years from 1975 to 1977. In 1978 the National Institute of Drug Abuse reported that of young adults (18–25 years old), 13.9% had used PCP.[50] The manufacture of phencyclidine was ultimately prohibited in 1978 when it was added to the list of federally controlled substances. Classifying PCP as a Schedule II drug led to its decrease in availability and, consequently, a decrease in its use. Although the 1980s brought about a cocaine epidemic that eclipsed PCP, PCP has remained consistently available, primarily regionalized to large cities in the northeastern United States and in the Los Angeles area,[103] where PCP use continues to rise and fall with societal trends. Because many of the PCP congeners made during the manufacturing process were being abused in place of PCP, the Controlled Substance Act of 1986 made these derivatives illegal and established that the use of PCP's precursor, piperidine, necessitated mandatory reporting. With this new law in place, those possessing similar but not identical illegal substances could be prosecuted. This led to a further decline in the popularity of phencyclidine. Beginning in 1984, the overall use of PCP declined, reaching a nadir in 1994.[185] Since 1994, however, there has been an increase of reported PCP abuse. DAWN reported that the number of PCP-related emergencies increased 28% between 1995 and 2002, with the highest rate in 2002 encountered in Washington, DC; Philadelphia; Los Angeles; Chicago; and Newark.[186,189,190] According to the 2002 National Survey on Drug Use and Health (NSDUH), lifetime use of PCP was highest among those 26 years of age and older (3.5%) compared with people aged 18 to 25 years (2.7%) and those aged 12 to 17 years (0.9%).[185] In the 2003 NSDUH report, the number of PCP users remained stable at approximately 200,000.[187] It reported that in 2006 approximately 187,000 persons aged 12 or older used PCP in the past year and that 6.6 million persons had used PCP in their lifetime.[189] This number has not changed according to the NSDUH report of 2008.

Laboratory investigation of phencyclidine derivatives led to the discovery of ketamine, a chloroketone analog. Ketamine was introduced for general clinical practice in 1970 and was marketed as Ketalar, Ketaject and, for veterinary use, Ketavet. Because ketamine has approximately 5% to 10% of the potency of PCP and a much shorter duration of action, it provides greater control in clinical use. Thirty-five years of clinical experience have established that ketamine provides adequate surgical anesthesia, a rapid recovery, and less prominent emergence reactions than PCP.[56,78,160,201] Because of the simplicity and efficacy of its use it is regularly used in operating rooms, emergency departments (EDs), and throughout the developing world where little clinical monitoring is available during surgical and emergency procedures.[53,77,78,80,81,83,161,200]

Abuse of ketamine was first noted on the West Coast in 1971.[171] During the 1980s there were reports of its abuse internationally, as well as among physicians.[3,68] The nonmedical use of dissociative anesthetics

has continued to increase throughout the 1990s and into the 2000s, in spite of the common complications associated with their use.[184] The same pharmacologic qualities that made ketamine more popular than PCP clinically are also responsible for its nonmedical popularity. Ketamine is regularly consumed at all-night "rave parties" and in nightclubs because of its "hallucinatory" and "out-of-body" effects, relatively inexpensive price, and short duration of effect: a single insufflation lasts between 15 and 20 minutes.[11,44,92,96,202]

The use of ketamine is not limited to the inner city. In the past decade, the media reported police arrests in affluent suburban communities for possession and sale of ketamine, as well as more in-depth and frequent reporting of the effects of its toxicity among users.[44,92,158,202] In contrast to PCP, ketamine is not manufactured illegally, but rather, it is diverted from legitimate medical, dental, and veterinary sources. Additionally, with the advent of the Internet, its availability has dangerously grown nationwide; a sham "biotech" Internet company was seized by New York City police in 2000 for selling so-called date-rape drugs, including ketamine.[133]

Adverse reactions do occur, although there are few reports of fatalities secondary to ketamine during this period of increased use.[72,112,116,138] Because of its abuse potential, ketamine was placed in Schedule III of the Controlled Substance Act in 1999.[160] In 2002, DAWN reported that there was a dramatic rise (more than 2000%) of ketamine-related ED visits between 1994 and 2001. Despite any clear reason, after peaking in 2001, there was a decline in ketamine-related ED visits in 2002.[187] The 2006 NSDUH estimated that 2.3 million persons aged 12 or older used ketamine in their lifetime, and 203,000 were past-year users.[188]

PHARMACOLOGY

■ CHEMISTRY

Phencyclidine's chemical name, 1-(1-phenylcyclohexyl)piperidine, provided the basis for its street acronym PCP. During its unlawful chemical synthesis, numerous analogs are made that have similar effects on the CNS and have been used as PCP substitutes. These "designer" arylcyclohexylamines are aliphatic- or aromatic-substituted amines, ketones, or halides, and appear similar to the parent compound. More than 60 psychoactive analogs are mentioned in the medical literature and the following salient points of the five most prevalent compounds are worth mentioning. TCP (1-[1-(2-thienyl)cyclohexyl] piperidine) and PCC (1-piperidino-cyclohexanecarbonitrile) are piperidine derivatives. Piperidine, the synthetic precursor, was formerly easily purchased for manufacturing PCP and its derivatives. TCP, a thiophene analog, produces even more intense effects than PCP. An intermediate of PCP synthesis, PCC was a constituent of up to 22% of illicit drug preparations analyzed for phencyclidine. This most likely resulted from a poor manufacturing process.[14,170] PCC degrades to piperidine, which is recognizable by its strong fishy odor. The presence of its carbonitrile group adds to its toxicity by generating cyanide when smoked.[12,14,177,178] The pyrrolidine derivative, PHP (phencyclohexylpyrrolidine), is clinically comparable to PCP and is not detected by many of the available drug-screening methods.[27,89] More potent than PCP, PCE (1-phenyl-cyclohexylethylamine) was commonly available on the street as a white powder indistinguishable from PCP.[170]

Ketamine and tiletamine, two legal analogs of PCP, are used clinically for sedation and anesthesia. In larger quantities, both are also used in veterinary medicine for animal sedation. Ketamine (Ketaset and Ketalar) is the only dissociative anesthetic product manufactured for human use for the purpose of anesthesia, conscious sedation, and the treatment of bronchospasm. The development of a mechanistic approach to pain therapy in the last 15 years has brought a renewed interest in the use of ketamine as an adjuvant to multimodal pain treatment. Ketamine is used prophylactically and therapeutically in children and adults in the management of postoperative pain. For the treatment of pain ketamine is administered intravenously (median dose: 0.4 mg/kg; range: 0.1–1.6), orally, intramuscularly, rectally, subcutaneously, intraarticularly, caudally, epidurally, transdermally, intranasally, or added to a patient-controlled analgesia device.[61,82,90,107,163]

The molecular structure of ketamine [2-(ortho-chlorophenyl)-2-methylaminocyclohexanone] contains a chiral center, producing a racemic mixture of two resolvable optical isomers or enantiomers, the D(+)-isomer and L(–)-isomer. Commercially available preparations of ketamine contain equal concentrations of the two enantiomers. These two molecules differ in their pharmacodynamic effects. In a randomized, double-blind evaluation of patients undergoing surgery, the D(+)-isomer of ketamine was a more effective anesthetic, but manifested a higher incidence of psychotic emergence reactions than the L(–)-isomer. In other studies, the D(+)-isomer caused a greater increase in both blood pressure and pulse than the L(–)-isomer, and also had more bronchodilating effects.[161,201]

■ PHARMACOKINETICS AND TOXICOKINETICS

Phencyclidine is a white, stable solid that is readily soluble in both water and ethanol. It is a weak base with a pK_a between 8.6 and 9.4 with a high lipid-to-water-partition coefficient. It is rapidly absorbed from the respiratory and the gastrointestinal tracts; as such, it is typically self-administered by oral ingestion, nasal insufflation, smoking, or IV and subcutaneous injection.

The effects of PCP are dependent on routes of delivery and dose. Its onset of action is most rapid from the IV and inhalational routes (2–5 minutes) and slowest (30–60 minutes) following gastrointestinal absorption.[42,43] Sedation is commonly produced by doses of 0.25 mg intravenously, whereas oral ingestion typically requires 1 to 5 mg to produce similar sedation. Signs and symptoms of toxicity usually last 4 to 6 hours, and large overdoses generally resolve within 24 to 48 hours, but effects may persist in a chronic user.[16,54,57,120,144,157] However, in the PCP-poisoned patient, the relationships between dosage, clinical effects, and serum concentrations are not reliable or predictable.

There are several explanations for the protracted CNS effects of PCP. Its large volume of distribution of 6.2 L/kg[42,206] and high lipid solubility account for its entry and storage in adipose and brain tissue. Also, on reaching the acidic cerebrospinal fluid (CSF), PCP becomes ionized, producing CSF concentrations approximately six to nine times greater than those of serum.[135]

PCP undergoes first-order elimination over a wide range of doses. It has an apparent terminal half-life of 21 ± 3 hours under both control and overdose settings.[42,95] More prolonged toxicity has been reported in patients who "body-pack" PCP in plastic bags.[95,209] Ninety percent of PCP is metabolized in the liver and 10% is excreted in the urine unchanged. PCP undergoes hepatic oxidative hydroxylation into two monohydroxylated and one dihydroxylated metabolites.[43] All three compounds are conjugated to the more water-soluble glucuronide derivatives and then excreted in the urine.

Urine pH is an important determinant of renal elimination of PCP. In acidic urine, PCP becomes ionized and then cannot be reabsorbed. Acidification of the urine increased renal clearance of PCP from 1.98 ± 0.48 L/h to 2.4 ± 0.78 L/h.[42] Additional studies have found a much higher renal clearance (8.04 ± 1.56 L/h) if the urine pH was decreased to less than 5.0.[10] Although this may account for a 23% increase in the renal clearance, it only represents a 1.1% increase of the total clearance.

Similarly, ketamine is water soluble but also has a high lipid solubility that enables it to distribute to the CNS readily. It has a pK_a of

7.5 and a volume of distribution of 1.8 ± 0.7 L/kg. Ketamine has approximately 10% of the potency of PCP,[78,97] and human trials demonstrate that its clinical effects, similar to PCP, are both route and dose dependent.[46,49,56,179] Peak concentrations occur within 1 minute of IV administration and within 5 minutes of a 5-mg/kg intramuscular (IM) injection.[201,210] Ketamine distributes immediately into the CNS with the duration of its hypnotic and anesthetic effects being principally caused by its redistribution from the brain to other tissues.[201] Recovery time averages 15 minutes for IV administration, but it is prolonged to between 30 and 120 minutes for IM administration. Oral or rectal doses are not well absorbed and undergo substantial first-pass metabolism.[161,201] In contrast to oral administration of ketamine where symptoms last 4 to 8 hours, symptoms after nasal administration last for 45 to 90 minutes.

Ketamine is extensively metabolized in the liver by the cytochrome P450 (CYP) isoenzyme CYP2B6 and to a lesser extent by CYP3A4 and CYP2C9.[208] Its biotransformation is complex with numerous metabolites described.[2,161,201] The major pathway involves its *N*-demethylation to norketamine, a metabolite with one-third the anesthetic potency of ketamine. Norketamine is hydroxylated at different sites within its hexanone ring, producing varying second chiral centers. The majority of these diastereoisomers are glucuronidated to more water-soluble derivatives that are then excreted in the urine.[78,161] Ketamine also undergoes ring hydroxylation prior to *N*-demethylation as a minor metabolic pathway. The elimination half-life, which reflects both metabolic and excretory phases, is 2.3 ± 0.5 hours and is prolonged when xenobiotics requiring hepatic metabolism are coadministered.[118] Because of the enzymatic hepatic metabolism, both tolerance and enzyme induction are reported following chronic administration.[78,161]

■ AVAILABLE FORMS

PCP is available on the street in a variety of forms, including powder, liquid, tablets, leaf mixtures, and rock crystal. Because of its uncontrolled illegal manufacture, the contents of PCP vary considerably, with powder often the purest form, containing approximately 5 mg per dose.[156] Leaf mixtures are made by sprinkling approximately 1 to 10 mg of phencyclidine onto parsley, oregano, mint, tobacco, or marijuana. A typical PCP joint (known as "crystal joint," "KJ," or "supergrass") is developed for smoking and contains about 1 mg per 150 mg of plant product.[7] Mentholated cigarettes dipped into liquid PCP are known as "supercools."

Since PCP's inclusion in the federal Controlled Substance Act of 1970, it has been infrequently incorporated into marijuana cigarettes. There are reports of marijuana cigarettes being adulterated with PCP and sold on the street under varying names like "Illy" in Connecticut, "Hydro" in New York City, "Dip" in New Jersey, "Wet" in Philadelphia, and "Fry" in Texas.[91] The cigarettes are treated with embalming fluid, which allegedly enhances the drug's euphoric effects. Embalming fluid, which contains formalin (formaldehyde in methanol), is used as a medium to allow a uniform distribution of PCP in these cigarettes.[91] It is difficult to discern whether this "enhanced" mixture is purchased intentionally or is placed in these cigarettes surreptitiously.

On the street and on the Internet, ketamine is known as "vitamin K," "Special K," "Super K," "Ket," or simply "K." It is available in a liquid form that is dried into a pure-white crystalline powder and is typically self-administered by ingestion or insufflation in a fashion similar to PCP. It is rarely injected intravenously or intramuscularly in liquid form.

When used by injection there is an observed demographic and behavioral difference among those who initiate drug injection use with ketamine and those who initiate injection use with another xenobiotic and later transition into ketamine injection.[115]

Ketamine is primarily sold as tablets, capsules, or powder. These formulations are often adulterated with caffeine, methylenedioxymethamphetamine (MDMA), ephedrine, methamphetamine, heroin, and cocaine (a mixture known as CK or Calvin Klein).[59,164] In fact, in addition to alcohol, MDMA (39%), heroin (17%), and cocaine (14%) are the most frequently mentioned xenobiotics used with ketamine.[191] Exemplifying the commercial growth of ketamine, some of the tablets are even found to contain a "K" logo.[59] Common sedating doses are 75 to 300 mg orally (30–75 mg for insufflation). Higher doses, ranging between 300 and 450 mg orally (100–250 mg for insufflation), result in substantial CNS toxicity. These manifestations are similar to the clinical "emergence reactions" that patients experience ketamine anesthesia.

PATHOPHYSIOLOGY

The arylcyclohexylamines, of which PCP and ketamine are prototypes, are a group of anesthetics that functionally and electrophysiologically "dissociate" the somatosensory cortex from higher centers.[46,200] The precise mechanisms by which PCP and ketamine achieve these effects are complex and not fully understood; however, investigation of the nature of PCP-induced psychosis has led to a substantial identification of the various sites of PCP activity.

Most studies demonstrate that PCP and ketamine bind with high affinity to sites located in the cortex and limbic structures of the brain.[123] They block the NMDA receptors at serum concentrations encountered clinically.[195,211] Analogs of PCP (TCP, PCE, PHP, ketamine) and dizocilpine (MK-801) also interact with the NMDA receptor in a dose–response manner that corresponds appropriately to their neurobehavioral effect.[26,167,203] These xenobiotics bind to the NMDA receptor at a site independent of glutamate.[97,102,123,205] As such they antagonize glutamate's action on this channel and noncompetitively block Ca²⁺ influx (Fig. 13-14).

PCP and ketamine bind to the biogenic amine reuptake complex with 10% to 20% of the affinity to which they bind to the NMDA receptor. Binding occurs at physiologic concentrations that normally take place after subanesthetic doses.[4,152] This weak inhibition of the catecholamine reuptake accounts for the respective sympathomimetic and psychomotor effects. An increase in blood pressure and heart rate is induced. Rapid IV infusion produces a more pronounced effect than by IM injection, with the D(+)-isomer having a greater effect than the L(−)-isomer.[201]

In significant overdoses, PCP and ketamine also stimulate σ receptors at concentrations generally associated with coma, although with lower affinity than NMDA receptors.[180,204] Both D_2 and σ receptors have an inhibitory effect on the cholinergic receptor pathways.[204] At the higher concentrations typically associated with death, PCP and ketamine also bind to the nicotinic, opioid, and muscarinic cholinergic receptors.[194]

Data indicate that NMDA antagonists produce effects on behavior, sensation, and cognition that resemble aspects of endogenous psychoses, particularly schizophrenia.[98,149] The behavioral abnormalities were first observed in studies in the late 1950s when PCP, administered to healthy volunteers, generated a form of organic psychosis that mimicked schizophrenia. When PCP was administered to schizophrenic patients it uniformly intensified their primary symptoms of profound disorganization, and some of these symptoms lasted for weeks.[120] PCP psychosis is so similar to schizophrenia that many psychiatrists cannot distinguish them without a prior indication of drug abuse history.[176]

Current interest in the role of excitatory neurotransmitter systems in the pathophysiology of schizophrenia has led to similar observations in patients after ketamine administration. Subanesthetic doses of

ketamine administered to both healthy and schizophrenic volunteers induced a mild, dose-related, short-lasting increase in psychotic symptoms. Although the normal and schizophrenic volunteers had different levels of baseline psychosis, the magnitude, time course, and dose–response changes in positive symptoms were similar across the two populations. Both groups experienced thought disorganization, such as concreteness and loose association, hallucinations, and delusions along a gradient of intensity.[110,112–114]

There is a connection between PCP psychosis and sensory processing. PCP and ketamine inhibit sensory perception in a dose-dependent manner. This processing in sensory information corresponds to their relative affinities to the NMDA receptor and not to the σ receptor.[6,152] Clinically, the impairment of sensory input produced by PCP resembles that of patients who are deprived of sensory stimulation.[134] When external stimulation was reduced by environmental sensory deprivation, the psychotomimetic effects of PCP were diminished,[40] giving credence to the theory that it may not be anxiety that causes perceptual dysfunction in schizophrenia, but the converse.

Many of the NMDA antagonists, including PCP and ketamine, have a negative effect on cognition and memory. There is substantial evidence in animal studies, including primates, where repeat administration of PCP and ketamine result in cognitive and memory impairement.[87,100] Both impair concentration, recall, learning, and retention of new information.[13,30,52,54,73,86–88,110,127,137,146] In human volunteers, ketamine selectively impairs explicit,[72] episodic,[51,141] and procedural memory,[141] and disrupts frontal cortical function, as measured by the Wisconsin Card Sorting Task and verbal fluency,[110,127] in a dose-dependent manner. Learning and memory impairments in volunteers who were administered subanesthetic doses of ketamine (0.65 mg/kg) are independent of the subject's attention and related psychosis.[127] Similar testing performed on chronic ketamine users produces similar results that are long lasting and have more marked effects on semantic and episodic memory.[51,52,142,143] Accordingly, it is presumed that the acute and repeated NMDA receptor antagonism interferes with those functions that integrate interoceptive and exteroceptive input in which goal-directed action becomes possible, similar to the organic psychosis in schizophrenia.

Hypofunction of the NMDA receptor causes neuroanatomical and neurobehavioral toxicologic effects. Animals exposed to NMDA antagonists such as PCP and dizocilpine transiently demonstrated neuronal vacuolar degeneration in the retrosplenial cortex and the posterior cingulate areas of the brain.[147,148] The major function of cingulate cortical neurons is to mediate affective responses to pain.[196] Single high doses or repeated exposure to NMDA receptor antagonists are associated with a higher incidence of cellular death.[45,62,63,147] This injury seems to be related to the induction of selective expression of individual heat shock proteins in this anatomical area.[169] Excitatory amino acids are neurotransmitters responsible for mediating seizure activity in the brain. As NMDA inhibitors, the anticonvulsant properties of PCP and ketamine are inconclusive. Animals administered PCP or PCP analogs progress through dose-related clonic activity followed by tonic–clonic convulsions, as is typical of classic convulsant compounds.[152] Animal research also demonstrates wide interspecies variability of the electroencephalographic (EEG) effects of PCP.[57] In a murine seizure model, ketamine possessed selective anticonvulsant properties.[31] In addition, ketamine preserves learning proficiency in rats when administered shortly after onset of status epilepticus, an effect that may prove useful in the clinical setting when combined with conventional antiepileptic medications.[181]

In humans, although these dissociative xenobiotics induce excitatory activity in the thalamus and limbic areas, they do not affect cortical regions.[48,49,56,69] Excitation, muscle twitching, posturing,[136] and tonic–clonic motor activity with or without EEG changes are reported with these subcortical EEG alterations.[34,47,69,136] In the clinical setting, many report ketamine to possess anticonvulsant properties at clinically relevant doses and may be explained by an NMDA inhibitory effect.[34,47]

The NMDA receptor is also responsible for the development of the neuronal organization of the central nervous system.[93,94,172,173] It is linked to hypoxic–ischemic brain injury by mediating calcium influx, a final pathway in cell death. The uninhibited firing of NMDA afferent neurons secondary to brain injury causes their death, as well as the death of efferent neurons downstream. In neonatal rats, ketamine increases the rate of neuronal apoptosis.[166] NMDA antagonists such as PCP block hypoxic brain injury from stroke and trauma.[17,119] In a rat model of ischemic stroke, PCP had a protective effect on the brain, demonstrated by a decreased rate of seizure activity.[17] This effect is transient and has not been studied in human subjects.

