1. **Soy** (*Glycine max*)—Soy contains two popularly advertised ingredients: protein and isoflavones. Diets high in soy protein are associated with decreased cholesterol and low-density lipoprotein concentrations. Soy isoflavone supplements (genisten, daidzen) are phytoestrogens (plant estrogens) that currently are suggested as alternative remedies for treatment of menopausal symptoms. There is current concern regarding how high concentrations of isoflavones will affect the risk of developing breast cancer in postmenopausal women.

2. **Cranberry** (*Vaccinium macrocarpon*)—Cranberry is a popular remedy for treatment of urinary tract infections and they may be effective in preventing recurrent urinary tract infections.[104] Cranberry appears to be safe in appropriate doses.[10]

TABLE 43–1. Laboratory Analysis and Treatment Guidelines for Specific Herbal Preparations

Herbal Preparation	Suggested Laboratory Analysis	Antidote
Cardiac xenobiotics		
Ch'an Su (Bufo Bufo)	Serum digoxin, potassium	Digoxin-specific Fab
Foxglove	Serum digoxin, potassium	Digoxin-specific Fab
Oleander	Serum digoxin, potassium	Digoxin-specific Fab
Squill	Serum digoxin, potassium	Digoxin-specific Fab
Central Nervous System Xenobiotics		
Henbane	None	Physostigmine
Jimson weed (Datura)	None	Physostigmine
Mandrake	None	Physostigmine
Gastrointestinal Xenobiotics		
Aloe	Serum electrolytes	Potassium repletion
Buckthorn	Serum electrolytes	Potassium repletion
Cascara	Serum electrolytes	Potassium repletion
Fo-Ti	Serum electrolytes	Potassium repletion
Senna	Serum electrolytes	Potassium repletion
Metals	Ag, As, Au, Cd, Cr, Cu, Hg, Pb, Th, or Zn	Metal chelators
	Abdominal radiograph (as appropriate)	
Hematologic Xenobiotics		
Dong Quai	PT	Vitamin K_1
Tonka bean	PT	Vitamin K_1
Woodruff	PT	Vitamin K_1
Hepatic xenobiotics		
Pennyroyal oil	AST/ALT	*N*-Acetylcysteine
Pyrrolizidine Alkaloids	AST/ALT	None available
Salicylates		
Medicated oils	Serum salicylate	Sodium bicarbonate, multiple-dose activated charcoal, hemodialysis
Cellular Xenobiotics		
Apricot pits (cyanogenic amygdalin)	Lactate	Cyanide antidote
Autumn crocus (colchicine)	WBC, BUN	? Glutamic acid
Elder (cyanide)	Lactate	Cyanide antidote
Periwinkle (vincristine)	WBC, BUN	? Glutamic acid
Podophyllum (podophyllin)	WBC, BUN	? Glutamic acid
Miscellaneous		
Licorice	Serum potassium	Potassium repletion
Quinine	