PCP induces modest tolerance in rats and squirrel monkeys. The development of tolerance is mostly secondary to PCP's pharmacologic effect rather than to biodispositional changes. Dependence was also observed in monkeys who self-administered PCP (10 mg/kg/d to serum concentrations of 100–300 ng/mL) over 1 month by the appearance of dramatic withdrawal signs when access was denied. Signs included vocalizations, bruxism, oculomotor hyperactivity, diarrhea, piloerection, difficulty remaining awake, tremors, and in one case convulsions.[15] These signs appeared within 8 hours of abstinence and were most severe at about 24 hours. When either PCP or ketamine (2.5 mg/kg/h) was readministered to the animals, PCP withdrawal symptoms were reversed, indicating cross-dependence from PCP to ketamine.[20,99,175]

Physiologic dependence in humans has not been formally studied. It is implied to occur by the observation that 68 chronic PCP users developed depression, anxiety, irritability, lack of energy, sleep disturbance, and disturbed thoughts after 1 day of abstinence from drug use.[159] Additionally, neonates whose mothers used PCP developed jitteriness, vomiting, and hypertonicity that lasted for at least 2 weeks.[183] These symptoms may represent PCP withdrawal or intrinsic teratogenic effects on neurologic development.[76,93] Although there are no controlled studies observing the physiologic symptoms of withdrawal in humans who chronically use PCP or ketamine, there is a definite psychological dependence on the sensations experienced during recreational use of the drugs.[171] There are few case reports of ketamine dependency in the medical literature where patients report a need to use an increased quantity of drug to get the same effect.[139,153] In addition, ketamine impairs response inhibition, which is found to be related to increases in subjective ratings of desire for the drug.[141]

CLINICAL MANIFESTATIONS

The reported signs and symptoms of patients presenting to the ED with PCP and ketamine toxicity are variable. The variations are a result of differences in dosage, the multiple routes of administration, concomitant xenobiotic use, and other associated medical conditions. In accordance with their pharmacologic effect, ketamine toxicity produces signs and symptoms similar to PCP with a shorter duration of action. Additionally, individual differences in xenobiotic susceptibility, the development of tolerance in chronic users, as well as contaminants in the drug manufacture, may account for erratic clinical findings.

■ VITAL SIGNS

Body temperature is rarely affected directly by PCP and ketamine. In one large series, only 2.6% of patients demonstrated hyperthermia (temperature greater than 101.8°F [38.8°C]).[130] In an experimental animal model, PCP failed to increase body temperature.[36,57] When

hyperthermia does occur, all the known complications, including encephalopathy, rhabdomyolysis, myoglobinuria, acute renal failure, electrolyte abnormalities, and liver failure, occur (Chap. 15).[8,19,39,154]

Most PCP- and ketamine-toxic patients demonstrate mild sympathomimetic effects. PCP consistently increases both the systolic blood pressure (SBP) and diastolic blood pressure (DBP) in a dose-dependent fashion.[36,57] (Doses of 0.06 mg/kg of IV PCP increased the SBP and DBP by 8 mm Hg, whereas 0.25 mg/kg produce a 26 and 19 mm Hg increase in SBP and DBP, respectively.) PCP also increases the heart rate, although inconsistently.[84] Likewise, ketamine produces mild increases in blood pressure, heart rate, and cardiac output via this same mechanism.[49,122,179,192,201] In fact tachycardia was the most common finding on physical examination in a case series of ketamine abusers presenting to the ED.[199]

CARDIOPULMONARY

Rarely are cardiovascular catastrophes encountered in PCP toxicity.[60,131] These complications may result from direct vasospasm,[5,35] causing severe systemic hypertension[61] and cerebral hemorrhage.[22] Hypertension, along with abnormal behavior, miosis, and nystagmus in children, strongly suggest toxicity due to a dissociative anesthetic.[105]

The effect of PCP and ketamine on cardiac rhythm is controversial. Dysrhythmias are only observed in animals poisoned with very large doses of PCP. Ketamine both enhances and diminishes epinephrine-induced dysrhythmias in animals.[21,58,85,106] The considerable experience in the use of ketamine anesthesia on humans undergoing surgery or cardiac catheterization has not demonstrated prodysrhythmic effects.[65,145]

As these dissociative anesthetics were designed to retain normal ventilation, hypoventilation is uncommon. In clinical studies, PCP increased the minute ventilation, tidal volume, and respiratory rate of volunteers.[84] Clinically, in PCP-toxic patients, irregular respiratory patterns occur with tachypnea much more often than with bradypnea.[8,130] Hypoventilation, when present, is usually secondary to the use of particularly high doses of PCP. Acute lung injury secondary to respiratory depression is also a rare occurrence. Large doses of PCP (20 mg/kg) administered to laboratory animals produced respiratory depression.[36] Although respiratory depression in humans is an extremely rare event, it has been reported with fast or high-dose infusions of ketamine.[79,201] In fact, ketamine has been successfully used to prevent intubation in patients with refractory asthma. Ketamine relaxes bronchial smooth muscles, decreases mean airway pressure and $Paco_2$, and increases Pao_2.[71,162,184,201]

NEUROPSYCHIATRIC

The majority of patients with PCP and ketamine toxicity who are brought to medical attention manifest diverse psychomotor abnormalities.[12,18,28,68,100,199] As dissociative anesthetics, these xenobiotics impair response to external stimuli by separating various elements of the mind. Consciousness, memory, perception, and motor activity appear dissociated from each other. This dissociation prevents the user from attaining cognition and properly assembling all this information to construct a reality. Clinically the person may appear inebriated, either calm or agitated, and sometimes violent. In large overdoses, the anesthetic effect causes patients to develop stupor or coma. In recreational use, "dissociatives" are not taken for these effects, but rather for so-called out-of-body experiences. In addition patients often have disordered thought processes (including disorientation as to time, place, and person) or amnesia, paranoia, and dysphoria.[67]

The manifestations of PCP and ketamine toxicity are better illustrated by the results of their effects in controlled human studies. Volunteers who took oral PCP doses of up to 7.5 mg/d, or ketamine 0.1 mg/kg, exhibited inebriation, but higher doses (PCP greater than 10 mg/d; ketamine 0.5 mg/kg) generally caused a more severe impairment of mental function.[57,110] Intravenous doses of 0.1 mg/kg of PCP[16,54,120,144,165] or 0.5 mg/kg of ketamine[110,152] causes diminution in all sensory modalities (pain, touch, proprioception, hearing, taste, and visual acuity) in a dose-dependent fashion. Both drugs also cause feelings of apathy, depersonalization, hostility, isolation, and alterations in body image.[16,54,70,101,110,120,126,142,152] The deficits in sensory modalities are evident prior to the development of the psychological effects of PCP, with pain perception disappearing first. This alteration in analgesic perception is caused by a blocking action on the thalamus and midbrain (Fig. 85–1).[144]

Abnormal stereognosis and proprioception occur in a dose-dependent manner. This disturbed perception results in body image distortions described as "numbness," "sheer nothingness," and "depersonalization." The decrease of proprioceptive sensation to gravity probably gives the sensation of "tripping" or "flying." Because all sensory modalities are affected, visual, auditory, and tactile illusions and delusions are common. Hallucinations are typically auditory rather than visual, which are more common with LSD use. Ketamine's hallucinogenic effects on healthy human volunteers are linearly related to steady-state concentrations between 50 and 200 ng/mL.[23] The majority of ketamine users report experiencing a "k-hole," a slang term for the intense psychological and somatic state experienced while under the influence of ketamine. This experience varies with the individual, but can include buzzing, ringing or whistling sounds, traveling through a dark tunnel, intense visions, and out-of-body or near-death sensations.[55]

The reaction to the misperceived or disconnected reality may result in unintentional actions and violent behavior. The hallmark of PCP toxicity is the recurring delusion of superhuman strength and invulnerability resulting from both its anesthetic and dissociative properties. There are case reports of patients presenting with trauma either from
FIGURE 85–1. Clinical effects of phencyclidine and ketamine. Phencyclidine and ketamine bind to different receptors in the CNS with varying degrees of affinity; that is, an increasing concentration is necessary to achieve the various clinical effects. ACh, acetylcholine, GABA = δ amino butyric acid, N_N = nicotinic receptor, M = muscarinic receptor, NMDA = N-methyl-D-aspartate, MAOI = monoamine oxidase inhibitor.

jumping from high altitudes, fighting large crowds or the police, or self-mutilation. The true extent and incidence of violence is probably less than previously suggested.[24]

Typically, neurologic signs include horizontal, vertical, and/or rotatory nystagmus, ataxia, and altered gait. Initially, except for ataxia, motor movement is not impaired until the patient becomes unconscious. On physical examination, use of dissociative anesthetics typically produces relatively small pupils, nystagmus, and diplopia. In the largest case series reported to date, nystagmus and hypertension were noted in 57% of patients who had taken PCP.[130] Smaller and more limiting studies have found an incidence of nystagmus of 89% or higher.[18] In comparison, nystagmus was only found in 15% of patients with ketamine abuse.[199] Other cerebellar manifestations were also encountered, most notably dizziness, ataxia, dysarthria, and nausea. A pooled data compilation of 35 reports demonstrated that emesis occurred 8.5% of the time.[79] In fact, Internet chat groups devoted to substance abuse commonly direct users to "mix dissociatives with marijuana" for its antiemetic effect.

Larger doses of PCP produce loss of balance and confusion, the latter characterized by inability to repeat a set of objects, frequent loss of ideas, blocking, lack of concreteness, and disordered linguistic expression.[51,57,110,120,165] Similarly, ketamine users report a high incidence of incoordination, confusion, unusual thought content, and an inability to speak.[55] In general, dissociative anesthetics stimulate the CNS but seizures rarely occur, except at high doses. The largest case series of PCP-toxic patients detected a 3.1% incidence of seizures.[130]

Although PCP- and ketamine-toxic patients also present with motor disturbances, it is unclear to what extent PCP and ketamine are actually responsible for these manifestations. The most common of the reported disturbances are dystonic reactions: opisthotonos, torticollis, tortipelvis, and risus sardonicus (facial grimacing). Myoclonic movements, tremor, hyperactivity, athetosis, stereotypies, and catalepsy also occur.[12,29,68,130] A slight increase in muscle tone results from a dopaminergic effect.[120] Laryngospasm requiring intubation has been reported after the use of ketamine anesthesia. The incidence of this complication is less than 0.017%.[78] In comparison, the incidence of laryngospasm following traditional general anesthesia is 2%.[150]

■ EMERGENCE REACTION

The acute psychosis observed during the recovery phase of PCP anesthesia limits its clinical use. This bizarre behavior, characterized by confusion, vivid dreaming, and hallucinations, is termed an "emergence reaction." These reactions occur most frequently in middle-aged men, with a reported incidence of 17% to 30%.[84,104] The most violent emergence reactions follow an intravenous dose of approximately 0.25 mg/kg (total: 20 mg) of phencyclidine.[57] The mildest degrees of agitation produced by phencyclidine resemble the effects of ethanol intoxication. These same postanesthetic reactions also limit the clinical use of ketamine. The incidence of emergence reactions following ketamine administration may approximate 50% in adults and 10% in children.[78] Patients older than age 10 years, women, persons who normally dream frequently and/or have a prior personality disorder, premorbid denial of presence of illness or anosognosia, and paranoia incur the greatest risk.[78,132] The incidence of the occurrence of emergence reactions appears to be exacerbated when dissociative anesthetics are rapidly administered intravenously, and in those patients who are exposed to excessive stimuli during recovery. Although it has not been proved in a controlled study, reducing external stimuli during the recovery phase might reduce emergence reactions.

Both cholinergic and anticholinergic clinical manifestations occur in the PCP- or ketamine-toxic patient. Miosis or mydriasis, blurred vision, profuse diaphoresis, hypersalivation, bronchospasm, bronchorrhea, and urinary retention may occur.[12,18,117,129,130] Clinically, ketamine stimulates salivary and tracheobronchial secretions; both of which are equally and effectively inhibited by atropine and glycopyrolate.[139] Furthermore, in a randomized, double-blind trial, after infusion of 1.5 mg/kg of ketamine in healthy volunteers, physostigmine decreased nystagmus, blurred vision, and the time to recovery.[191]

Ironically, the very characteristics that were thought to make phencyclidine ideal for anesthesia—the preservation of muscle tone and cardiopulmonary function—magnify the difficulties in managing an individual who manifests dysphoria after an overdose. The course of delirium, stupor, and coma associated with PCP and ketamine is extremely variable, although the manifestations are much milder and shorter acting following ketamine use.

DIAGNOSTIC TESTING

If it is necessary to confirm the suspicion of PCP usage, urine is most commonly used for analysis, although serum, and possibly gastric contents, can be used. Rarely is it essential to make this determination. Most hospital laboratories do not perform quantitative analysis of PCP, but many can do a qualitative urine test for the presence of the drug. Qualitative testing is more important than a quantitative determination as serum concentrations do not correlate closely with the clinical effects. When a routine toxicologic screen is reported as negative this result should not lead to the erroneous conclusion that PCP exposure has been excluded. Routine toxicologic screening tests may not include PCP and it may be necessary to request a specific analysis if confirmation is required.

PCP is qualitatively detected by an enzyme immunoassay at a sensitivity of 10 ng/mL. High-affinity antibodies were once studied as specific PCP antagonists to reverse PCP-induced toxicity.[151,193] The detection of PCP is thus dependant on the concentration of PCP in the body fluid tested and the affinity of the antibody for the PCP molecule. As such, the immunoassay antibody binding to a molecule similar to PCP can produce false-positive reactions. Metabolites of PCP, such as PCE, PHP, TCP and its pyrrolizidine derivative TCPy, cross-react with the immunoassay at concentrations 30 times higher than those used to detect PCP. Because of its similar structure to PCP, dextromethorphan and its metabolite dextrorphan, also cross-react with Syva enzyme-multiplied immunoassay and fluorescence polarization PCP assays (Chap. 6).[92,198]

Although nonspecific, laboratory findings resulting from PCP use can include leukocytosis, hypoglycemia, and elevated concentrations of muscle enzymes, myoglobin, BUN, and creatinine.[130] The EEG reveals diffuse slowing with θ and δ waves, which may return to normal before the patient improves clinically.

There is no commercially available quantitative immunoassay for ketamine. When necessary, ketamine is detected by gas chromatography and mass spectroscopy. The increase in popularity in ketamine use in certain parts of the world has led to the development of rapid-detection urine assays that are sensitive, specific, and accurate.[37,197] There is anecdotal evidence that ketamine also cross-reacts with the urine PCP immunoassay because of their structural similarity.[168] Other authors, including the manufacturer who tests the reactivity of the commercially available PCP immunoassay with ketamine, do not find such results.[32,199]

MANAGEMENT

■ AGITATION

Conservative management is indicated for PCP and ketamine toxicity and includes maintaining adequate respiration, circulation, and thermoregulation. The psychobehavioral symptoms observed during acute

dissociative reactions and during the emergence reaction are similar. To treat the symptoms of agitation and alteration of mental status of acutely toxic PCP patients, it is helpful to recognize that both pharmacologic[1,33,38,41,64,77,78,124,128] and behavioral[40,41,78,111] modalities have been used to diminish agitation and emergence phenomena during conscious sedation with ketamine. To prevent self-injury, a common form of PCP-induced morbidity and mortality, the patient must be safely restrained, initially physically, and then chemically. An IV line must be inserted and blood drawn for electrolytes, glucose, BUN, and creatinine concentrations. The use of 0.5 to 1.0 g/kg of body weight of dextrose and 100 mg of thiamine HCl intravenously should be considered if indicated.

Although body temperature is directly affected by PCP and ketamine, hyperthermia may occur secondary to psychomotor agitation and should be rapidly identified. Treatment should be accomplished immediately with adequate sedation to control motor activity. At presentation, placing the patient in a quiet room with low sensory stimuli will help achieve this goal. Physical restraint should only be used temporarily, if necessary, until chemical sedation is achieved. Rapid immersion in an ice water bath may be necessary because body temperatures greater than 106°F (41.1°C) place the patient at a great risk for end-organ injury. These patients will need volume repletion and electrolyte supplementation because hyperthermia increases fluid loss from sweat.

In the pharmacologic treatment of emergence reactions, benzodiazepines have been used with great success. A benzodiazepine such as diazepam, administered in titrated doses of up to 10 mg intravenously every 5 to 10 minutes until agitation is controlled, is usually safe and effective. Numerous studies demonstrate the benefits of benzodiazepines, although under certain conditions[38,78] they may prolong recovery time. Midazolam may be more effective than diazepam under certain circumstances.[33,128] Additionally, in a double-blind placebo-controlled study, lorazepam reduced the anxiety associated with ketamine without antagonizing ketamine's cognitive or psychotomimetic effects.[109] In contrast, phenothiazines may lower the seizure threshold, and both phenothiazines and butyrophenones may cause acute dystonic reactions. Phenothiazines may also cause significant hypotension due to their α-blocking effects on the vasculature, worsen hyperthermia, and exacerbate any anticholinergic effects from these drugs.

Some behavioral modalities have also been implemented in the treatment. Early studies demonstrated that the psychotomimetic effects of PCP were diminished when external stimulation was reduced by environmental sensory deprivation.[40] The practice of placing patients in a quiet room with minimal sensory stimulation is recommended by many, but has never been formally studied in a double-blind, controlled trial. Conversely, it is observed in patients undergoing ketamine anesthesia that emergence reactions are less violent when patients are talked to or when music is played.[111,174]

Although it is always important to ask the patient the names, quantities, times, and route of all xenobiotics taken, the information obtained from such a patient may be unreliable. Even when the patient is trying to cooperate and give an accurate history, many street psychoactive xenobiotics are mixtures whose contents are unknown to the patient. Consequently, pharmacologic management is complex and often sign or symptom dependent. Although some authors have attempted to define the appropriate therapy for specific PCP congeners and for ketamine-induced psychosis, no single approach has been consistently efficacious.[73,74,108,125]

■ DECONTAMINATION

Patients with a history of recent oral use of PCP are candidates for gastrointestinal decontamination. Although there is rarely, if ever, an indication, if coingestion is suspected, orogastric lavage may be initiated but the patient may need to be sedated. Activated charcoal, 1 g/kg, should be administered as soon as possible, and repeated every 4 hours for several doses. Activated charcoal will effectively adsorb PCP and increase its nonrenal clearance; even without prior gastric evacuation this approach is usually adequate.[158] Unless there are specific contraindications, a single dose of a cathartic, such as sorbitol, may be given.

Theoretically, xenobiotics that are weak bases, such as PCP, can be eliminated more rapidly if the urine is acidified. Although urinary acidification with ammonium chloride was previously recommended,[9] we do not recommend this approach. The risks associated with acidifying the urine—simultaneously inducing a systemic acidosis, thereby potentially increasing urinary myoglobin precipitation—outweigh any perceived benefits (Chap. 9).

As opposed to the problems in applying ion trapping to renal excretion, ion trapping results in the active mobilization of PCP into gastric secretions. Phencyclidine is in a substantially ionized (and therefore non–lipid-soluble) form in the acid of the stomach and can be absorbed only when it reaches the more alkaline intestine. As a result, gastric suction can remove a significant amount of the drug, as well as interrupt the gastroenteric circulation by which the xenobiotic is secreted into the acid environment of the stomach only to be reabsorbed again in the small intestine.[9] Continuous gastric suction, however, is unnecessary and can also be dangerous. It should be considered only in comatose patients. Continuous suction may result in trauma to the patient as well as in fluid and electrolyte loss, which can further complicate management and possibly interfere with the efficacy of activated charcoal. For these reasons the administration of multiple-dose activated charcoal rather than continuous nasogastric suction appears to be the safest and most effective way of removing ion-trapped drug from the stomach.

Most patients rapidly regain normal CNS function anywhere from 45 minutes to several hours after its use. However, those who have taken exceedingly high doses or who have an underlying psychiatric disorder may remain comatose or exhibit bizarre behavior for days, or even weeks, before returning to normal. Those who rapidly regain normal function should be monitored for several hours and then, after a psychiatric consultation, should receive drug counseling and any additional social support available. Patients whose recovery is delayed should be treated supportively and monitored carefully in an intensive care unit.

Many patients become depressed and anxious during the "post-high" period, and chronic users may manifest a variety of psychiatric disturbances.[207] These individuals typically present with repeated drug use, hospitalizations, and poor psychosocial functioning in the long term.

The major toxicity of PCP appears to be behaviorally related: self-inflicted injuries, injuries resulting from exceptional physical exertion, and injuries sustained as a result of resisting the application of physical restraints are frequent. Patients appear to be unaware of their surroundings and sometimes even oblivious to pain because of the dissociative anesthetic effects. In addition to major trauma, rhabdomyolysis and resultant myoglobinuric renal failure account in large measure for the high morbidity and mortality associated with PCP intoxication. If significant rhabdomyolysis[39,154] has occurred, myoglobinuria may be present. Early fluid therapy should be used to avoid deposition of myoglobin to the kidneys, leading to renal failure. Urinary alkalinization as part of the treatment regimen for rhabdomyolysis would potentially increase PCP reabsorption and deposition in fat stores, but this is only theoretical.

Although the clinical experience with recreational use of ketamine is limited, toxic manifestations appear to be similar, yet milder and shorter lived, when compared with PCP. In a study of 20 patients who presented with acute ketamine toxicity, all were treated conservatively and successfully with intravenous hydration, and sedation with benzodiazepines.[199]

SUMMARY

As "dissociative" anesthetics became clinically available, their abuse potential was also discovered. The popularity of PCP and ketamine results from their ability to produce an "out-of-body experience" with seemingly hallucinatory effects. The action of these drugs is largely mediated by the NMDA receptor. Their toxicity, in great part neuropsychiatric in nature, is managed by supportive care. The popularity of ketamine may be related to its lesser toxicity and milder distortion of the personality.

CHAPTER 86
ALUMINUM

Brenna M. Farmer

Aluminum (Al)		
Atomic number	=	113
Atomic weight	=	26.98 daltons
Normal concentrations		
Serum	≤	2 µg/L (< 0.074 µmol/L)
Whole blood concentration	<	12 µg/L (< 4.43 µmol/L)
Urine (24 hour)	=	4–12 µg/g creatinine (< 1.48–4.45 µmol/L)

Aluminum (Al) is the most abundant metal in the crust of the earth with ^{27}Al as the naturally occurring isotope. Aluminum is found in cookware, infant formula,[21] foil, vaccines as an adjuvant to boost immune response,[28] antiperspirants, antacids, and phosphate binders. It is also known to contaminate in hemodialysis (HD) fluids, intravenous (IV) fluids, total parenteral nutrition (TPN),[38] albumin,[39] and as alum solution (potassium aluminum sulfate or ammonium aluminum sulfate)—an astringent for bladder irrigation.[97] It has many industrial uses after extraction from bauxite. In the body, aluminum exists as a trivalent cation (Al^{3+}). In this chapter, aluminum metal is discussed as an occupational toxin with mainly lung manifestations. Aluminum salts, the more common form discussed for aluminum toxicity, primarily act as neurotoxins with both acute and chronic toxicity.

CHEMISTRY

Aluminum is a nonessential element and a trace metal with a single oxidation state, Al^{3+}. Aluminum is the most abundant metal in the earth's crust where it is found in many types of ores: bauxite, gibbite, boehmite, as alumina, and in gems like ruby, sapphire, and turquoise.

The aluminum industry is one of the world's largest industries. Aluminum ores are converted to alumina and then reduced to aluminum metal. The first step usually involves refining bauxite at high temperature and pressure in a caustic soda to form alumina (aluminum oxide, Al_2O_3). The second step occurs by a special method, the Hall-Heroult process, in potrooms and uses electrolytic reduction to form aluminum. Aluminum is then used alone or is processed into alloys to build a variety of products that are anticorrosive.[16]

HISTORY AND EPIDEMIOLOGY

The first case of aluminum toxicity with neurologic findings was reported in 1921. This patient had memory loss, tremor, and impaired coordination.[86] Subsequently, a case series described occupational asthma in Norwegian aluminum potroom workers ("potroom asthma"). These workers had a higher incidence of asthma than the general population.[22] In 1947, another report described German workers who developed pulmonary fibrosis after exposure to high concentrations of aluminum dust (also called "pyro powder") mixed with mineral oil–based lubricants. This pulmonary fibrosis, "aluminosis," was present in 26% of the workers.[24] Some potroom workers also developed neurologic findings described as a progressive encephalopathy and termed "potroom palsy."[45,51] Initially described in 1962, these patients had balance problems, impaired memory, an intention tremor, and decreased cognitive ability.[51,70]

In the 1970s, encephalopathy in patients with renal failure was attributed to using aluminum-salt-containing phosphate binders or, more rarely, to aluminum-contaminated dialysis fluid. This clinical syndrome known as "dialysis dementia" developed after years of HD. Manifestations included dyspraxia and multifocal seizures.[7] By 1976, elevated serum aluminum concentrations were reported in encephalopathic HD patients.[6] Both the relationship between aluminum and microcytic anemia and the connection between aluminum and osteomalacia in dialysis patients were recognized in 1978.[17,89] Treatment with the aluminum chelator deferoxamine to chelate the aluminum improved both symptoms. Since the recognition of chronic aluminum toxicity, phosphate binders rarely contain aluminum and dialysate is tested to ensure that very little aluminum is in the solution as a contaminant.

In 1982 alum (potassium aluminum sulfate or ammonium aluminum sulfate) was first used in the treatment of hemorrhagic cystitis.[64] Neurotoxicity can develop if patients absorb alum systemically, especially if renal insufficiency is present. This now appears to be the most common cause of acute aluminum toxicity.

Recently, aluminum has been linked to the spongioform leukoencephalopathy that rarely develops in heroin abusers "chasing the dragon." These patients inhale the pyrolysate of heroin heated on aluminum or tin foil. A 2007 study showed elevated urinary aluminum concentrations in patients abusing heroin in this way.[18] They then can develop bizarre behavior, and slowed speech and movements, as well as cognitive abnormalities.[44]

There is also a concern over the relationship between aluminum and Alzheimer disease. This linkage was studied because of the dialysis encephalopathy syndrome (dialysis dementia) and the association of aluminum with neuropsychiatric deficits and electroencephalographic (EEG) changes seen in welders of aluminum.[71] Although aluminum is a component of neurofibrillary tangles in senile plaques associated with AD, to date no studies have proven that aluminum is the cause of the disease.[57,66] Regardless, this association has led to several agencies in the United States and Canada to decrease the amount of aluminum contamination allowable in food and water products.[93]

ALUMINUM-CONTAINING XENOBIOTICS

■ ANTACIDS

Aluminum-containing products are rarely prescribed. However, patients may take antacids containing aluminum hydroxide for symptomatic control of dyspepsia and gastroesophageal reflux disease (GERD). Aluminum hydroxide is usually packaged with magnesium hydroxide to counteract the induced delay of gastric emptying and constipation caused by aluminum hydroxide. These antacids are poorly absorbed and are cleared from the stomach in about 30 minutes. The neutralizing effects of antacids last for 2 to 3 hours, especially in the presence of food.

■ SUCRALFATE

Sucralfate, an aluminum-containing salt with sucrose sulfate, is used for symptomatic control of ulcer disease, to accelerate healing of peptic ulcer disease, and as a protectant against stress ulcer formation. This sucrose aluminum complex is poorly absorbed from the gastrointestinal (GI) tract, and the little that is absorbed is excreted by the kidney without undergoing any metabolic changes. Although not approved by

the US Food and Drug Administration (FDA) as a phosphate binder, it does have phosphate-binding properties.[14]

■ ALUM

Alum is usually a potassium aluminum sulfate salt [KAl(SO$_4$)$_2$*12H$_2$O] or an ammonium aluminum sulfate salt [NH$_4$Al(SO$_4$)$_2$*12H$_2$O], as a 1% solution, and is typically used as an astringent during bladder irrigation for hemorrhagic cystitis. It is rarely absorbed unless there is a defect in the bladder wall that allows for systemic absorption.

PHARMACOKINETICS AND TOXICOKINETICS

Aluminum is ubiquitous in the food we eat and water we drink.[65] The daily intake of aluminum in the United States is estimated to be 5 to 10 mg from food products alone.[93]

■ ABSORPTION

Gastrointestinal absorption mainly occurs in the proximal small intestine with uptake by the mucosal cells. Uptake is by both passive transport methods such as diffusion and active transport methods including active transferrin-mediated mechanisms.[25] Transferrin may also mediate methods leading to absorption into the blood.[25] Only approximately 0.3% of ingested aluminum is absorbed.[56,96] However, GI absorption increases in the presence of citrate, other small organic acids, and in uremia.[25,29,62,83] The GI absorption of aluminum is decreased in the presence of phosphorus and silicon.[29] There is negligible dermal absorption from the use of antiperspirants containing aluminum.[19] Pulmonary absorption is 1.5% to 2%, based on increased urinary aluminum excretion in workers exposed to aluminum-containing metal fumes.[58,81]

■ DISTRIBUTION

The initial distribution of aluminum appears to be consistent with blood volume 0.06 L/kg with equal distribution between plasma and cells in the blood.[90] Aluminum then becomes 90% bound to transferrin and approximately 10% bound to citrate.[87,92] From the blood, it distributes to many tissues including 50% to the bone, where it is concentrated at the mineralization front,[96] and approximately 1% to the brain, primarily in the gray matter.[6] The rest appears to variably distribute to the heart, liver, kidney, and other organ systems. The primary carrier in the cerebrospinal fluid (CSF) is citrate.[92] Intracellularly, aluminum appears to localize in the lysosomes of brain neurons, liver (not the Kupffer cells), spleen, kidney epithelial tubules and glomerular mesangium cells, cardiac myocytes,[5,74] and in the mitochondria of osteoblasts.[15]

■ METABOLISM/EXCRETION

Aluminum is not metabolized in the body, and is excreted unchanged in the urine (greater than 95% of the aluminum) with a daily urinary excretion of 4 to 12 μg.[61] Citrate in the blood may enhance the excretion of aluminum.[48] Less than 2% of aluminum is excreted by the bile.[40,68,94] Because of aluminum's primary renal excretion, patients with renal insufficiency or failure have decreased aluminum excretion. The elimination half-life for aluminum is approximately 85 days in dialysis patients.[75] Based on urinary excretion in workers (with preserved renal function) with prolonged occupational exposure, the apparent half-life is extended to years.[43] This prolonged half-life may be related to deposits of aluminum metal dust in the lungs of those workers (such as in those patients with pulmonary fibrosis from exposure to the aluminum dust). There is no normal reference point for elimination half-life.

■ PATHOPHYSIOLOGY

Little is known about the pathophysiology of aluminum toxicity. The information that follows is based on a summary of limited research. Some animal studies provide insight into mechanisms that may be responsible for the toxicity of aluminum, but the studies should not be considered to form a comprehensive understanding of aluminum toxicity as the basic science studies raise more questions. There remain many gaps in our knowledge of aluminum toxicity to different organ systems.

Pulmonary System   In rats exposed to alumina and aluminum through intratracheal injection, fibrosis develops.[35,36] These animals develop epithelialization of alveoli with focal fibrosis occurring in the respiratory bronchioles and alveolar ducts with alveolar proteinosis.[27,67]

Central Nervous System   Aluminum is associated with acute encephalopathy, dialysis dementia, seizures, and Alzheimer Disease.

The primary site of aluminum entry into the brain appears to be the cerebral microvasculature. Following IV administration in rats and rabbits, aluminum concentrations are higher in the frontal cortex than in the lateral ventricles. The cortex concentrations should result from blood supply while lateral ventricle concentration may represent blood supply or be CSF derived as the lateral ventricles are bathed in CSF.[95] The mechanisms of entry are postulated to be transferrin-mediated, endocytosis and other active processes.[2] Aluminum interacts with the acetylcholine pathways in the brain and decreases acetylcholine activity. Aluminum decreases the amount of high affinity choline uptake in the brains of rats and also decreases the activity of choline acetyltransferase in rabbit brains.[30,42] Aluminum-treated rabbits have significantly decreased acetylcholine outflow compared with controls that does not improve with potassium addition to the neurons. This finding suggests that aluminum may attenuate the response of neurons to potassium-induced depolarization.[95] Adult rabbits exposed to aluminum also have a significant reduction in conditioned responses compared with rabbits exposed in utero or in the first or second month postpartum.

Hematologic System   Aluminum typically affects hematopoiesis prior to alterations on the central nervous system (CNS). A microcytic hypochromic anemia results. In rats, aluminum inhibits cell growth, while in humans hematopoietic cells are inhibited. In mice, aluminum decreases cell proliferation and hemoglobin synthesis.[3,55] It inhibits δ-aminolevulinic acid dehydrogenase in the heme synthesis pathway,[1,52] leading to the accumulation of erythrocyte protoporphyrins. Please see Fig. 24-3 for a diagram demonstrating this pathway. This effect is most noted in HD patients with aluminum overload.[9]

Musculoskeletal System   Vitamin-D resistant osteomalacia and osteopathy occurs in patients with aluminum toxicity. It is characterized by hyperosteoidosis, minimal osteoblastic activity, and decreased mineralization. Calcium, magnesium, and phosphate metabolism/kinetics do not appear to be affected in these patients.[12] Aluminum concentrates in the mitochondria of the osteoblasts at the mineralization front.[15] It is theorized that aluminum competes and replaces other cations in the bone, leading to osteopathy.[26] The osteomalacia is not caused solely by chronic renal failure, but develops in the presence of aluminum exposure.[72] In rat studies exogenous parathyroid hormone (PTH) enhanced aluminum deposition into bone, leading to osteopathy.[49,50]

MANIFESTATIONS

■ ACUTE TOXICITY

Regardless of etiology, patients with acute aluminum toxicity develop encephalopathy, myoclonus, and seizures. The encephalopathy manifests as disorientation, confusion, and coma. All symptoms appear

to develop within days to a few weeks of receiving massive systemic aluminum exposure (usually to an aluminum salt). Serum concentrations range from barely elevated to extremely elevated. Most patients who manifest toxicity have systemically absorbed aluminum usually in the presence of renal insufficiency. In several case reports of acute aluminum toxicity, the initial exposure to aluminum is associated with alum bladder irrigations for hemorrhagic cystitis. In two patients, these symptoms developed after only weeks of exposure to aluminum containing phosphate binders in the presence of citrate,[37] and two neonates with uremia developed neurotoxicity after exposure to infant formula with high aluminum content over a 1 to 2 month period.[20] Recovery occurs in patients treated with deferoxamine and/or HD.[34,59] Patients in whom aluminum toxicity is not recognized and/or treated usually die (despite supportive care in the intensive care unit [ICU]), never recovering a normal mental status.[37,76,80]

■ CHRONIC TOXICITY

Two distinct types of chronic aluminum toxicity are reported: occupationally related lung problems, such as asthma and pulmonary fibrosis, and a multisystem syndrome most often noted in HD patients, which was initially described as dialysis encephalopathy syndrome or "dialysis dementia." As these names only describe one organ system involvement, they should not be used.

Pulmonary Potroom asthma consists of dyspnea, cough, wheezing, bronchitis, and chest tightness.[53] These symptoms may present after only a few months of exposure to the fumes and aluminum dust. The asthma may improve upon cessation of work in the potroom, although some workers never fully improve.[63] These symptoms may be a cause for high turnover in potroom workers and appears to have made long-term follow-up difficult.[33,85]

Pulmonary fibrosis from aluminum is very similar to the other pneumoconiosis, like silicosis, and appears to progress in a similar manner. This manifestation develops in workers exposed to aluminum metal dust. Patients experience cough, shortness of breath, dypsnea on exertion, and they eventually develop restrictive lung function.[41,54] Abnormal chest radiograph findings include decreased lung fields, distortion of pleura and diaphragms, and irregular opacities.[23,31,77,78] Recovery of lung function does not occur and several patients have died from complications of pulmonary disease such as pneumonia.

Multisystem Toxicity The other form of chronic aluminum toxicity has multisystem manifestations. It primarily affects three organ systems: hematopoietic, nervous, and musculoskeletal. In patients with renal insufficiency, the toxicity appears to occur after months to years of exposure to aluminum salt–contaminated dialysate and/or aluminum salt–containing phosphate binders such as aluminum hydroxide and sucralfate. A similar presentation has been reported in a patient using aluminum-coated cookware to boil methadone for intravenous abuse. The patient experienced 3 months of chronic aluminum toxicity (prior to presentation) after 4 years of processing his methadone this way.[21,97] Three industrial workers exposed to aluminum metal powder have also been reported to have encephalopathy. One of these workers was found to have a brain aluminum concentration 20 times normal.[45] One infant with renal insufficiency developed focal seizures, which eventually progressed to generalized seizures, hypotonia, poor head control, ataxia, and developmental delay in the presence of elevated serum aluminum concentration after 10 months of exposure to aluminum salt–containing phosphate binders.[69]

Microcytic hypochromic anemia is unresponsive to iron replacement therapy.[32] This clinical finding usually precedes encephalopathy and osteomalacia.[79] The encephalopathy of chronic aluminum toxicity was known as "dialysis dementia." Its features include speech disturbances,

EEG abnormalities, myoclonic jerks, and dementia.[84] The characteristic speech disturbances include dyspraxia, dysphasia, stuttering, and possibly mutism.[46,73,84] EEG abnormalities include slowing of the normal rhythm and high voltage biphasic or triphasic spikes.[47,84] The myoclonic activity can include uncontrolled twitching movements, myoclonus, or seizures.[84] The osteopathy and osteomalacia can lead to bone pain and fractures.[13,93] Death is common in these patients when aluminum toxicity is not recognized and treated.

DIAGNOSTIC TESTS

Blood glucose status should also be tested in any patient with an altered mental status being evaluated for aluminum toxicity to ensure that hypo- or hyperglycemia is not a cause of this clinical manifestation.

Serum and urine concentrations of aluminum can estimate exposure. A serum aluminum concentration should be less than or equal to 2 μg/L[88] while a whole blood aluminum concentration should be less than 12 μg/L.[82] Daily urinary excretion of 4 to 12 μg aluminum is considered normal.[61] Toxicity has occurred in a wide range of serum and urine concentrations with patients dying who had severe manifestations and concentrations only slightly above normal.

Pulmonary function testing can be performed to evaluate for restrictive lung function, as occurs with aluminosis.

MANAGEMENT

Patients should be removed from their exposure once it has been identified. Exposure to aluminum in industry and exposure to antacids containing aluminum salts should also be limited. Patients with occupational asthma from aluminum exposure should be symptomatically treated with bronchodilators and steroids.

The only chelator with proven benefit is deferoxamine (DFO). Chelation therapy is recommended for both acute and chronic toxicity from aluminum salts. Chelation appears to limit and improve manifestations of neurotoxicity, anemia, and osteomalacia (see Antidotes in Depth A7–Deferoxamine). Other chelators such as *d*-penicillamine and 2,3-dimercapto-1-propanol have been tried in chronic HD patients without any improvement in their manifestations or aluminum concentrations.[11] A review of numerous chelator studies revealed that no other chelator has been found as an alternative to deferoxamine.[91]

■ ACUTE TOXICITY

A deferoxamine dose of 15 mg/kg/d intravenously is recommended. Adults have received doses ranging from 1 to 2 g for aluminum toxicity. Deferoxamine chelates the aluminum to form aluminoxamine, which is excreted in the urine or removed by HD.[92] Chelation mobilizes aluminum from its storage sites in blood and increases its renal elimination.

In patients with renal failure, chelation therapy is usually followed 6 to 8 hours later by HD with a high-flux membrane in order to clear the aluminoxamine (the aluminum-DFO product) in patients with renal insufficiency or failure.[59] Patients with normal kidney function may not require hemodialysis, as the aluminoxamine is excreted in the urine.

■ CHRONIC TOXICITY

Chelation therapy with DFO reverses dialysis dementia, osteomalacia, and anemia. Numerous case reports have demonstrated the reversal of the neurotoxicity, vitamin D–resistant bone disease, and iron-resistant anemia.[4,8,10] The National Kidney Foundation has issued complicated

guidelines for the treatment of dialysis dementia. It consists of 4 months of once weekly DFO 5 mg/kg over 1 hour given 5 hours before a regularly scheduled HD session in patients with aluminum greater than 300 µg/L. In patients with aluminum concentrations between 50 and 300 µg/L, DFO 5 mg/kg is given the last hour of HD, once a week for 2 months. Serum aluminum concentrations are then monitored and this therapy is repeated as needed.[60]

SUMMARY

Both acute and chronic toxicity are associated with exposure to aluminum and aluminum salts. Aluminum metal causes pulmonary toxicity. Acutely, aluminum salts are neurotoxins with manifestations of encephalopathy and seizures. Chronically, aluminum salts affects at least three systems with manifestations of anemia, encephalopathy, dementia, and osteomalacia. Limiting or ending exposure, chelation, and HD have proven beneficial in the treatment of aluminum toxicity.

I.
METALS

CHAPTER 87
ANTIMONY

Asim F. Tarabar

Antimony (Sb)

Atomic number	=	51
Atomic weight	=	121.75 daltons
Normal concentrations:		
Serum	=	0.8–3 μg/L (6.6–24.6 nmol/L)
Urine (24 hour)	=	0.5–6.2 μg/L (4.1–50.1 nmol/L)
	<	3.5 μg/g creatinine (<28.7 nmol/g creatinine)

Antimony (Sb) and its compounds are among the oldest known remedies in the practice of medicine.[82,126] Because of a strong chemical similarity to arsenic, the features of antimony poisoning closely resemble arsenic poisoning (see Chap. 88), and antimony poisoning has many features in common with other metal poisonings. Although relatively uncommon, antimony poisoning still occurs, usually as a complication of the treatment of visceral leishmanias.[75] Acute overdose represents an even more rare but potentially lethal event.[112]

HISTORY AND EPIDEMIOLOGY

Objects discovered during exploration of ancient Mesopotamian life (third and fourth millennium BC) suggested that both the Sumerians and the Chaldeans were able to produce pure antimony.[82,126] The reference to eye paint in the Old Testament suggested the use of antimony.[82] For several thousand years, Asian and Middle Eastern countries used antimony sulfide in the production of cosmetics, including rouge and black paint for eyebrows, also known as kohl or surma.[78,83] Because of the scarcity of antimony sulfide, lead replaced antimony as a main component in more modern cosmetic preparations.

One of the first monographs on metals, written in the 16th century, included a description of antimony.[118] The medicinal use of antimony for the treatment of syphilis, whooping cough, and gout dates to the medieval period. Paracelsus was credited with establishing antimony compounds as therapeutic agents and increasing their popularity. In spite of being aware of its toxic potential, many of the disciples of Paracelsus enthusiastically continued the use of antimony.[82] Various antimony compounds were also used as topical preparations for the treatment of herpes, leprosy, mania, and epilepsy.[126] Orally administered tartar emetic (antimony potassium tartrate) was used for treatment of fever, pneumonia, inflammatory conditions, and as a decongestant, emetic, and sedative, but it was abandoned because of its significant toxicity.[18,38,54,66] The use of antimony as a homicidal agent[113] continued well into the 20th century (Chap. 1).

The current medical use of antimony is limited to the treatments of leishmaniasis and schistosomiasis, and to sporadic use as aversive therapy for substance abuse.[112] Pentavalent compounds are used because they are better tolerated. In the endemic regions of the world, generic pentavalent antimonials remain the mainstay of therapy because of their efficacy and low cost; however, the growing incidence of resistance may reduce future use.[87]

Some contemporary homeopathic[49] and anthroposophical[107] practices still recommend use of antimonial compounds as home remedies; however, these practices are rare.[82,126] In spite of its anticancer effects in vitro,[38] there is no current oncologic use of antimony.

The elemental form of antimony has very few industrial uses because of its physical limitations, particularly the fact that it is not malleable. In contrast, its alloys with copper, lead, and tin have important applications. Various antimony compounds can be used in the production of textiles, enamels, ceramics, fireworks, and pigments, and as catalysts in chemical reactions. Industrial and occupational exposure to antimony occurs mainly by the inhalation of dust or fumes during the processing or packaging of antimony compounds.[10] Smelter workers can also be occupationally exposed to antimony as it is often present arsenic-containing ore.[48] Antimony concentrations in cigarette smoke range from 10 to 60 mg/kg,[48,90] which may be responsible for a substantial percentage of antimony found in workers' lungs.[48]

In developed countries, antimony poisoning rarely occurs following intentional ingestion of antimony preparations.[126] Most recent descriptions of antimony toxicity result from parenteral exposures during the treatment of schistosomiasis and leishmaniasis. Oral exposures usually occur following the use of antimony potassium tartrate–containing compounds. Several cases were described after the use of old porcelain house ware or after use of antimony compounds as home remedies.[2,73,86,112]

CHEMISTRY

Antimony is located in the same group on the periodic table as arsenic (As), and as such it shares many chemical, physical, and toxicologic properties. Because it can react as both a metal and a nonmetal, antimony is classified as a metalloid (Chap. 11).[10,109] Pure antimony is a lustrous, silver-white, brittle, hard metal that is easily pulverized.[85,126] However, because elemental antimony is rapidly converted to either antimony oxide or antimony trioxide, it is extremely rare to find elemental antimony in nature.[10] It has been suggested that even its name originates from *anti monon* (enmity to solitude) because antimony is almost always found with some other metal.[82] Thus, for the purposes of this chapter, the term *antimony* refers to antimony ions.

In nature, antimony can be found in more than 100 different minerals,[68,82] including stibnite, cervantite, valentine, and kermesite.[43] The sulfide ore (stibnite) is the most abundant form,[82] and Bolivia and South Africa are among the leading producers.[126] Like arsenic, antimony forms both organic and inorganic compounds with

trivalent (3^+) and pentavalent (5^+) oxidation states. Common inorganic trivalent antimony compounds include antimony potassium tartrate ($C_8H_4K_2O_{12}Sb_2$), antimony trichloride ($SbCl_3$), antimony trioxide (SbO_3), antimony trisulfide (SbS_3), and stibine (SbH_3). Antimony pentasulfide (Sb_2S_5) and pentoxide (Sb_2O_5) are inorganic compounds that can act as oxidizing agents.[55] Antimony pentachloride ($SbCl_5$) is used as a chemical reagent with acidic properties. It reacts with water, forming hydrochloric acid that causes a direct corrosive effect on skin and mucous membranes.[30]

From an industrial perspective, the most important application of antimony is the use of antimony oxychloride ($Sb_6O_6Cl_4$) as a flame retardant.[82]

Tartar emetic (antimony potassium tartrate) is an odorless trivalent antimony compound with a sweet metallic taste[56] and a potent emetic effect.[55] Antimony potassium tartrate is considered to be one of the most toxic antimony compounds, with minimal lethal doses reported between 200 mg[86] and 1200 mg.[82] There are large species variations of the LD_{50} in experimental animals, with a reported range of 115 mg/kg in rabbits and rats to 600 mg/kg in mice. In comparison, because of a low water solubility, antimony trioxide is considered to be nontoxic, with an LD_{50} greater than 20,000 mg/kg.[46]

PHARMACOLOGY

The antiparasitic mechanisms action of antimony may result from the inhibition of phosphofructokinase which is the rate-limiting step in the glycolytic pathway of schistosoma.[24] Trivalent antimony compounds inhibit phosphofructokinase, leading to energy failure from impaired adenosine triphosphate (ATP) synthesis.[21,126] It is speculated that antimonial preparations exert their antiparasitic effect through selective targeting of the guanosine diphosphate-mannose pryophosphorylase (GDP-MP), which interferes with nucleoside and mannose metabolism.[44] The result is that the parasites cannot synthesize purines and cannot survive without these mannose-containing glycoconjugates. Even less is known about the effects of antimony in humans. It has been proposed that, like other metals, antimony inactivates thiol-containing proteins and enzymes by binding to sulfhydryl groups.[35]

TOXICOKINETICS

■ ABSORPTION

Antimony may be absorbed by inhalation, ingestion, or transcutaneously. Absorption from the gastrointestinal tract begins immediately following ingestion, and the oral bioavailability of antimony ranges from 15% to 50%.[47,119] It is suggested that antimony absorption might be a saturable process, given that several studies failed to demonstrate a dose–response relationship for absorption.[1,110] In fact, after a lethal ingestion of antimony tartrate, the total body antimony burden was only 5% of the ingested dose.[77] This poor gastrointestinal absorption in humans, in addition to the concomitant emesis, necessitates parenteral administration of many antimony-based pharmaceuticals.

Pulmonary absorption of many inorganic antimony compounds is very slow and limited by low solubility.[82] In contrast, animal data suggest that inhaled trivalent antimony is well absorbed from the lung, distributed to various organs, and subsequently excreted in the feces and urine.[37]

Transcutaneous absorption of antimony trioxide and pentoxide was documented in studies with rabbits.[89] However, dermal absorption in humans of antimony trioxide is considered negligible.[103]

■ DISTRIBUTION

Distribution depends on the oxidation state of antimony. In animals, more than 95% of trivalent antimony is incorporated into the red blood

cells within 2 hours of exposure, whereas in a similar time frame, 90% of pentavalent antimony remains in the serum.[39]

When administered intravenously or orally, antimony is predominantly distributed among highly vascular organs, including liver, kidneys, thyroid, and adrenals.[93,126] The antimony that was detected in the liver and spleen was predominantly in the pentavalent form whereas the thyroid accumulated trivalent forms.[9] Uptake by the liver occurs through the mechanisms of diffusion and saturable binding.[106] In a hamster model, following a single injection of organic antimonials, the greatest concentration of antimony was found in the liver.[47] After inhalation, antimony accumulates predominantly in red blood cells, and to a significantly lesser extent in liver and spleen.[37,39] It is possible that inhaled antimony is retained in the lungs for a prolonged period of time without significant systemic absorption and distribution.[48] Animal data also reported accumulation of antimony in the skeletal system and in fur.[40,41]

■ METABOLISM

Although antimony and arsenic share many toxicokinetic properties, unlike arsenic, inorganic trivalent antimony is not methylated in vivo.[5] Some microorganisms, however, are capable of biomethylation of antimony.[13] Rather, in humans antimony is converted by binding to macromolecules, by incorporation into lipids,[12] and by covalent interactions with sulfhydryl groups and phosphates. Pentavalent antimony may be converted to trivalent compounds in the liver.[126]

■ EXCRETION

Trivalent antimony is excreted in the bile after conjugation with glutathione. A significant proportion of excreted antimony undergoes enterohepatic recirculation.[5] The remainder is excreted in urine. The overall elimination is very slow, with only 10% of a given dose cleared in the first 24 hours, 30% in the first week,[7] and some urinary antimony is still detected in the urine 100 days after administration.[79,126] Pentavalent antimony is much more rapidly excreted by the kidneys than trivalent antimony (50%–60% versus 10% over the first 24 hours).[126] Urine and serum antimony concentrations remain elevated for several years following therapeutic use.[81] In actuality, renal excretion of sodium stibogluconate can be as high as 90% within 6 hours of an intramuscular administration.[100] In workers, urine concentrations of pentavalent antimony correlate well with the extent of exposure.[5]

The clearance of tartar emetic has a biphasic pattern, with 90% being excreted within 24 hours after acute exposure, followed by a second slower phase with an estimated half-life of approximately 16 days.[40]

The renal elimination half-life of inhaled stibine was estimated at approximately 4 days following occupational exposure.[74]

PATHOPHYSIOLOGY

Antimony has no known biological functions and is considered to be potentially toxic even at very low concentrations.[105] Like other toxic metals, antimony binds to sulfhydryl groups to inhibit a variety of metabolic functions.[25,35] Trivalent antimony compounds are more toxic than the pentavalent compounds because of their higher affinity for erythrocytes and sulfhydryl groups.[76] Tartar emetic and other antimony salts are also considered gastrointestinal irritants. One proposed mechanism for this local effect is the activation of enterochromaffin cells, which produce and secrete serotonin. Released serotonin acts on the 5-HT$_3$ receptors, stimulating vagal sensory fibers and activating the vomiting center.[53,121] In addition, there is apparent direct central medullary action, particularly after administration of higher doses of antimony.[126]

CLINICAL MANIFESTATIONS

Data on human toxicity of antimony are very limited, and are largely extrapolated from occupationally exposed patients and adverse effects that have occurred during treatment of leishmaniasis and schistosomiasis, and very few case reports of intentional antimony exposures.[86]

Workers with occupational exposures usually present with subtle clinical symptoms as chronic toxicity develops slowly over time. It is important to recognize that antimony ore contains a small concentration of arsenic, making it difficult to determine whether the effects on workers are caused by contaminants such as arsenic or by the antimony. Therapeutic side effects of antiparasitic treatment may have acute and subacute clinical manifestations, as some patients with leishmaniasis require prolonged antimonial treatment to achieve cure,[116] exposing them, over time, to very large cumulative doses.

Patients with ingestions present with acute symptoms mimicking the toxicity of arsenic and other metal and metalloid salts.

■ LOCAL IRRITATION

The most common manifestations of antimony toxicity involve local irritation. In sufficient concentration, antimony acts as an irritant to the eyes, skin, and mucosa. Chronic exposure can cause conjunctivitis.[15,43,101] Irritation of the upper respiratory tract can lead to pharyngitis and frequent nose bleeds.[124]

Antimony pentachloride is very irritating and can cause local dermal and mucosal burns. It reacts with water, releasing hydrochloric acid, heat, and antimony pentaoxide (Sb_2O_5). Following ingestion, contact with the water in saliva produces sufficient hydrochloric acid to potentially result in consequential gastrointestinal burns.

Ocular exposure to Sb_2O_5 can cause typical caustic injury resulting in blepharospasm, lacrimation, photophobia, and even corneal burns. Exposure to antimony trichloride fumes can cause similar ocular symptoms.[50]

Systemic ocular toxicity can manifest in optic atrophy, uveitis, and retinal hemorrhage with exudates resulting with diminished visual acuity.[27,72] Some of these changes can be permanent.[72]

Thrombophlebitis is common after intravenous (IV) use of antimony, but has been reported even when poisoning occurs orally.[77]

Gastrointestinal Following acute exposures, antimony can rapidly produce anorexia, nausea, vomiting, abdominal pain, and diarrhea.[77,122] Some patients may report a metallic taste in the mouth.[5,33] It is possible to sense a garlic odor on the breath, but this might be due to concomitant arsenic exposure. In severe overdose, gastrointestinal irritation can progress to hemorrhagic gastritis.[77] Workers chronically exposed to antimony dusts have a much higher incidence of gastrointestinal ulcers in comparison to controls (63 per 1000 versus 15 per 1000).[19] Many patients develop pancreatitis following treatment with pentavalent antimonial agents.[34,45,84] Because most cases improved despite continuation of treatment, a mechanism other than direct pancreatic toxicity is presumed. In another series, several patients with human immunodeficiency virus (HIV) who were treated with high doses of meglumine antimonate developed severe pancreatitis and died.[36]

Cardiovascular In animals, antimony decreases myocardial contraction, decreases coronary vasomotor tone producing decreased systolic pressure, and causes bradycardia.[32,126] The majority of reported human cardiac effects are related to the electrocardiographic (ECG) changes. Prolongation of the QT interval, inversion or flattening of T waves, and ST segment changes are frequently described during treatment of visceral leishmaniasis with pentavalent antimonial compounds (sodium stibogluconate and meglumine antimonate).[26,125] Torsades de pointes was described in the patients treated with pentavalent antimonial preparations.[92,115] In patients with underlying myocardial disease such as a cardiomyopathy, ECG changes can occur even at subtherapeutic antimony doses.[52] These changes are not necessarily associated with deterioration in cardiac function.[59] However, it is important to recognize that pentavalent antimonial drugs used for the treatment of leishmaniasis are associated with sudden deaths, probably as a result of the development of ventricular dysrhythmias.[23,111]

Respiratory Local irritation from antimony trioxide can produce laryngitis, tracheitis, and pneumonitis.[48,101,114] Pneumonitis is usually reversible after exposure ceases and can be followed radiologically.[101] Acute lung injury was reported after acute exposure to antimony pentachloride.[30,31]

Although antimony oxides are capable of causing metal fume fever,[4,42] this is much less common in comparison to exposure to zinc oxide (see Chap. 101).[4,42] Antimony metal fume fever is reported to occur even with air concentrations below 5 mg/m³.[29]

Workers chronically exposed to antimony compounds for many years may develop "antimony pneumoconiosis."[28,83] Patients present with cough, wheezing, and exertional dyspnea that can progress to obstructive lung disease. Radiologically, antimony pneumoconiosis appears as diffuse, dense, punctate nonconfluent opacities with a predominant distribution in middle and lower lung lobes with or without pleural adhesions.[97]

Renal Patients treated with sodium stibogluconate can develop varied manifestations of renal toxicity ranging from renal cell casts, proteinuria, and increased blood urea nitrogen concentration[27] to renal failure.[6,99] Some patients can also develop renal tubular acidosis[65] and acute tubular necrosis.[98]

Hepatic Chronic therapeutic use of antimony compounds for the treatment of leishmaniasis can cause liver toxicity that can range from reversible elevations of aminotransferase concentrations to hepatic necrosis.[61,64,104,126]

Hematologic Severe anemia was reported in HIV-positive patients during treatment with sodium stibogluconate. Bone marrow biopsy documented transient severe marrow dyserythropoiesis, followed by complete recovery on discontinuation of the therapy.[63,80]

Patients treated with sodium stibogluconate for visceral leishmaniasis occasionally develop thrombocytopenia.[16,60,70] Rare cases of epistaxis are described during the treatment, and it is unclear if they are associated with thrombocytopenia.[71] Visceral leishmaniasis itself is known to be associated with pancytopenia, probably as a result of increased destruction of peripheral blood cells.[96] It may be difficult to determine whether this phenomenon is caused by disease itself or is secondary to the treatment, although some authors suggested a drug-induced immune thrombocytopenia.[96]

Leukopenia is frequently observed in patients treated with antimonial compounds.[36,126,127] Some authors speculate that antimony-induced lymphopenia is associated with an increased frequency of herpes zoster in HIV patients.[127]

Dermatologic Antimony spots[108] are papules and pustules that develop around sweat and sebaceous glands and may resemble varicella. Chronically exposed patients can develop areas of eczema and lichenification that typically occur in the summer and are usually found on the arms, legs, and in the joint creases with sparing of the face, hands, and feet.[83,101] A similar skin rash was described in the 18th century after external application of antimony tartrate for medicinal use.[82] Interestingly, these eruptions were usually interpreted as a sign of cure.[54] It is also suggested that antimony trioxide can cause contact dermatitis.[88]

Neurologic A patient with cutaneous leishmaniasis who was treated with sodium stibogluconate (pentavalent antimony) developed a

reversible, peripheral sensory neuropathy in temporal association with treatment.[20]

Musculoskeletal Therapeutic use of parenteral antimonials can be associated with diffuse muscle and joint pain.[22,33,104,126]

Reproductive In animal studies, antimony exposure causes ovarian atrophy, uterine metaplasia, and impaired conception.[11] An association between spontaneous abortion and premature births is reported in women who were occupationally exposed to antimony salts. Antimony was found in the blood, urine, placenta, amniotic fluid, and breast milk of these women.[11]

Carcinogenicity Female rats developed lung tumors after inhalational exposure to antimony trioxide and antimony trisulfide.[14,51,120] A survey among antimony smelter workers suggested an excess of lung cancer, with a latency of 20 years, in comparison to a nonexposed population. However, concomitant exposure to arsenic and its effects could not be excluded and the data were poorly or inadequately controlled for workers' smoking habits.[69] Exposure to antimony oxide over 9 to 31 years did not suggest increased incidence of lung cancer in one group of workers.[97] Patients with schistosomiasis have an increased incidence of bladder tumors, and antimony compounds are considered to be one potential cause.[126]

Genotoxicity Both stibine and trimethylstibine are capable of damaging DNA, presumably by the generation of reactive oxygen species. No other forms of antimony tested including potassium antimony tartrate, potassium hexahydroxyantimonate, and trimethylantimony dichloride were found to be genotoxic.[3]

STIBINE

Antimony compounds can react with nascent hydrogen, forming an extremely toxic gas, stibine (SbH_3), which resembles arsine (AsH_3) (Chap. 88). Stibine is probably the most toxic antimony compound. It is a colorless gas with a very unpleasant smell that rapidly decomposes at temperatures above 302°F (150°C).[58,126] Historically, stibine release was reported during charging of lead storage batteries.[126] In addition to the onset of gastrointestinal symptoms that include nausea, vomiting, and abdominal pain, stibine has strong oxidative properties that may result in massive hemolysis (Chap. 24). Similar to arsine,[102] severe stibine exposure may result in hematuria, rhabdomyolysis, and death. Maintenance workers are advised to avoid use of drain cleaners containing sodium hydroxide, which is capable of releasing hydrogen in situations where antimony may be present.[94]

DIAGNOSTIC TESTING

Standard laboratory testing to help identify volume depletion and renal injury is indicated for patients with acute antimony toxicity. A complete blood count, electrolytes, renal function studies, and a urinalysis should be obtained. When there is a known or suspected exposure to stibine, additional studies should include tests for hemolysis, such as determinations of bilirubin and haptoglobin. Blood should also be obtained for a blood type and cross-match, as transfusions are likely to be required.

An ECG should be obtained to evaluate for QT prolongation and dysrhythmias. Patients with known myocardial disease should have frequent evaluations of cardiac function,[52] and continuous ECG monitoring is recommended for all patients with significant symptoms or abnormal cardiovascular status.

Antimony concentration in a 24-hour urine collection can be used for assessment of the intensity of exposure to either trivalent or pentavalent antimony.[5] A normal urinary antimony concentration in nonexposed patients is reported in the range of 0.5 to 6.2 μg/L.[95,123] A serum antimony concentration cannot be determined in a timely fashion. The normal serum concentration of antimony is 0.8 to 3 μg/L,[81] although some laboratories use higher values.[91]

TREATMENT

■ DECONTAMINATION

Following a significant acute ingestion, the majority of patients develop vomiting. Induction of emesis is unlikely to offer any additional benefit. In contrast, gastric lavage may be beneficial, especially if performed before the onset of spontaneous emesis. Although it is unknown whether antimony is adsorbed to activated charcoal, based on experience with salts of arsenic, thallium, and mercury, administration of activated charcoal is appropriate. Additionally, because antimony has a documented enterohepatic circulation, multiple-dose activated charcoal may be of value.[5] For patients exposed to stibine, decontamination involves removal from the exposure followed by the administration of high-flow oxygen. Theoretically, patients with severe stibine exposures may require exchange transfusion for removal of the stibine–hemoglobin complex.[102] Dermal exposures, particularly to antimony tri- or pentachloride, may require decontamination with soap and water. Prompt removal from the contaminated area is important for patients exposed to stibine. Rescuers need to take appropriate precautions to ensure their own safety (see Chap. 130).

■ SUPPORTIVE CARE

The mainstay of treatment for antimony poisoning is good supportive care. Clinicians should anticipate massive volume depletion and begin rehydration with isotonic crystalloid solutions. Electrolytes and urine output should be followed closely. A central venous pressure monitor may be required in patients with cardiovascular instability. Antiemetics are indicated both for patient comfort and to facilitate the administration of activated charcoal. Following stibine exposure, the hematocrit should be followed closely and blood should be transfused based on standard criteria.

■ CHELATION

Human experience with regard to chelation of antimony is rather limited because of the scarcity of serious toxicity and the rarity of instances when patients have received chelation. Most of the available data are based on animal experimentation. Dimercaprol, succimer, and dimercaptopropane-sulfonic acid (DMPS) all improve survival of experimental animals.[8,17,67,117] A group from Shanghai demonstrated the ability of the sodium salt of succimer to increase the murine LD_{50} of tartar emetic 16-fold.[128] One animal study that compared survival after treatment with multiple chelators concluded that the most effective antidotes were DMPS and succimer.[8]

A single case series documented survival in three of four patients exposed to tartar emetic who were treated with intramuscular dimercaprol at a dose of 200 to 600 mg/d. All four patients had increased urinary excretion of antimony.[77] In another case report, a patient survived after chelation with dimercaprol, but without evidence of enhanced urinary excretion of antimony.[5] Although specific recommendations are difficult to make, it is reasonable to begin therapy with intramuscular dimercaprol until it is certain that antimony is removed from the gastrointestinal tract, at which time the patient can be switched to oral succimer. Because chelation doses for antimony poisoning are not established, chelators should be administered in doses and regimens that

are determined to be safe and effective for other metals (see Antidotes in Depth A26: Dimercaprol [British Anti-Lewisite or BAL] and Antidotes in Depth A27: Succimer [2,3-Dimercaptosuccinic Acid]).

SUMMARY

Antimony is an element whose physical, chemical, and toxicologic properties closely resemble arsenic. Although uncommon, antimony toxicity does occur. The hallmarks of toxicity are gastrointestinal manifestations leading to profound volume depletion and renal injury. ECG findings may assist in the identification of this xenobiotic. Treatment is largely supportive, although chelation may be indicated in life-threatening cases.

CHAPTER 88
ARSENIC

Stephen W. Munday and Marsha D. Ford

Arsenic (As)

Atomic number	=	33
Atomic weight	=	74.92 daltons
Normal concentrations		
Whole blood	<	5 µg/L (<0.067 µmol/L)
Urine (24 hour)	<	50 µg/L (< 0.67 µmol/L)
		1.33 µmol/g (<13.3 µmol/g creatinine)

The therapeutic use of arsenic (arsenic trioxide) for acute promyelocytic leukemia (APL), as well as its emergence as a significant environmental toxin, has renewed interest in its pharmacology and toxicology. The role of arsenic in our pharmacopeia may expand; its efficacy in treating various other leukemias, lymphomas, and multiple myeloma is being studied.[142] This chapter predominantly discusses the properties and toxicity of inorganic arsenic, the most prevalent toxic form.

HISTORY AND EPIDEMIOLOGY

Arsenic poisoning can be unintentional, suicidal, homicidal, occupational, environmental, or iatrogenic.[95,96,126,148] Mass poisonings have occurred. Nearly 400 residents of Hong Kong fell ill after eating contaminated bread from the Esing Bakery in 1857; two bakery foremen were thought to have tampered with the recipe.[79] The 1900 Staffordshire beer epidemic in England saw 6000 beer drinkers fall ill and 70 die from beer brewed with sugar made with arsenic-contaminated sulfuric acid.[95] In Wakayama, Japan, 67 people were poisoned by eating intentionally contaminated curry at a festival in 1998.[200] In 2003, the largest recent outbreak of arsenic poisoning in the United States occurred in New Sweden, Maine, when intentionally adulterated church coffee resulted in the death of one parishioner and the hospitalization of an additional 15 victims.[16] Arsenic trioxide reemerged as a treatment for acute promyelocytic leukemia in the 1990s after physicians in Harbin, China, found a high remission rate in patients given Ailing-1, a crude arsenic trioxide infusion.[111,236]

Contaminated soil, water, and food are the primary sources of arsenic for the general population. Pentavalent arsenic is the most common inorganic form in the environment.[49] Inorganic arsenic exposure from food is generally low and usually occurs from soil-derived foods such as rice and produce.[29,177,227,235] Exposure to organic arsenic compounds of low toxicity occurs from consumption of algae, fish, and shellfish. In the past 2 decades, consumption of contaminated water has emerged as the primary cause of large-scale outbreaks of chronic arsenic toxicity. Arsenic leaches from certain minerals and ores, as well as from industrial waste.[133] In Bangladesh, millions of people have been poisoned by drinking water from wells contaminated with arsenic leached from ground minerals.[151] Ironically, the wells were dug to obtain safer groundwater. Hydroarsenicism has also been reported in Chile, Taiwan, Brazil, India, Mexico, and Argentina.[32,43,49,89,133,151,216] In 2001, the US Environmental Protection Agency decreased the maximum contaminant level of arsenic in drinking water to 10 parts per billion (ppb), or 10 µg/L, after statistical modeling indicated an increased risk of lung and bladder cancer from water contaminated with arsenic at the formerly acceptable level of 50 ppb.[57] The World Health Organization also recommends a maximum concentration of 10 ppb.

CHEMISTRY

Arsenic is a metalloid that exists in multiple forms: elemental, gaseous (arsine), organic, and inorganic [(As^{3+} [trivalent, or arsenite] and As^{5+} [pentavalent, or arsenate])]. Tables 88–1 and 88–2 list sources of arsenic and regulatory standards about arsenic, respectively. Arsenic metal is considered nonpoisonous because of its insolubility in water and bodily fluids.[176] Arsine, which is highly toxic, is discussed in Chap. 24. Trivalent arsenicals include arsenic trioxide (As_2O_3), tetra-arsenic tetrasulfide (realgar; As_4S_4), and diarsenic trisulfide (orpiment; As_2S_3). Realgar and orpiment have been used by the Chinese to treat malignancies, diarrhea, and infections of the chest and liver.[124] Organic arsenicals vary in toxicity. Arsenobetaine, which is synthesized from inorganic arsenic by fish and crustaceans, and arsenosugars, which are synthesized by fish, crustaceans, and algae, have very low toxicity.[12,55,116] In contrast, the organoarsenical medication melarsoprol, used to treat the meningoencephalitic stage of African trypanosomiasis, has toxicity similar to inorganic arsenite.[24,165]

PHARMACOLOGY/PHYSIOLOGY

Arsenic trioxide (As_2O_3) is administered therapeutically for treating APL in doses of 0.15 to 0.16 mg/kg/d by either the intravenous or oral route.[109,111,183] At this dose its beneficial effects in APL occur predominantly by initiating cellular apoptosis when arsenic concentrations reach 0.5 to 2.0 µmol/L. Apoptosis is triggered by several mechanisms. The trivalent arsenic ion binds to mitochondrial membrane sulfhydryl (SH) groups, damaging mitochondrial membranes and collapsing membrane potentials. Cytochrome c is released from the damaged mitochondria with subsequent activation of caspases 9, 3, and 8, and initiation of apoptosis. Cells may be more susceptible if the intracellular concentrations of catalase and glutathione peroxidase (H_2O_2 scavenging enzymes) and glutathione-S-transferase (responsible for conjugating glutathione to xenobiotics) are reduced.[36,69,97,169] Arsenic trioxide also facilitates apoptosis by downregulating gene expression of BCL2, a prosurvival protein that protects against apoptosis.[33] Finally, arsenic trioxide can arrest cells early in mitosis, subsequently leading to apoptosis.[82]

Low-dose arsenic trioxide treatment (0.08 mg/kg/d) beneficially promotes cell differentiation of APL cells when arsenic concentrations reach 0.1 to 2.0 µmol/L. This differentiation is impaired by the promyelocytic leukemia-retinoic acid receptor α (PML-RARα) oncoprotein. This oncoprotein results from the APL-defining translocation of chromosomes 15 and 17. The PML portion of this oncoprotein plays a key role in leukemogenesis by interfering with RARα activity that is essential for normal myeloid cellular development. Trivalent arsenic degrades this PML portion, freeing RARα to facilitate cell differentiation.[36,137,144]

Melarsoprol is a trivalent organic arsenical compound used in Africa and parts of Europe to treat the meningoencephalitic stages of both species of African trypanosomes. It is ineffective against American trypanosomiasis and is available in the United States only directly from the Centers for Disease Control and Prevention (CDC) as it is not approved by the Food and Drug Administration (FDA). The mechanism of action is still poorly understood, but is believed to be related to inhibition of glycolysis and oxidation-reduction reactions.

TABLE 88–1. Sources of Exposure to Arsenic
Inorganic
Occupational/manufacturing
Animal feed (additive)
Brass/bronze
Ceramics/glass
Computer chips (same as semiconductors)
Dyes/paints
Electron microscopy
Fireworks (Chinese)
Fossil fuel combustion—coal
Herbicides
Insecticides/pesticides
Metallurgy
Mining
Rodenticides
Semiconductors (gallium arsenide)
Smelting—copper, lead, zinc, sulfide minerals
Soldering
Wood preservatives
Medicines/contaminated xenobiotics
Chemotherapy (acute promyelocytic leukemia)
Depilatory
Herbals/alternative medicines
Homeopathic remedies
Kelp
"Moonshine" ethanol
Opium
Other
Contaminated well water
Contaminated foods/candies, eg, licorice
Organic
Melarsoprol (trypanocidal)
Thiacetarsamide (heartworm therapy in dogs)
Seafood (arsenobetaine)

The pharmaceutical compound also contains dimercaprol (BAL), which seems to reduce toxicity without diminishing effectiveness. The therapeutic use of melarsoprol can produce many of the toxic effects that occur with inorganic arsenic, including fever, encephalopathy, and acute cerebral edema with seizures and coma. Whether these effects are caused by drug toxicity or by an immune reaction elicited by trypanosomal antigens is unknown.[24,152] Other adverse effects include vomiting, abdominal pain, peripheral neuropathy with hypersensitivity reactions, hypertension, myocardial damage, and albuminuria. Hemolysis can occur in patients with glucose-6-phosphate dehydrogenase deficiency, and erythema nodosum in patients with leprosy.[24,152] In a study of the usefulness of melarsoprol as a treatment for refractory or advanced leukemia, efficacy was very limited, and reported adverse effects included fatigue, vomiting, diarrhea, vertigo, fever, seizures, headache, back pain, and injection site pain.[184]

TOXICOLOGY/PATHOPHYSIOLOGY

Investigations of the pathophysiologic effects induced by toxic doses of arsenic are discussed below. The apoptotic mechanisms[27] thought to be responsible for some therapeutic effects of arsenic trioxide have not been studied in toxicity models.

■ TRIVALENT ARSENIC

The primary biochemical lesion of As^{3+} is inhibition of the pyruvate dehydrogenase (PDH) complex (Fig. 88–1). Normally, dihydrolipoamide is recycled to lipoamide, a necessary cofactor in the conversion of pyruvate to acetylcoenzyme A (acetyl-CoA). As^{3+} binds the sulfhydryl groups of dihydrolipoamide, blocking lipoamide regeneration.[164] Acetyl-CoA is a central molecule in metabolism, and the resulting decrease leads to several deleterious effects:

- Decreased citric acid cycle activity and thus decreased adenosine triphosphate (ATP) production. Disruption of oxidative phosphorylation leads to production of hydrogen peroxide and oxygen radicals.
- Decreased gluconeogenesis that can worsen hypoglycemia. Pyruvate carboxylase catalyzes the conversion of pyruvate to oxaloacetate (initial step in gluconeogenesis), and this reaction requires the carboxylation of biotin, a CO_2 carrier attached to pyruvate carboxylase. Biotin cannot be carboxylated unless acetyl-CoA is attached to the enzyme.[165,188]

In the citric acid cycle, oxidation of α-ketoglutarate to succinyl-CoA uses an α-ketoglutarate dehydrogenase complex that contains the same cofactors as the PDH complex, including lipoamide. Succinyl-CoA is necessary for production of porphyrins and amino acids, and deficiency may contribute to the anemia and wasting seen with chronic arsenic poisoning. Arsenic inhibition of thiolase, the catalyst for the final step in fatty acid oxidation, also impairs ATP production. Diminished fatty acid oxidation results in decreased acetyl-CoA, in the loss of the reduced form of nicotinamide adenine dinucleotide (NADH) and the reduced form of flavin adenine dinucleotide ($FADH_2$) (electron carriers reduced during fatty acid breakdown whose subsequent oxidation yields ATP). Trivalent arsenic also inhibits glutathione synthetase, glucose-6-phosphate dehydrogenase (required to produce nicotinamide adenine dinucleotide phosphate [NADPH]), and glutathione reductase.[8] These inhibitions result in decreased levels of reduced glutathione, which is required to facilitate arsenic metabolism, protect red blood cells (RBCs) from oxidative damage, maintain hemoglobin in the ferrous state, and scavenge hydrogen peroxide and other organic peroxides.

Arsenic affects cardiac repolarization currents. When toxicity occurs, the result is ventricular dysrhythmias, including torsades de pointes. An in vitro study of cells exposed to As^{3+} demonstrated blockade of the delayed rectifier channels I_{Ks} and I_{Kr}. Interestingly, activation of $I_{K\text{-}ATP}$, a weak inward rectifier channel, also occurred; this activation could potentially counteract some of the effects of As^{3+} on the I_{Ks} and I_{Kr} channels.[52]

Animal experiments with phenylarsine oxide, a trivalent arsenical, demonstrate inhibition of insulin-induced glucose transport involving vicinal sulfhydryl groups, as well as β-cell damage in pancreatic islets attributed to inhibition of the α-ketoglutarate dehydrogenase complex.[22] The impaired glucose transport, plus the inhibited gluconeogenesis (discussed above), can lead to glycogen depletion and hypoglycemia.[166] Several animal experiments indicate improved central nervous system (CNS) glucose content[165] and increased in survival time with glucose treatment.[165]

TABLE 88–2. Regulations and Guidelines Applicable to Arsenic and Arsenic Compounds

Agency	Guideline Description	Concentration	Source
Air			
ACGIH	TLV (TWA) for arsenic and inorganic arsenic compounds	0.01 mg/m^3	ACGIH 2004
NIOSH	REL (15-min ceiling limit) for arsenic and inorganic compounds	0.002 mg/m^3	NIOSH 2005
	IDLH for arsenic and inorganic compounds	5 mg/m^3	
OSHA	PEL (8-h TWA) for arsenic organic compounds (general industry, construction, and shipyard)	0.5 mg/m^3	OSHA 2005 29 CFR 1910.1000; 1926.55; 1915.1000
	PEL (8-h TWA) for general industry for arsenic inorganic compounds	10 μg/m^3	OSHA 2005 29 CFR 1910.1018
Water			
EPA	National primary drinking water standards for arsenic		EPA 2002
	MCL	10 μg/L (10 ppb)	
	MCLG	Zero	
FDA	Bottled drinking water	10 μg/L	FDA 2005 21 CFR 165.110
WHO	Drinking water quality guidelines for arsenic	10 μg/L	WHO 2004
ACGIH			ACGIH 2004
Confirmed human carcinogen

ACGIH, American Conference of Governmental Industrial Hygienists; CFR, Code of Federal Regulations; DWEL, drinking water equivalent level; EPA, Environmental Protection Agency; FDA, Food and Drug Administration; IARC, International Agency for Research on Cancer; IDLH, immediately dangerous to life or health; IRIS, Integrated Risk Information System; MCL, maximum contaminant level; MCLG, maximum contaminant level goal; MW, molecular weight; NIOSH, National Institute for Occupational Safety and Health; NTP, National Toxicology Program; OSHA, Occupational Safety and Health Administration; PEL, permissible exposure limit, REL, recommended exposure limit; TLV, threshold limit value; TWA, time-weighted average; WHO, World Health Organization.

Effects on RBCs include decreased membrane fluidity and ATP depletion.[223] Chronic arsenic exposure is associated with vascular disease; in vitro studies demonstrate inhibition of endothelial cell proliferation and glycoprotein synthesis in addition to lipid peroxidation.[34] A study on rodent and human platelets demonstrates increased platelet aggregation and arterial thrombosis.[118] Noncirrhotic hepatic portal fibrosis can develop. In a controlled study where mice chronically ingested water containing equal parts As^{3+} and As^{5+} for up to 15 months, the development of portal fibrosis was preceded by decreased hepatic glutathione (GSH), increased lipid peroxidation, and diminished levels or activities of numerous enzymes involved in regenerating GSH or scavenging free radicals.[174] Proposed mechanisms by which arsenic induces cancer include DNA damage induced by a dimethyl sulfide (DMS)-derived peroxyl radical, gene amplification, replacing phosphate in DNA during replication, increased cell proliferation, and decreased DNA repair efficiency.[14,102,226] Experimental evidence
FIGURE 88–1. Effect of trivalent arsenicals (As^{3+}) on pyruvate dehydrogenase (PDH) complex. (A) The PDH complex is composed of the three enzymes, which use thiamine pyrophosphate (TPP) and lipoamide as cofactors to decarboxylate pyruvate and form acetyl CoA. (B) Arsenic interferes with the regeneration of lipoamide from dihydrolipoamide, thereby altering the function of the PDH complex.
FIGURE 88–2. Pathophysiologic effects of pentavalent arsenic (As^{5+}; arsenate). (**A**) Arsenate (chemical formula AsO$_4^{3-}$) substitutes for inorganic phosphate (Pi; * indicates substitutions), bypassing the formation of 1,3-bisphosphoglycerate (1,3-BPG), and thus losing the ATP formation that occurs when 1,3-BPG is metabolized to 3-phosphoglycerate. (**B**) Energy loss also occurs if arsenate substitutes for Pi and blocks the formation of ATP from ADP. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

and human studies support a number of etiologic or contributing factors for skin keratosis and cancer,[1] including chronic stimulation of keratinocyte-derived growth factors such as transforming growth factor-α (TGF-α), impaired methylation, mutation in the p53 tumor-suppressor gene, inhibition of poly(adenosine diphosphate [ADP]-ribose) polymerase vital for DNA repair, and interference with mitotic spindle and microtubular function.[7,71,92,122,225] Pigmentary changes also occur, and hyperpigmentation is attributed to increased melanin.

■ PENTAVALENT ARSENIC

Several mechanisms can cause toxicity from As^{5+}. Pentavalent arsenic can be reduced to As^{3+}.[93,208] Pentavalent arsenic also resembles phosphate chemically and structurally, may share a common transport system for cellular uptake with phosphate,[93] and can inhibit oxidative phosphorylation by substituting for inorganic phosphate (P$_i$) in the glycolysis reaction catalyzed by glyceraldehyde 3-phosphate dehydrogenase (Fig. 88–2).[31,167] The resulting unstable product, 1-arseno-3-phosphoglycerate, spontaneously hydrolyzes to 3-phosphoglycerate, so glycolysis continues but the ATP normally produced during conversion of 1,3-bisphosphoglycerate to 3-phosphoglycerate is lost. Uncoupling may also occur if ADP forms ADP-arsenate, instead of ATP, in the presence of As^{5+}. The ADP-arsenate rapidly hydrolyzes, thus uncoupling oxidative phosphorylation.

PHARMACOKINETICS AND TOXICOKINETICS

■ ABSORPTION

Inorganic arsenic is tasteless and odorless and can be absorbed by the gastrointestinal (GI), respiratory, intravenous, and mucosal routes. *Gastrointestinal* absorption is facilitated by increased solubility and smaller particle size, and occurs predominantly in the small intestine, followed by the colon. Poorly soluble trivalent compounds such as

arsenic trioxide (As$_2$O$_3$) are less well absorbed than more soluble trivalent and pentavalent compounds that, in aqueous solution, have an oral bioavailability greater than 90%. Therefore, when placed in an aqueous solution, As$_2$O$_3$ is more toxic than an identical dose of undissolved As$_2$O$_3$ eaten in food because of its failure to dissolve, thereby limiting absorption.[205] Organic arsenicals tend to be well absorbed; for example, a rodent study demonstrated approximately 70% GI absorption of the commonly used organic arsenical herbicide, dimethylarsinic acid (cacodylic acid).[186] Systemic absorption via the *respiratory* tract depends on the particulate size, as well as the arsenic compound and its solubility. Large, nonrespirable particles are cleared from the airways by ciliary action and swallowed, allowing GI absorption to occur. Respirable particles lodging in the lungs can be absorbed over days to weeks or remain unabsorbed for years.[25,220] *Dermal* penetration of arsenic through intact skin does not pose a risk for acute toxicity but potentially may be problematic with chronic application. Arsenic acid (H$_3$AsO$_4$) applied to intact skin in rhesus monkeys resulted in absorption of a mean of 2.0% to 6.4% of the applied dose.[221] Skin irritation and damage may increase systemic absorption.[68,168]

■ PHARMACOKINETICS OF ARSENIC TRIOXIDE

Intravenous administration of a single 10-mg dose of As$_2$O$_3$ to eight patients showed mean pharmacokinetic values as follows: maximum plasma concentration (Cp$_{max}$) of 6.85 µmol/L, α elimination half-life (t$_{1/2}$ α) of 0.89 ± 0.29 hours, and β elimination half-life (t$_{1/2}$ β) of 12.13 ± 3.31 hours.[180] In six patients, only 1% to 8% of the daily dose was eliminated in a 24-hour urine. Repeat pharmacokinetic studies on day 30 of treatment were not statistically different.[180] Another study of patients receiving a single dose of 5 mg of As$_2$O$_3$ intravenously demonstrated mean pharmacokinetic values as follows: Cp$_{max}$ of 2.636 µmol/L, t$_{1/2}$ α of 1.413 hours, t$_{1/2}$ β of 9.411 hours, serum clearance of 1.987 L/h, and area under the plasma drug concentration versus time curve (AUC) of 12.706 µmol/L/h. A single dose of 10 mg intravenously showed a Cp$_{max}$ of 6.799 ± 0.314 µmol/L.[179] Arsenic trioxide 10 mg given orally for APL demonstrated total plasma and blood AUC values that were 99% and 87%, respectively, of the corresponding values reported for a 10-mg intravenous dose administered in the same nine patients.[109]

A study in humans receiving intravenous radioarsenic isotope (^{74}As) showed arsenic clearing from the blood in three phases:

Phase 1 (2 to 3 hours)—Arsenic is rapidly cleared from the plasma with a t$_{1/2}$ of 1 to 2 hours; more than 90% may be cleared during this phase because of redistribution to tissue and renal elimination.

Phase 2 (3 hours to 7 days)—A more gradual plasma decline occurs, with an estimated t$_{1/2}$ of 30 hours.

Phase 3 (10 or more days)—Clearance continues from the plasma slowly with an estimated t$_{1/2}$ of 300 hours.[135]

The rapid clearance in phases 1 and 2 explains why blood testing for arsenic is unreliable, except early in acute poisoning.

Initial distribution is predominantly to liver, kidney, muscle, and skin. The skin is rich in sulfhydryl groups; the elimination t$_{1/2}$ of arsenic by the skin was estimated to be 1 month in a rabbit study.[53] Distribution to brain also occurs quickly. In the ^{74}As study, 0.30% of the administered dose was found in brain biopsy samples in the first hour postinfusion. This peak declined to 0.16% by day 7.[135] Ultimately, arsenic distributes to all tissues. In the single patient in this study who was followed for 18 days, 96.6% of the total injected arsenic dose was recovered in the urine. Fecal arsenic recovery was less than 1% of the total dose.[135] Other studies in humans demonstrate renal arsenic

elimination of 46% to 68.9% within the first 5 days postingestion.[26,29,98,157] Approximately 30% is eliminated with a half-life of greater than 1 week, while the remainder is slowly excreted with a half-life of greater than 1 month.[26,134] Fecal elimination is considerably less, with reported amounts as much as 6.1% in humans.[190] Dog studies have revealed that the mechanisms of urinary elimination of unchanged arsenic and its methylated metabolites are via glomerular filtration and tubular secretion; active reabsorption also occurs.[198]

Arsenic crosses the placenta and accumulates in the fetus,[125] but two studies of breast milk excretion from women exposed to drinking water with arsenic levels of approximately 200 µg/L came to opposite conclusions. Breast milk arsenic levels were low in both studies, and only one of them demonstrated a correlation between maternal arsenic levels and levels in breast milk.[44,173]

Metabolism, by adding methyl groups, occurs primarily in the liver, as well as in the kidneys, testes, and lungs (Fig. 88–3). If the arsenic is pentavalent, approximately 50% to 70% will first be reduced to trivalent arsenic.[43,187,206] This bioactivation step requires the oxidation of glutathione[50] and can begin within 15 minutes of exposure.[206] S-adenosylmethionine (SAM) is the primary methyl donor. Nonenzymatic methylation has also been demonstrated in an in vitro study using human liver cytosol; here, methylcobalamin (methyl B$_{12}$) was the methyl donor.[232] Dietary and vitamin deficiencies, as well as high doses of inorganic arsenic, may diminish the ability to methylate arsenic, and folate supplementation has been shown to lower blood arsenic in a folate-deficient population.[65–67,84,85,156,207] However, a study in pregnant Bangladeshi women showed efficient arsenic methylation despite nutritional deficiencies.[121] Addition of one methyl group produces monomethylarsonic acid (MMA^V); adding a second methyl group produces dimethylarsinic acid (DMA^V).
FIGURE 88–3. Metabolism of arsenate [As^{5+}] and arsenite [As^{3+}]. DMA, dimethylarsinic acid; GSH, glutathione; MMA, monomethylarsonic acid; SAHC, S-adenosylhomocysteine; SAM, S-adenosylmethionine. The asterisk (*) denotes MMA^V reductase, the rate-limiting enzyme in rabbit studies of arsenic metabolism; the analogy to humans is unknown.

Production of a trivalent intermediate in this reaction, monomethylarsonous acid (MMA^{III}), is catalyzed by MMA^V reductase. In rabbits this is the rate-limiting enzyme in the biotransformation pathway; however, no data exist to confirm a similar role in human metabolism.[204,233] Conversion of MMA^V to DMA^V is catalyzed by a methyltransferase.

These monomethylation and dimethylation steps were previously thought to detoxify As, but this has been questioned because of the generation of these trivalent intermediates, which are more toxic than the parent compounds.[202] Estimated human LD$_{50}$ (median lethal dose for 50% of test subjects) doses were reported to be arsenic trioxide, 1.43 mg/kg; MMA^V, 50 mg/kg; and DMA^V, 500 mg/kg. However, it is important to note that the doses cited for MMA and DMA apply to arsenic existing in the pentavalent form (As^{5+}). Studies in animals and cell cultures indicate that MMA^{III} may be more toxic than As^{3+}.[129,154,155] Cytotoxicity studies in human hepatocytes revealed descending toxicity of arsenic and its metabolites as follows: MMA^{III} > arsenite > arsenate > MMA^V = DMA^V.[154] Thus, toxicity increases with the formation of MMA^{III}.

There is some evidence that these findings have clinical relevance. In a study from a blackfoot disease–hyperendemic area of Taiwan, lower capacity to methylate inorganic arsenic to DMA^V was associated with increased risk of blackfoot disease. The capacity to methylate arsenic to DMA^V was measured as the ratio of DMA^V to MMA^V and the ratio of MMA^V to the sum of As^{III} and As^V.[196] In addition, a cohort study found that the odds of premalignant skin lesions increased with increasing urinary MMA^V and decreasing urinary DMA^V.[3] They also found that there was an increased risk of skin lesions associated with genetic polymorphisms of glutathaione S-transferase and borderline increased risk with polymorphisms of methylenetetrahydrofolate reductase. The authors suggested that the conversion of MMA^V to DMA^V may be saturable and that arsenic metabolism and toxicity are affected by genetics.[3]

Arsenobetaine (AsB) is also well absorbed and is excreted unchanged in the urine.[205] Elimination occurs more rapidly than with inorganic arsenic. In a study involving human volunteers, 25% was excreted within 2 to 4 hours, 50% by 20 hours, and 70% to 83.7% after 166 hours. A two-component exponential model shows nearly 50% of the AsB eliminated, with a first component t$_{1/2}$ of 6.9 to 11.0 hours and a second component t$_{1/2}$ of 75.7 hours.[98]

CLINICAL MANIFESTATIONS

■ INORGANIC ARSENICALS

Toxic manifestations vary, depending on the amount and form of arsenic ingested, as well as the chronicity of ingestion. Other influencing factors include individual variations in methylation and excretion. Larger doses of a potent compound, such as arsenic trioxide, will rapidly produce manifestations of acute toxicity, whereas chronic ingestion of substantially lower amounts of pentavalent arsenic in groundwater will result in a different clinical picture over time. Manifestations of subacute toxicity can develop in patients who survive acute poisoning, as well as in patients who are slowly poisoned environmentally.

Acute Toxicity Gastrointestinal signs and symptoms of nausea, vomiting, abdominal pain, and diarrhea, which occur 10 minutes to several hours following ingestion, are the earliest manifestations of acute poisoning by the oral route. The diarrhea has been compared to that seen with cholera and may resemble "rice water." Severe multisystem illness can ensue with extensive exposure. Cardiovascular signs, ranging from sinus tachycardia and orthostatic hypotension to shock,

can develop. Reported cases have mimicked myocardial infarction or systemic inflammatory response syndrome, with intravascular volume depletion, capillary leak, myocardial dysfunction, and diminished systemic vascular resistance.[13,19,21,75,99,178] Acute encephalopathy can develop and progress over several days, with delirium, coma, and seizures attributed to cerebral edema and microhemorrhages.[61,178] Seizures may be secondary to dysrhythmias, and the underlying cardiac rhythm should be assessed. Seizures secondary to torsades de pointes associated with a prolonged QT interval developed 4 days to 5 weeks after acute arsenic ingestion.[19,73,185] Acute lung injury, acute respiratory distress syndrome and respiratory failure, hepatitis, hemolytic anemia, acute renal failure, rhabdomyolysis, other ventricular dysrhythmias, and death can occur.[21,59,78,139,189] Death may occur after suddenly developing bradycardia, followed by asystole.[21,99,126] Fever may develop, misleading the practitioner to diagnose sepsis.[54,99] Hepatitis can occur and may be a result of altered intrahepatic heme metabolism causing an increased synthesis of bilirubin or a result of altered protein transport between hepatocytes.[6] Acute renal failure may be secondary to ischemia caused by hypotension, tubular deposition of myoglobin or hemoglobin, renal cortical necrosis, and direct renal tubular toxicity.[23,70,175,199] Glutathione depletion may be contributory.[90] Unusual complications include phrenic nerve paralysis, unilateral facial nerve palsy, pancreatitis, pericarditis, and pleuritis.[15,234] Fetal demise has been reported, with toxic arsenic concentrations found in the fetal organs.[21,125]

Acutely poisoned patients with less severe illness may experience gastroenteritis and mild hypotension that persist despite antiemetic and intravenous crystalloid therapies. Hospitalization and continued intravenous fluids may be required for several days.[117] The prolonged character of the GI symptoms is atypical for most viral and bacterial enteric illnesses and should alert the physician to consider arsenic poisoning, especially if there is a history of repetitive GI illnesses. A metallic taste or oropharyngeal irritation, mimicking pharyngitis, can occur.[21,87] Gastrointestinal ulcerative lesions and hemorrhage have been reported.[61,75] Toxic erythroderma and exfoliative dermatitis result from a hypersensitivity reaction to arsenic.[191]

In the days and weeks following an acute exposure, prolonged or additional signs and symptoms in the nervous, GI, hematologic, dermatologic, pulmonary, and cardiovascular systems can occur. Encephalopathic symptoms of headache, confusion, decreased memory, personality change, irritability, hallucinations, delirium, and seizures may develop and persist.[54,64,170] Sixth cranial nerve palsy and bilateral sensorineural hearing loss are reported.[42,73] Peripheral neuropathy typically develops 1 to 3 weeks after acute poisoning, although in one series nine patients developed maximal neuropathy within 24 hours of exposure.[42,87,117,218] Sensory symptoms develop first, and diminished to absent vibratory sense may be present. Progressive signs and symptoms include numbness, tingling, and formication with physical findings of diminished to absent pain, touch, temperature, and deep-tendon reflexes in a stocking-glove distribution. Superficial touch of the extremities may elicit severe or deep aching pains, a finding that also occurs with thallium poisoning. Motor weakness may then develop. The most severely affected patients manifest an ascending flaccid paralysis that mimics Guillain-Barré syndrome.[42,87,117] Respiratory problems can include dry cough, rales, hemoptysis, chest pain, and patchy interstitial infiltrates.[87,153] These findings may be misinterpreted as viral or bronchitic disease. Leukopenia, and less commonly anemia and thrombocytopenia, occur from days to 3 weeks after an acute exposure, but resolve as bone marrow function returns.[95,120]

Dermatologic lesions can include patchy alopecia, oral herpetiform lesions, a diffuse pruritic macular rash, and a brawny nonpruritic desquamation (see Chap. 29). Diaphoresis and edema of the face and extremities can develop.[1] Mees lines (transverse striate leuconychia of

FIGURE 88–4. Mee's lines, parallel white bands across the nails result from exposures to metals, radiation, and chemotherapeutic agents, among others. *(Image contributed by the New York City Poison Center Toxicology Fellowship Program.)*

the nails) are 1- to 2-mm-wide horizontal nail bands that represent disturbed nail matrix keratinization (see Fig. 88–4). They are uncommon in arsenic poisoning. A minimum of 30 days after exposure is required for the lines to extend visibly beyond the nail lunulae.[87,225] Contact dermatitis has been reported from topical exposure in an occupational setting. Other possible toxic manifestations of subacute inorganic arsenic toxicity include nephropathy, fatigue, anorexia with weight loss, torsades de pointes, and persistence of GI symptoms.[13,130]

Chronic Toxicity Chronic low-level exposure to inorganic arsenicals typically occurs from occupational or environmental sources. Malignant and nonmalignant skin changes, hypertension, diabetes mellitus, peripheral vascular disease, and lung, bladder, and hepatic malignancies are associated with drinking water containing arsenic that is consumed by study populations.[136,151,158,229] The skin is very susceptible to the toxic effects of arsenic; multiple dermatologic lesions have been reported in populations suffering from hydroarsenicism.[133,229] Alterations in pigmentation occur first, with hyperpigmentation being the most common. Hypopigmentation ("raindrop" pattern) can also occur (see Fig. 88–5). Hyperkeratoses typically develop on the palms and soles, but can be diffuse (see Fig. 88–6). Squamous and basal cell

FIGURE 88–5. Characteristic hemorrhagic vesicles of arsenical dermatitis is shown. *(Image contributed by New York University Department of Dermatology.)*

FIGURE 88–6. Characteristic vesicular xerotic arsenical dermatitis is shown. *(Image contributed by New York University Department of Dermatology.)*

carcinomas and Bowen disease (intraepidermal squamous cell carcinoma) may occur. Bowen disease usually proliferates in multiple sites, especially on the trunk, and is noted for developing on sun-protected areas. Latency periods for developing keratoses, Bowen disease, and squamous cell carcinoma were 28, 39, and 41 years, respectively, in 17 patients chronically exposed to environmental or medicinal arsenic.[48,224] Gastrointestinal symptoms of nausea, vomiting, and diarrhea are less likely but can occur. Hepatomegaly was present in 120 of 156 patients with hydroarsenicism; liver biopsy in 45 cases revealed a noncirrhotic portal fibrosis in 91.1%.[133] Rodent studies have also demonstrated hepatic fibrosis from inorganic arsenic exposure.[174] Portal hypertension and hypersplenism have occurred.[133,174] Hepatic angiosarcomas have been linked to arsenic exposure.[40,101,115]

Population studies in areas of Bangladesh and Taiwan with arsenic-contaminated water show an increased prevalence of diabetes mellitus (DM), pulmonary fibrosis, and other organ system effects.[160,161,197] A cross-sectional drinking water study from the United States revealed an odds ratio of 3.58 for prevalence of type 2 DM among those at the 80th percentile, as compared to those at the 20th percentile, despite a median total arsenic concentration of only 7.1 ppb.[114,143] The mechanism of this low-concentration arsenic effect is unclear. Animal studies have demonstrated that arsenic can decrease insulin-mediated uptake of glucose by cells and can also disrupt insulin transcription factor signal transduction.[150,213] In a study from West Bengal, restrictive lung disease was reported in nine of 17 patients, and a restrictive plus obstructive pattern occurred in another seven cases.[133] Lung disease has also been noted in other populations.[80] Proposed mechanisms include arsenic-induced inflammation and oxidative stress.[149] Aplastic anemia and agranulocytosis are documented in patients exposed to arsenic.[54] A dose–response relationship between arsenic exposure and vascular disease is reported in several populations.[215] After adjusting for age, sex, hypertension, DM, cigarette smoking, and alcohol consumption, a significant relationship was observed with cerebrovascular disease in a region of Taiwan.[39] Blackfoot disease, an obliterative arterial disease of the lower extremities, occurring in Taiwan, is linked to chronic arsenic exposure,[32,195] as is ischemic heart disease.[30] The incidence of Raynaud phenomenon and vasospasm was reported to be increased in smelter workers exposed to arsenic, compared with a control group.[113] Encephalopathy and peripheral neuropathy are the neurologic manifestations most commonly reported.[18,86] Electromyographic studies of 33 patients with chronic ingestion of arsenic-contaminated water revealed 10 patients with findings consistent with sensory neuropathy.

The minimum duration of exposure was 2 years. Interestingly, three of these patients consumed water with an arsenic concentration that only slightly exceeded the contaminant concentration of 50 ppb previously permissible in the United States.[89]

Arsenic is classified as a definite carcinogen by the International Agency for Research on Cancer (IARC, Group 1) and the National Toxicology Program (NTP). Cancers known to develop include lung, skin, and bladder.[12,41,94,173,182] Transitional cell bladder carcinoma was the most common type in one large epidemiologic study.[38] A critical literature review of animal and human studies found that exposure to environmental arsenic was unlikely to cause reproductive or developmental toxicity.[51] However, a more recent rodent study revealed fetal growth retardation and neurotoxicity at doses relevant to human exposure and in the absence of maternal toxicity.[214] More concerning, two recent drinking water cohort studies from Bangladesh showed small but statistically significant increases in birth defects and fetal loss.[110,160,203] Moreover, in addition to possibly increasing the risk of birth defects there is also cross-sectional evidence that in utero or early childhood exposure may be associated with persistent neurocognitive effects in children.[28,46,194,211,216,217] Finally, there is evidence that in utero or early childhood exposure to arsenic in drinking water increases the risk of malignant and nonmalignant lung diseases in young adults.[182] In summary, there is accumulating evidence of persistent adverse effects from in utero or early childhood exposure, but prospective studies are needed to confirm these findings by decreasing the effects of confounding and bias that may explain the results.

Many of the questions regarding the chronic health effects of exposure to arsenic in drinking water are currently being investigated in the Health Effects of Arsenic Longitudinal Study (HEALS). This study was designed to evaluate the health effects of a full range of drinking water arsenic exposures including mortality, premalignant and malignant skin tumors, pregnancy outcomes, and children's cognitive development.[5]

This study is a prospective cohort study in Araihazar, Bangladesh. Participants were between the ages of 18 and 75 years and married, although both members of a couple were not required to enroll. A total of 11,764 subjects enrolled, 6704 women and 5042 men. The participation rate in the initial enrollment was 97.5% of those approached.[5]

Of those who agreed to participate 98% completed an extensive questionnaire that included demographic and lifestyle components and a validated food-frequency questionnaire. They also participated in a clinical examination with an extensive skin evaluation. Over 90% of this group also provided blood and spot urine arsenic samples.[5]

Approximately one-third of the participants consumed water in each of three groups: greater than 100 µg/L, 25 to 100 µg/L, and less than 25 µg/L. Average urinary concentrations of arsenic were approximately 140 µg/L.

Some findings from this cohort have been published. Studies of persons with arsenic-induced skin lesions have shown increasing risk of disease as exposure increases.[4] Modification of risk was noted in relationship to sunlight exposure, smoking, and some occupational exposures such as fertilizers and pesticides.[35] A dose–response relationship was also found for subclinical sensory neuropathy as measured by tactile thresholds.[81]

■ ADVERSE DRUG EFFECTS: ARSENIC TRIOXIDE

The most common adverse effects are *dermatologic* (skin dryness, pigmentary changes, maculopapular eruptions with or without pruritus); *GI* (nausea, vomiting, anorexia, diarrhea, and dyspepsia); *hematologic* (leukemoid reactions); *hepatic* (elevation of aminotransferase concentrations typically less than or equal to 10 times the upper limit of normal values, with a reported incidence of 20% with low-dose and 31.9% with conventional-dose therapy[179]); *cardiac* (prolonged QT interval in 40% to 63% of patients, first-degree

atrioventricular block, ventricular ectopy, monomorphic nonsustained ventricular tachycardia, torsades de pointes, sudden asystole, and death);[172,179,183,201,222] *facial edema*; and *neurologic* (paresthesias, peripheral neuropathy, and headache). All of these effects occurred more commonly in one case series with conventional-dose therapy (0.16 mg/kg/d) when compared to low dose therapy. The majority are treated symptomatically without discontinuing As_2O_3 treatment. Leukemoid reactions, defined as white blood cell counts greater than $50 \times 10^9/L$, develop in nearly 50% of patients between 14 and 42 days of beginning treatment. Such patients are at risk for intracerebral hemorrhage or infarction and for the APL syndrome. This syndrome is similar to the differentiation syndrome (DS) that was formerly known as the retinoic acid syndrome.[138] The remission induction treatment phase is the period of greatest risk.[180] Common clinical findings in this syndrome include pulmonary interstitial infiltrates and/or pleural effusions, dyspnea, tachypnea, fluid retention, myalgias, arthralgias, fever, and weight gain; approximately 20% to 25% of patients treated with arsenic trioxide will develop one or more signs or symptoms of this syndrome.[131,142,172,179,180]

DIAGNOSTIC TESTING

Timing of testing for arsenic must be correlated with the clinical course of the patient and whether the poisoning is acute, subacute, chronic, or remote with residual clinical effects. To properly interpret laboratory measurements, confounding factors, such as food-derived organic arsenicals or accumulated arsenic (DMA and arsenobetaine) in patients with chronic renal failure, must be considered.[47,237,238] Failure to understand potential confounders, as well as the time course of arsenic metabolism, clearance, and effect on laboratory parameters, can cause erroneous assessment of possible arsenic poisoning.

■ URINE AND BLOOD

Diagnosis ultimately depends on finding an elevated urinary arsenic concentration. In an emergency, a spot urine may be sent prior to beginning chelation therapy. A markedly elevated arsenic concentration verifies the diagnosis in a patient with characteristic history and clinical findings, but a low concentration does not exclude arsenic toxicity.[212] In nine acutely symptomatic patients, initial spot urine arsenic concentrations ranged from 192 to 198,450 μg/L.[103] Definitive diagnosis of arsenic exposure hinges on finding a 24-hour urinary concentration equal to or greater than 50 μg/L, 100 μg/g creatinine, or 100 μg total arsenic. A study on arsenic exposure from drinking water showed excellent correlations between spot and 24-hour urine arsenic concentrations. There are not enough data to determine if this relationship holds true in acutely poisoned patients, so a 24-hour collection is still preferred.[29] Challenge testing with dimercaptopropane sulfonate (DMPS) has been performed in individuals exposed to arsenic in drinking water and clearly increases arsenic excretion; however, it also alters the percentages of the arsenic species recovered compared with controls and has not been correlated with clinical effects.[11] All urine should be collected in metal-free polyethylene containers; acid-rinsed containers are not recommended since the acid alters the arsenic species.[58] If testing is performed by an outside reference laboratory, specimens from acutely ill patients should be sent via express transportation with a request for a rapid result.

When interpreting slightly elevated urinary arsenic levels, laboratory findings must also be correlated with the history and clinical findings, because seafood ingestion is reported to transiently elevate urinary total arsenic excretion up to 1700 μg/L.[12] When seafood arsenic is a consideration, speciation of arsenic can be accomplished by high-performance liquid chromatography (HPLC) separation, followed by inductively coupled plasma-mass spectrometry (ICPMS), HPLC via ion-pair chromatography coupled with hydride-generation atomic-fluorescence spectrometry (HGAFS), or by hydride generation coupled with cold-trap gas chromatography-atomic absorption spectrometry. These techniques separate AsB, As^{3+}, As^{5+}, MMA, and DMA.[58] Arsenobetaine can also be directly measured by silica-based cation-exchange separation, followed by atomic absorption spectrometry.[145] Two other methods, selective hydride-generation atomic-absorption spectrometry (HGAAS) and resin-based ion-exchange chromatography, do not directly measure AsB; instead, they indirectly derive this value by subtracting the sum of all measured arsenic species from the total arsenic concentration.[145] If arsenic speciation cannot be done, the patient can be retested after a 1-week abstinence from fish, shellfish, and algae food products.

Conditions under which urine is stored can affect total arsenic recovery, as well as proportionality of the species. The various arsenic species—arsenate (As^{5+}), arsenite (As^{3+}), MMA, DMA, and AsB—remain stable for 2 months in urine stored without preservatives at either –4°F (–20°C; freezer) or 39.2°F (4°C; refrigerator); AsB is stable for 8 months under these conditions. Storage for longer than 2 months can alter the recovery of various species. Addition of 0.1% hydrochloric acid (HCl) facilitates reduction of arsenate to arsenite and also decreases MMA and DMA levels. Acid-washed collection containers should not be used if measurement of the various arsenic species is planned. Total arsenic recovery can be diminished by any of the following: specimen storage for greater than 2 months, acidification, or testing using HPLC-ICPMS and HPLC-HGAFS, since all these methods usually require that the samples be filtered prior to undergoing HPLC separation.[58]

Diagnostic evaluation of chronic toxicity should include laboratory parameters that may become abnormal within days to weeks following an acute exposure. Tests should include a complete blood count, renal and liver function tests, urinalysis, and 24-hour urinary arsenic determinations. Complete blood count findings can include a normocytic, normochromic, or megaloblastic anemia; an initial leukocytosis followed by development of leukopenia, with neutrophils depressed more than lymphocytes, and a relative eosinophilia; thrombocytopenia; and a rapidly declining hemoglobin, indicative of hemolysis or a GI hemorrhage.[112] Basophilic stippling of RBCs can be seen; this can occur in other toxic and clinical disorders. Karyorrhexis, a rupture of the RBC cell nucleus with chromatin disintegration into granules that are extruded from the cell, and dyserythropoiesis are reported in both lead- and arsenic-toxic patients. Both findings are caused by arsenic-induced inhibition of DNA synthesis and damage to the nuclear envelope.[56] The karyorrhexis can occur within 4 days and resolve by 2 weeks after poisoning, and may be an early indication of arsenic toxicity.[112] Elevated serum creatinine, aminotransferases, and bilirubin, as well as depressed haptoglobin concentrations, may develop. Urinalysis may reveal proteinuria, hematuria, and pyuria. Cerebrospinal fluid examination in patients with CNS findings can be normal or exhibit mild protein concentration elevation, measured at 26.5 mg/dL in one case.[87] Urinary arsenic excretion in subacute and chronic cases varies inversely with the postexposure time period, but low-level excretion can continue for months after exposure. In a study of 41 cases of arsenic-induced peripheral neuropathy, most patients with a neuropathy of 4 to 8 weeks duration had total 24-hour urinary arsenic measurements of 100 to 400 μg.[87]

■ HAIR AND NAIL TESTING

In cases of suspected arsenic toxicity, in which the urinary arsenic measurements fall below accepted toxic concentrations, analysis of

hair and nails may yield the diagnosis. Arsenic can be detected in the proximal portions of hair within 30 hours of ingestion.[230] Inorganic arsenic is the form best absorbed by these tissues and the form most commonly found in human poisoning cases; small amounts of methylated metabolites may also be detected.[159] Arsenobetaine has not been found in hair and tissues in human and animal studies.[227,228] Hair grows at rates varying from 0.7 to 3.6 cm per month, with a mean rate of 1 cm per month.[219] The Society of Hair Testing has made the following recommendations for collection of hair specimens; however, these have only been validated for testing drugs of abuse: (1) collect approximately 200 mg of hair from the posterior vertex region of the scalp using scissors to cut as close to the scalp as possible, and (2) tie the hairs together, wrap in aluminum foil to protect from environmental contamination, and store at room temperature.[219] Nails grow approximately 0.1 mm per day. Total replacement of a fingernail requires 3 to 4 months, whereas toenails require 6 to 9 months of growth. These facts, plus the frequency of hair cutting, should be considered when estimating the usefulness of measuring arsenic levels in these tissues. The normal values of the testing laboratory should be used to determine whether arsenic concentrations are elevated. In cases of remote toxicity, hair and nail arsenic measurements may or may not be elevated, depending on the time elapsed since exposure. Sequential hair analysis to assess the time(s) of exposure can be performed by solid sampling graphite furnace atomic absorption spectrophotometry, or by X-ray fluorescence spectrometry.[104,192,193]

■ OTHER TESTS

Abdominal radiographs might demonstrate radiopaque material in the GI tract soon after an ingestion.[2,37,75,76,88] However, even after an acute ingestion the absence of radiopaque materials on abdominal radiographs is reported.[45] The incidence of positive radiographs after an ingestion is unknown, and a negative radiograph should not eliminate arsenic as a diagnostic consideration. Electrocardiographic changes reported include QRS widening, QT prolongation, ST segment depression, T-wave flattening, ventricular premature contractions, nonsustained monomorphic ventricular tachycardia, and torsades de pointes.[17,147,183,201] Nerve conduction studies (NCS) can confirm or diagnose clinical or subclinical axonopathy. Both the sensory nerve action potential (SNAP) and the motor compound muscle action potential (CMAP) measure the number of axons that can conduct impulses. However, the sensory studies are more sensitive than motor studies in detecting axonal degeneration and demyelination; decreased SNAP measurements can indicate subclinical neuropathy. In motor nerve studies, the amplitude (height of the CMAP) is a more sensitive measure of the number of axons that can conduct impulses than is the conduction velocity; this can be explained by the pattern of axonal destruction as opposed to myelin injury (which mainly affects conduction velocity). Nerve biopsies have confirmed disintegration of both axons and myelin in patients with arsenic-induced peripheral neuropathy; the axonal loss begins distally in the lower extremities and is initially scattered. Thus, conduction along the remaining functional axons can be sufficient to produce normal or only slightly decreased conduction measurements on NCS.[72,87,105,117,141,146]

MANAGEMENT

■ GENERAL

Acute arsenical toxicity is life threatening and mandates aggressive treatment. Advanced life support monitoring and therapies should be initiated when necessary, but with a few caveats. Careful attention to

fluid balance is important because cerebral and pulmonary edema may be present. Xenobiotics that prolong the QT interval, such as the class IA, class IC, and class III antidysrhythmics, should be avoided (see Chap. 63). Potassium, magnesium, and calcium concentrations should be maintained within normal range to avoid exacerbating a prolonged QT interval. Glucose concentrations and glycogen stores should be maintained parenterally with dextrose and hyperalimentation solutions, or with enteral feedings, in view of their beneficial effects, in experimental models of arsenic poisoning.[123,165,166,188]

Gastrointestinal decontamination of patients acutely poisoned with arsenic is controversial. Arsenic poorly adsorbs to activated charcoal, cholestyramine, and bentonite.[163] Moreover, significantly poisoned patients usually have nausea and vomiting and may have altered mental status which make charcoal administration difficult. Despite these concerns, many medical toxicologists would give charcoal, in conjunction with airway protection if necessary, because of the relatively low likelihood of harming the patient and the hope that preventing even a small amount of absorption might prevent or lessen the potentially disastrous consequences of arsenic poisoning. If radiopaque material is visualized in the GI tract, whole-bowel irrigation can be administered until the radiopaque material is no longer visualized on repeat abdominal radiograph. Continuing nasogastric suction may be important in removing arsenic resecreted in the gastric or biliary tract. Arsenite was still detectable in the gastric aspirate in three patients 5 to 7 days following an ingestion.[128] There is no clinical experience with the use of *N*-acetylcysteine to increase glutathione levels; an animal experiment suggested a protective effect.[162]

In cases of chronic toxicity, patients should be removed from the arsenic source and gastric decontamination should be performed if there is evidence of arsenic in the GI tract. Arsenic can be readily removed from skin with soap, water, and vigorous scrubbing. In this situation, when homicidal intent is suspected, all hospital visitors should be closely monitored and outside nutritional products should be forbidden.

■ CHELATION THERAPY

Chelators Dimercaprol (BAL) and 2,3-dimercaptosuccinic acid (succimer) are the two chelators available in the United States. A third drug, DMPS, is distributed by Heyl, a German pharmaceutical company, as Dimaval, but it is not approved or marketed in the United States (see Antidotes in Depth, A26, A27). All contain vicinal dithiol moieties that bind arsenic to form stable 1,2,5-arsadithiolanes (Fig. 88–7), and all are most effective when administered in doses equimolar to the arsenic burden.[140] Dosing regimens and adverse effects are listed in Table 88–3.

The decision to initiate chelation therapy should depend on the clinical condition of the patient as well as the laboratory results for arsenic in urine, hair, or nails. A severely ill patient with known or suspected acute arsenic poisoning should be chelated immediately, prior to laboratory confirmation. In the United States, BAL remains the initial chelating drug for acute arsenical toxicity.[140] In a series of

BAL adduct
$R_1 = H$, $R_2 = CH_2OH$

DMPS adduct
$R_1 = H$, $R_2 = CH_2SO_2Na$

Succimer adduct
$R_1 = R_2 = COOH$
FIGURE 88–7. 1,2,5-Arsadithiolane adducts with BAL, DMPS, and DMSA.

TABLE 88–3. Chelators for Arsenical Poisoning	
Dosage	Adverse Effects
BAL 3–5 mg/kg every 4–6 h	Hypertension; febrile reaction; diaphoresis; nausea; vomiting; salivation; lacrimation; rhinorrhea; headache; painful injection; injection site sterile abscess; hemolysis in G6PD-deficient patients; chelation of essential metals (prolonged course)
SUCCIMER 10 mg/kg/dose every 8 h for 5 d, then 10 mg/kg/dose every 12 h	Nausea; vomiting; diarrhea; abdominal gas and pain; transient elevations of hepatic aminotransferases and alkaline phosphatase; ferases and alkaline phosphatase concentrations; rash; pruritus; sore throat; rhinorrhea; drowsiness; paresthesias; thrombocytosis; eosinophilia
DMPS (not FDA approved) Dose: 5 mg/kg/dose IM, administered as a 5% solution Day 1: q6–8h Day 2: q8–12h Day 3 and thereafter: q12–24h End point: for chelation is a 24 hour urinary arsenic concentration of <50 μg/L	Allergic reactions; increased copper and zinc excretion; nausea; pruritus; vertigo; weakness, toxic epidermal necrolysis

G6PD, glucose-6-phosphate dehydrogenase; IM, intramuscularly.

33 patients who had coma, seizures, or both, 24 patients were treated with BAL within 6 hours (mean: 1 hour) and 75% survived, compared with a survival rate of 45% of nine patients who were treated later (range: 9–72 hours; mean: 30 hours).[54] Cases of subacute and chronic toxicity can await rapid laboratory confirmation prior to beginning chelation, unless the clinical condition deteriorates.

In a cellular study of glucose uptake impaired by a lipophilic arsenical, BAL was superior to succimer and DMPS in restoring cellular equilibrium.[140] A human case series found increased survival with early use of BAL and improvement in encephalopathy within 24 hours of initiating therapy.[54] However, other acute cases treated promptly with BAL developed peripheral neuropathy.[117] In a study of subacute cases with peripheral neuropathy, BAL accelerated neurologic recovery but did not affect the overall recovery rate.[42] Despite starting BAL therapy 8 hours postexposure, a man who had ingested 2.15 g of arsenic developed severe toxicity and neurologic deficits.[60] Most concerning are the animal experiments indicating that BAL shifts arsenic into the brain and testes, two organs that have blood–organ barriers susceptible to this lipophilic drug.[10,91,107] It is clear that BAL has limitations, and that we need a safer, more effective intracellular/extracellular parenteral chelator.

Succimer is an oral hydrophilic analog of BAL and is the chelator of choice for subacute and chronic toxicity. It has proven effective in animal studies and in reported human cases.[10,106,119,127,181] In mice exposed to sodium arsenite, succimer was more effective than either DMPS or BAL in decreasing lethality, and more potent than BAL in restoring activity in the pyruvate dehydrogenase complex.[10] It is equal or superior to BAL in speeding arsenic elimination.[140] Liver function tests and essential metal concentrations should be monitored in patients requiring prolonged therapy.[63,77]

DMPS is also a water-soluble analog of BAL. It is not approved for use in the United States. It can be administered by the oral, intravenous, and intramuscular routes. It is eliminated from the body more slowly than succimer and has the advantage of intracellular as well as extracellular distribution.[7] It predominantly binds MMA^{3+} and possibly removes the MMA^{3+} from endogenous ligands. The $DMPS–MMA^{3+}$ complex is eliminated in the urine.[9,11,74] It may also work by synergistically increasing the nonenzymatic methylation of As^{3+}.[232] Two brothers ingested nearly pure arsenic trioxide (1 and 4 g each) and were treated with intravenous and oral DMPS. The brother who ingested 4 g developed hypotension, renal failure, respiratory insufficiency, and asystolic cardiac arrest. DMPS was started 32 hours postingestion, and the patient survived with normal renal function and no neurologic dysfunction. His sibling had a milder course; DMPS was started 48 hours postingestion, and there were no neurologic sequelae on follow-up examination.[139] DMPS significantly increased biliary excretion of arsenic in a guinea pig model, but did not increase fecal excretion. The latter is most likely a result of enterohepatic recirculation of the DMPS–As complex.[163] However, in another guinea pig model, the addition of oral cholestyramine to either DMPS or DMSA increased fecal arsenic excretion; this effect cholestyranine was not seen with BAL.[140]

D-Penicillamine has not demonstrated efficacy in chelating or reversing the biochemical lesions of arsenic and should not be used. Its previous advantage of oral administration is no longer relevant with the availability of succimer.

Because of the limitations of currently available chelators, research is ongoing to find better chelators to treat arsenic toxicity. For example, some analogs of DMSA, especially its monoisoamyl ester, have increased intracellular penetration relative to the parent compound and have been shown to increase survival in arsenic-poisoned rats.[62,100] In addition to improved chelators, other treatments for arsenic toxicity are being investigated. Some rodent studies have suggested that certain micronutrients, such as zinc or selenium, can decrease arsenic toxicity.[62] However, early findings from the HEALS cohort are mixed. A cross-sectional substudy from this group revealed an inverse relationship between the severity of skin lesions and dietary intake of folate, pyridoxine, riboflavin, and vitamins A, C, and E.[231] In contrast, another study from the same cohort did not find a statistically significant relationship between the severity of skin lesions and supplementation with vitamin E, selenium, or both.[210] Until more data are available, nutritional supplementation, in the absence of dietary deficiency, remains controversial.

Hemodialysis Hemodialysis removes negligible amounts of arsenic, with or without concomitant BAL therapy, and is not indicated in patients with normal renal function.[20,83,132] In patients with renal failure, hemodialysis clearance rates have ranged from 76 to 87.5 mL/min, with or without concomitant BAL therapy.[209] In two acutely toxic patients with renal failure, total arsenic removed during a 4-hour dialysis measured 4.68 mg in one and 3.36 mg in the other. Concomitant 24-hour urinary arsenic excretions were 3.12 mg and 2.03 mg, respectively. When renal function returned, however, the 24-hour urinary excretion of arsenic far exceeded that recovered with dialysis, with reported levels of 18.99 mg in the first patient and 75 mg in the second patient.[209] There are no published rigorous data regarding hemodialysis removal of a water-soluble complex such as DMPS–As.[108]

SUMMARY

Environmental contamination of water sources has become a major health problem in many countries, including the United States. Arsenicals produce multisystem toxicity by a variety of pathophysiologic

mechanisms. A thorough understanding of inorganic arsenic metabolism and excretion as well as the different clinical manifestations of acute, subacute, and chronic toxicity are necessary to avoid misdiagnosis. Chelation therapy with BAL in the United States, or with DMPS elsewhere, if available, should be started immediately in the severely ill patient. Treatment can await laboratory results for patients with subacute or chronic toxicity, unless clinical deterioration intervenes.

DIMERCAPROL (BRITISH ANTI-LEWISITE OR BAL)

Mary Ann Howland
BAL (2,3-Dimercaptopropanol; dimercaprol) is a metal chelator used clinically in conjunction with edetate calcium disodium (CaNa$_2$EDTA) for lead encephalopathy and severe lead toxicity.[22,29] In this instance BAL should precede the first dose of CaNa$_2$EDTA by 4 hours to prevent redistribution of lead to the central nervous system (CNS). Because BAL has a narrow therapeutic index and must be given intramuscularly (IM), succimer is used for patients with less severe lead toxicity. Likewise, the roles of BAL in arsenic and mercury poisoning are being supplanted by succimer and the investigational agent 2,3-dimercaptopropane sulfonate (DMPS), unless the gastrointestinal tract is compromised and IM BAL is indicated.

HISTORY

Investigation into the use of sulfur donors as antidotes was precipitated by the World War II threat of chemical warfare with lewisite (dichloro[2-chlorovinyl]arsine) and mustard gas (dichlorodiethyl sulfide[ClCH$_2$CH$_2$]$_2$S).[1,30,31] Both are vesicant gases that cause tissue damage when combined with protein sulfhydryl (SH) groups (Chap. 131).[34] The investigations of Stocken and Thompson at Oxford led to the discovery of the dithiol 2,3-dimercaptopropanol, called British anti-Lewisite, which combines with lewisite to form a stable five-membered ring.[39,41]

CHEMISTRY

BAL has a molecular weight of 124.2 daltons and a specific gravity of 1.21.[32] Dimercaprol is an oily liquid with only 6% weight/volume water solubility, 5% weight/volume peanut oil solubility, and a disagreeable odor. Aqueous solutions are easily oxidized and therefore unstable. Peanut oil stabilizes BAL and benzyl benzoate (in the ratio of one part BAL to two parts of benzyl benzoate) renders the BAL miscible with peanut oil.[35]

PHARMACOKINETICS

There are no recent pharmacokinetic studies with BAL. The limited amount of information available dates back to the late 1940s.[1,23] Serum concentrations of BAL peak about 30 minutes after IM administration and distribution occurs quickly.[35,38] Within 2 hours after IM administration to rabbits, serum concentrations drop quickly. Urinary excretion of BAL metabolites, perhaps partially as glucuronic acid conjugates, accounted for nearly 45% of the dose within 6 hours and 81% of the dose within 24 hours.[35,37] Very little is excreted unchanged in the urine.[35] BAL is concentrated in the kidney, liver, and small intestine.[33] BAL can also be found in the feces, suggesting that enterohepatic circulation exists. Hemodialysis may be useful in removing the BAL–metal chelate in cases of renal failure.[22,28,40]

USE OF BAL FOR ARSENIC EXPOSURE

■ ANIMAL STUDIES

The fear of lewisite attack causing skin lesions, led researchers to investigate the potential for cutaneous application of BAL.[39] This was based on its limited water solubility and high lipid solubility. In a rodent model, low concentrations of topical BAL were very effective both in preventing lewisite-induced toxicity and in reversing toxicity when administered within 1 hour of skin exposure.[32,34] In rabbits, ocular application of BAL proved effective in preventing eye destruction if applied within 20 minutes of exposure.[22] Additionally, urinary arsenic concentrations were significantly increased after the application of BAL.[34]

The effectiveness of both parenteral single-dose and multiple-dose BAL against lewisite and other arsenicals was studied in rabbits. When begun within 2 hours of lewisite exposure, BAL injections of 4 mg/kg every 4 hours led to a 50% survival of exposed rabbits. This dosing regimen was demonstrated to be one-seventh of the maximum tolerated dose of BAL.[16]

The most recent animal studies demonstrate that although BAL increases the LD$_{50}$ (median lethal dose for 50% of test subjects) of sodium arsenite, the therapeutic index of BAL is low and arsenic redistribution to the brain occurs.[4,6,7,19,36] In these same animal models, succimer and DMPS also increased the LD$_{50}$, but with a better therapeutic index and without causing redistribution to the brain.[3,4]

Ocular damage caused by lewisite is partly a result of the liberation of hydrochloric acid, which results in an acid injury causing localized superficial opacity of the cornea and deep penetration of lewisite into the cornea and aqueous humor with resultant rapid necrosis. In an experimental model, a 5% BAL ointment or solution applied within 2 minutes of exposure prevented the development of a significant reaction; application at 30 minutes lessened the reaction, but did not prevent permanent damage.[20]

■ HUMAN STUDIES

Earlier experiments in human volunteers who were given minute amounts of arsenic demonstrated that BAL increased urinary arsenic concentration by approximately 40%, with maximum excretion

occurring 2 to 4 hours after BAL administration.[43] BAL was subsequently used in the treatment of arsenical dermatitis resulting from organic arsenicals used to treat syphilis. When applied to affected skin, topical BAL produced erythema, pruritus, and dysesthesias, but had no adverse effects on unaffected skin. Intramuscular BAL produced both subjective and objective improvement, limited the duration of the arsenical dermatitis, and increased urinary arsenic elimination.[12,26,27]

In a study of 227 patients with inorganic arsenic poisoning, maximal efficacy and minimal toxicity were achieved when 3 mg/kg of BAL was administered IM every 4 hours for 48 hours and then twice daily for 7 to 10 days. This regimen resulted in complete recovery in six of seven patients with severe arsenic-induced encephalopathy and demonstrated the importance of administering BAL as soon as possible after the exposure. Of 33 patients with severe arsenic-induced encephalopathy, 18 of 24 (75%) treated within 6 hours survived, versus only four of nine (44%) treated after a delay of at least 72 hours.[15] Furthermore, the effectiveness of BAL was also demonstrated in three patients who were treated successfully after mistakenly receiving 10 to 20 times the therapeutic dose of Mapharsen (oxophenarsine hydrochloride). A fourth patient, treated with inadequate doses of BAL, died.[15] These cases support the effectiveness of BAL in treating arsenic-induced agranulocytosis, encephalopathy, dermatitis, and probably arsenical fever.[15]

When BAL first became more widely available, 42 children who were treated following arsenic ingestions were compared with a historical group of 111 other children who had ingested arsenic and were not treated with BAL.[44] The percentage of children exhibiting symptoms on presentation were similar between groups (46%), but in the group of treated children the advantages were significant as there were fewer deaths (zero versus three), a shorter average hospital stay (1.6 versus 4.2 days), and fewer cases of persistent symptoms at 12 hours (0% versus 29.3%).

USE OF BAL FOR MERCURY EXPOSURE

Because mercury also reacts with sulfhydryl groups, animal studies were performed to assess the affinity and ability of thiols to competitively chelate inorganic mercury and prevent toxicity. As in the case of arsenic, the dithiols BAL and BAL glucoside were more effective than the monothiol 1-thiosorbitol in preventing mercury-induced death and uremia.[18] The clinical efficacy of BAL in treating inorganic mercury poisoning was substantiated in patients who ingested mercuric chloride.[24,25] Thirty-eight patients ingesting more than 1 g of mercuric chloride who were treated with BAL within 4 hours of exposure were compared with historical controls.[24] There were no deaths in the 38 patients treated with BAL as compared to 27 deaths in the 86 untreated patients. Death typically resulted from hemorrhagic gastritis and renal failure.[24] BAL is particularly useful for patients who have ingested a mercuric salt, as the associated gastrointestinal toxicity of the mercuric salt limits the potential of an orally administered antidote such as succimer.[42]

Animal models demonstrate that when BAL is administered following poisoning from elemental mercury vapor or exposure to short-chain organic mercury compounds, brain levels of mercury may increase.[9,11] As a result BAL therapy is not recommended in these circumstances.[2,5,22] Other therapies may have greater usefulness (Chap. 96).

USE OF BAL FOR LEAD EXPOSURE

BAL may be used in combination with CaNa$_2$EDTA to treat patients with severe lead poisoning. In all other cases, succimer has become the chelator of choice. When administering BAL to patients with lead encephalopathy, it is essential to administer the BAL first, followed 4 hours later by CaNa$_2$EDTA, concomitantly with the second dose of BAL. This regimen prevents the CaNa$_2$EDTA from redistributing lead into the brain.[13,14] Providing two different chelators also reduces the blood lead concentration significantly faster than either one alone, and maintains a better molar ratio of chelator to lead.[13] Once the mobilization of lead has begun, it is important to provide uninterrupted therapy to prevent redistribution of lead to the brain (see Chap. 94).[13]

ADVERSE EFFECTS AND SAFETY ISSUES

BAL has an LD$_{50}$ in mice via intraperitoneal administration of 90 to 180 mg/kg, which is significantly lower than CaNa$_2$EDTA at 4 to 6 g/kg, succimer at 2.48 g/kg, and DMPS at 1.1 to 1.4 g/kg.[2]

The toxicity of BAL is dose dependent and affected by urinary pH. Acidic urine allows dissociation of the BAL–metal chelate. Less than 1% of 700 IM injections resulted in minor reactions, such as pain at the injection site, among patients who received 2.5 mg/kg of BAL every 4 to 6 hours for 4 doses.[12] When doses of 4 mg/kg and 5 mg/kg were given, the incidence of adverse effects rose to 14% and 65%, respectively.[15] At these higher doses, the following symptoms were reported in decreasing order of frequency: nausea; vomiting; headache; burning sensation of lips, mouth, throat, and eyes; lacrimation; rhinorrhea; salivation; muscle aches; burning and tingling of extremities; tooth pain; diaphoresis; chest pain; anxiety; and agitation.[26] These effects were maximal within 10 to 30 minutes of exposure, and usually subsided within 30 to 50 minutes.[15] Elevations in systolic and diastolic blood pressure and tachycardia commonly occurred and correlated with increasing doses.[22,29] Thirty percent of children given BAL may develop a fever that can persist throughout the therapeutic period.[22] A transient reduction in the percentage of polymorphonuclear leukocytes may also occur.[22] Doses above 5 mg/kg should not be administered because of the high risk of adverse reactions. Doses above 25 mg/kg can be expected to produce a hypertensive encephalopathy with convulsions and coma.[44]

BAL is not very effective in the presence of arsenic-induced hepatotoxicity.[27] Moreover, in rats preexistent hepatotoxicity was exacerbated when BAL was used for treatment of arsenic poisoning. Therefore, unless the hepatotoxicity is considered to be arsenic induced, hepatic dysfunction is a contraindication to BAL use.[34] BAL should not be used for patients poisoned by methylmercury because animal studies demonstrate a redistribution of mercury to the brain.[5,22]

Because dissociation of the BAL–metal chelate will occur in acidic urine, the urine of patients receiving BAL should be alkalinized with hypertonic NaHCO$_3$ to a pH of 7.5 to 8.0 to prevent renal liberation of the metal.[22] BAL should be used with caution in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, as it may cause hemolysis.[21] In these cases, a risk-to-benefit analysis must be made because G6PD-deficiency syndromes are variably expressed in young cells. In addition, chelators are relatively nonspecific and may bind metals other than those desired, thus causing deficiency of an essential metal. For example, BAL given to mice increased copper elimination to three times normal.[10] BAL is formulated in peanut oil; therefore, the patient should be questioned regarding any known peanut allergy. Limited evidence suggests that iron supplements should not be given to patients who are receiving BAL because the BAL–iron complex appears to cause severe vomiting and decreases metal chelation.[13,14,17]

Unintentional intravenous (IV) infusion of BAL could theoretically produce fat embolism, lipoid pneumonia, chylothorax, and associated hypoxia.[37]

DOSING

There has never been a clinical trial to identify the best dose of dimercaprol. The dosing for dimercaprol has been expressed in both mg/m^2 and mg/kg. Dimercaprol should only be administered by deep IM injection. The dose of BAL for lead encephalopathy is 75 mg/m^2 IM every 4 hours for 5 days in children.[13,14] As noted earlier, the first dose of dimercaprol should precede the first dose of $CaNa_2EDTA$ by 4 hours. Thereafter, IV $CaNa_2EDTA$, in a dose of 1500 mg/m^2/d (up to a maximum of 2–3 g) as a continuous infusion, or divided into two to four doses, should be administered. These daily doses are equimolar. For adults the dose of BAL is 4 mg/kg every 4 hours.[8]

The dose of BAL for severe inorganic arsenic poisoning has not been established. One regimen suggests the use of 3 mg/kg IM every 4 hours for 48 hours and then twice daily for 7 to 10 days.[15] Another regimen uses 3 to 5 mg/kg IM every 4 to 6 hours on the first day and then tapers the dose and frequency, depending on the patient's symptomatology. A third regimen reduces the number of injections by day 2 and terminates therapy within 5 to 7 days.[44]

The dose of BAL for patients exposed to inorganic mercury salts is 5 mg/kg IM initially, followed by 2.5 mg/kg every 12 to 24 hours until the patient appears clinically improved, up to a total of 10 days.[8]

Table 26–1

Calculations for average deep intramuscular (IM) BAL use when using body surface area (M^2)

Child	Avg. Height (in)	Avg. Weight (lbs)	M²	75 mg/m²* Every 4 h IM	50 mg/m²** Every 4 h IM
2-year-old boy	36	30.5	0.593	44.5 mg	30 mg
2-year-old girl	35	29	0.57	43 mg	28.5 mg
4-year-old boy	42	39.75	0.73	55 mg	36.5 mg
4-year-old girl	41.75	38.75	0.72	54 mg	36 mg

*approximately 4 mg/kg
**approximately 3 mg/kg

AVAILABILITY

Commercially available BAL is a yellow, viscous liquid with a sulfur odor. It is available in 3-mL ampules containing 100 mg/mL of BAL, 200 mg/mL of benzyl benzoate, and 700 mg/mL of peanut oil.[8] BAL is for deep IM use only.

SUMMARY

BAL (dimercaprol) is a metal chelator used clinically in conjunction with $CaNa_2EDTA$ for lead encephalopathy and severe lead toxicity.[22,29] In this instance BAL should precede the first dose of $CaNa_2EDTA$ by 4 hours. The roles of BAL in arsenic and mercury poisoning are being supplanted by succimer and the investigational agent DMPS, unless the gastrointestinal tract is compromised and IM BAL is indicated.

CHAPTER 89
BISMUTH

Rama B. Rao

Bismuth (Bi)		
Atomic number	=	83
Atomic weight	=	208.98 daltons
Normal concentrations		
Blood	<	5 µg/dL (239.5 nmol/L)
Plasma	<	1 µg/dL (<47.9 nmol/L)
Urine	<	20 µg/L (<95.7 nmol/L)

Bismuth is a metal that is available either in its elemental form or compounded as a salt. Elemental bismuth is nontoxic. Bismuth salts have therapeutic uses and are responsible for the toxicities described in this chapter. Thus, the term "bismuth" in this chapter refers to bismuth salts. Bismuth is one of many xenobiotics commonly used in prescription and nonprescription oral preparations for treatment of traveler's diarrhea, nausea, and vomiting, as well as in bismuth-impregnated surgical packing paste for treatment of the flatus and odor associated with ileostomies and colostomies,[9,57] and as an adjunct in the treatment of ulcers.[14]

In the gastrointestinal (GI) tract, bismuth binds to sulfhydryl groups and decreases fecal odor through formation of bismuth sulfide.[50] Sulfhydryl binding is also the proposed mechanism of bismuth's antimicrobial effect, causing lysis of *Helicobacter pylori*, the causative bacteria in peptic ulcer formation. Bismuth may also inhibit bacterial enzyme function, as well as prevent adhesion of *H. pylori* to the gastric mucosa.[56]

HISTORY AND EPIDEMIOLOGY

Nearly 300 years ago, bismuth was recognized as medicinally valuable. It was included in topical salves and oral preparations for various GI disorders. Renal toxicity was described as early as 1802. In the early 20th century, renal failure was reported in children administered intramuscular bismuth salts for the treatment of gingivostomatitis.[7,25,47,48] Administration of bismuth thioglycollate and its related water-soluble compounds, triglycollamate and trithioglycollamate, was responsible for the renal failure.[8,12,29,55] Children with renal toxicity would typically present with abdominal pain, oliguria, anuria, malaise, depressed mental status, and vomiting. Renal failure occurred with as little as one or two treatments.[34,38,39] Alterations in consciousness usually abated with treatment or resolution of the uremia. As the use of intramuscular injections was abandoned, this form of bismuth-induced renal failure became uncommon. Syphilis was previously treated with intramuscular bismuth. A rash known as "erythema of the 9th day," consisting of a diffuse macular rash of the trunk and extremities, occasionally occurred and resolved without intervention.[16]

In patients administered "Analbis" antipyretic rectal suppositories, hepatic failure was described histopathologically as yellow atrophy with vacuolization.[3,22] An investigation of the suppositories suggested that diallylacetic acid, and not bismuth, was the hepatotoxin. This agent is no longer marketed in the United States. Enemas have been used.[54]

More recently, epidemics of bismuth-induced encephalopathy, particularly among patients with ileostomies or colostomies, were reported in France, Britain, and Australia. As a result, some countries banned or restricted bismuth preparations to prescription only. Bismuth subsalicylate, which is currently available in the United States as a nonprescription agent, is still periodically responsible for cases of encephalopathy.[15,17,30] Other reported causes of bismuth-induced encephalopathy include systemic absorption from bismuth-impregnated surgical packing paste and transdermal absorption from chronic application of a bismuth-containing skin cream.[24]

In 2006, the Food and Drug Administration (FDA) of the United States issued a warning on an alternative health product known as "bismacine" or "chromacine." This nonpharmaceutical product is not FDA approved, but has been used by some practitioners as an injectable treatment for Lyme disease, for which efficacy data are lacking. The product contains bismuth citrate and was associated with at least one death and other adverse events in patients administered this product.[2]

CHEMISTRY

Bismuth salts are divided into four groups based on their water or lipid solubility. The highly lipid-soluble compounds such as bismuth subsalicylate or bismuth subgallate are most commonly associated with neurotoxicity (Table 89–1). See Pathophsyiology section below.

TOXICOKINETICS

Bismuth is present in nature in both the trivalent and pentavalent forms. The trivalent form of bismuth is used for all medicinal uses, usually as the bismuthyl (BiO) moiety generated by hydrolysis of trivalent bismuth compounds to yield a low solubility alkaline salt. Most orally administered bismuth remains in the GI tract, being excreted in the feces, and only 0.2% is systemically absorbed.[19] Absorption of some bismuth preparations such as colloidal bismuth subcitrate may increase as gastric pH increases.[36] The time to peak absorption ranges between 15 and 60 minutes with high intra- and interindividual variation.[23,25] The serum-to-blood ratio of bismuth is 1.55.[4] The distribution and elimination of orally administered bismuth follows a complex, multicompartmental model. The volume of distribution in humans is unknown.[5,44]

Once in the circulation, bismuth binds to α_2-macroglobulin, IgM, β-lipoprotein, and haptoglobin. Bismuth rapidly enters liver, kidney, lungs, and bone.[51] Bismuth can cross the placenta and enter the amniotic fluid and fetal circulation.[53] It also readily crosses the blood–brain barrier.[35] Evidence in a rat model suggests that, when administered intramuscularly, bismuth can access the central nervous system (CNS) via retrograde axonal transport.[49] In both animal models and human reports bismuth is identified in the fenestrated membranes of synaptosomes,[38,41] localizing in the thalamus and cerebellum with diffuse cortical uptake as well.[25,35] Ninety percent of absorbed bismuth is eliminated through the kidneys, where it induces the production of its own metal-binding protein.[51]

Some authors propose three different half-lives to describe the pharmacokinetics of orally administered therapeutic doses of bismuth.[5,44] The first, a distribution half-life, is approximately 1 to 4 hours. The second, the apparent plasma half-life, lasts 5 to 11 days. The third is the apparent half-life of urinary excretion lasting between 21 and 72 days[4] with urinary bismuth detected as late as 5 months after the last oral dose.[23]

PATHOPHYSIOLOGY

Like other metals, bismuth toxicity involves multiple organ systems. The effect of different bismuth salts can be categorized into four groups based on solubility and GI absorption (see Table 89–1).[43]

TABLE 89–1. The Physiochemical Characteristics of Bismuth Salts

Group	Chemistry	Toxicity	Examples
I	Insoluble in water Inorganic	Minimal	Bismuth subnitrate Bismuth subcarbonate
II	Lipid soluble Organic	Neurologic	Bismuth subsalicylate Bismuth subgallate
III	Water soluble Organic	Renal	Bismuth triglycollamate
IV	Hydrolyzable Water soluble Organic	Minimal	Bismuth bicitropeptide

The mechanism of bismuth-induced encephalopathy is thought to be related to neuronal sulfhydryl binding. In patients who die of bismuth encephalopathy, the gray-matter concentration of bismuth is nearly twice that of white matter.[25] In a bismuth encephalopathic patient dying from concomitant sepsis, the autopsy revealed loss of cerebellar purkinje cells not expected from sepsis alone.[26] The factors predisposing some individuals to encephalopathy from group II bismuth salts, however, are not well defined. Age, gender, and duration of therapeutic use do not predict the likelihood of developing encephalopathy, but typically patients are on chronic bismuth therapy with a lipid soluble (group II) agent.

CLINICAL MANIFESTATIONS

■ ACUTE

Acutely, massive overdoses of bismuth may result in abdominal pain and oliguria or anuria. Acute renal failure can occur and is not limited to exposure to the water-soluble bismuth salts (group III).[34,39] In reported cases, overdoses of colloidal bismuth subsalicylate or tripotassium dicitratobismuthate (TDC) caused acute tubular necrosis.[1,18,20,48,52] Histopathologically, bismuth causes degeneration of the proximal tubule, similar to other heavy metals. While these substances are potentially neurotoxic, signs of encephalopathy are generally absent.[11,17] In one case, a patient with bismuth-induced renal failure was described as having diminished deep-tendon reflexes, muscle weakness, and myoclonus, without an alteration in consciousness.[18]

■ CHRONIC

The most common toxicologic finding associated with repeated therapeutic doses of oral bismuth compounds is a diffuse, progressive encephalopathy.[11,17] Affected patients exhibit neurobehavioral changes, such as apathy and irritability. With continued exposure, these patients may develop difficulty concentrating, diminished short-term memory, and occasionally, visual hallucinations.[27,28] A movement disorder characterized by muscle twitching, myoclonus, ataxia, and tremors may ensue.[11] This is often described as a myoclonic encephaloathy. Weakness and, rarely, seizures may advance to immobility.[30,32] With continued bismuth administration these patients can develop coma and die.

Rarely, patients recovering from severe encephalopathy may complain of scapular, humeral, or vertebral pain because of fractures caused by severe neuromuscular manifestations such as myoclonus.[13]

Like several other heavy metals, bismuth can cause a generalized pigmentation of skin. Deposition of bismuth sulfide into the mucosa causes a blue-black discoloration of gums.[58] This can occur in the absence of toxic effects. Formation of the same compound in the GI tract causes blackening of the stool. Liver failure is rarely reported, except in patients with multisystem organ failure from fatal neurotoxicity.

DIAGNOSIS

The clinician must have an index of suspicion based on the acute or chronic nature of the exposure. Patients with acute massive overdoses should be observed and evaluated for possible renal failure. The earliest findings suggestive of renal compromise may be hematuria and proteinuria on urinalysis. Formation of nuclear inclusion bodies can be identified on renal biopsy or on postmortem examination of the kidney.[12,40]

The diagnosis of bismuth-induced encephalopathy is based on a history of exposure coupled with diffuse neuropsychiatric and motor findings.[28] Other causes of encephalopathy should be entertained and excluded (Table 89–2). An abdominal radiograph will likely demonstrate radiopacities of bismuth in the intestines. Stool will be black and test negative for occult blood.

The presence of bismuth in the blood is confirmatory of exposure, but absolute concentrations correlate poorly with morbidity.[5] In a review of 310 patients with bismuth-induced encephalopathy, 288 patients (93%) had a blood concentration greater than 100 ng/mL, with the majority of these blood concentrations between 100 ng/mL and 1000 ng/mL.[27] Twenty-two patients suffered encephalopathy at blood concentrations below 100 ng/mL.[27] In another report, two patients with encephalopathy had blood concentrations of 900 ng/mL and 2500 ng/mL, both of whom recovered when the concentration fell below 500 ng/mL.[6] Just as blood concentrations do not reflect severity of illness, tissue concentrations may also poorly correlate with severity of illness. An example was noted in a patient who recovered from a severe encephalopathy. On discharge, he had low blood bismuth concentrations and died 3 months later of unrelated trauma. At autopsy he was found to have an elevated CNS bismuth burden but no reported symptoms at the time of the trauma.[10]

The electroencephalographic (EEG) findings of patients with bismuth encephalopathy generally demonstrate nonspecific slow wave changes.[15,18] In one study, the EEG findings were described in association with blood concentrations. At less than 50 ng/mL, the EEG was normal or demonstrated diffuse slowing. In patients with blood concentrations of less than 1500 ng/mL, the findings of sharp wave abnormalities were noted. At higher concentrations (greater than 2000 ng/mL), some patients with neurological events, such as myoclonic jerks, did not have corresponding EEG changes. The authors

proposed that an elevated body burden might have an inhibitory effect on the cerebral cortex.[10]

In encephalopathic patients with blood concentrations greater than 2000 ng/mL diagnostic imaging such as computed tomography may demonstrate a diffuse cortical hyperdensity of the gray matter. These findings tend to resolve with recovery. Magnetic resonance imaging was normal in another encephalopathic patient.[15]

TREATMENT

Typically, supportive care results in a complete recovery. Some authors suggest GI decontamination with activated charcoal and polyethylene glycol solution.[45] Although evidence for this approach is lacking, it appears to be a reasonable initial intervention, especially in patients with severe encephalopathy. In patients with renal toxicity, resolution is generally observed with supportive care and whole-bowel irrigation. The use of chelators in patients with acute overdose without neurotoxicity is probably not indicated.

It is uncertain whether different chelators affect the clinical course of encephalopathic patients. Withdrawal of the source of bismuth results in complete reversal of symptoms within days to weeks, even in severely ill patients. The precise timing, dosage, indications, and choice of chelator is not known; however, chelation with succimer has few side effects and may potentially limit the potentially fatal complications associated with prolonged immobilization. British anti-Lewisite (BAL), which has more side effects, can be considered in encephalopathic patients with renal failure in whom no neurological improvement is noted within 48 hours of whole-bowel irrigation and bismuth withdrawal (see Chelation section below).

Prevention is the most effective means of avoiding neurotoxicity. Blood concentrations of bismuth are not routinely performed, but a bismuth concentration above 100 ng/mL or symptoms at lower levels warrant withdrawal of bismuth therapy.

CHELATION

In general the data regarding chelation are limited and in vitro and animal models do not clearly predict in vivo human models. Chelation therapy with BAL is beneficial in experimental models,[45,48] reportedly beneficial in humans,[31] and often recommended, although clear evidence of efficacy is lacking. BAL undergoes biliary elimination, offering a major advantage over other chelators in patients who may develop renal insufficiency. One study advocated the addition of dimercaptopropane sulfonate (DMPS), as BAL with hemodialysis did not affect clearance, whereas the addition of DMPS to patients needing hemodialysis was effective in enhancing elimination.[48] It is uncertain whether the clinical course of the patients was improved. In human volunteers given colloidal bismuth subcitrate, succimer and DMPS, both at a dose of 30 mg/kg, increased urinary elimination of bismuth by 50-fold.[46]

In an animal model, D-penicillamine was most efficacious in enhancing elimination of bismuth. In a human volunteer model using therapeutic doses of tripotassium-dicitrato-bismuthate, however, a single dose of D-penicillamine did not enhance urinary excretion.[33]

BISMUTH DRUG INTERACTIONS AND REACTIONS

The coadministration of proton pump inhibitors (PPIs) may increase the absorption of some bismuth preparations. In a prospective evaluation of patients receiving different treatment regimens for

H. pylori–induced dyspepsia or peptic ulcer disease, individuals taking PPIs had a statistically significant elevation in their blood bismuth concentrations with three patients exceeding 50 µg/L, compared with a similar group administered bismuth without PPIs. The authors suggest that the bismuth preparation used, colloidal bismuth subcitrate, is more soluble and absorbable at the higher gastric pH of patients on PPIs.[19] All of these patients received short courses of therapy (2 weeks). While the investigators did not attempt to follow neurobehavioral or neuropsychiatric changes, none of the patients had clinically evident bismuth toxicity.[36]

Based on this investigation, coadministration of PPIs with longer courses of colloidal bismuth subcitrate should be avoided or only offered with extreme caution. Ranitidine, which is frequently prescribed with a bismuth compound for dyspepsia or ulcer disease, does not affect the pharmacokinetics of bismuth absorption.[23]

In the United States, where bismuth subsalicylate is the most common oral bismuth-containing compound, up to 90% of the salicylate is absorbed.[37,42] Salicylate toxicity has been reported and salicylate concentrations should be determined in both acute and chronic exposures.[42,47] Methemoglobinemia from subnitrate salt of bismuth is uncommonly described.[21]

SUMMARY

The most likely manifestations of bismuth toxicity are either neuropsychiatric or renal, depending on the type of compound and whether the etiology is related to chronic therapy or acute overdose, respectively. The factors predisposing some individuals to neurotoxicity from therapeutic use of oral bismuth compounds are poorly understood. Thus, patients using therapeutic bismuth with new movement disorders or alterations in mental status should be assessed for possible bismuth-induced encephalopathy.
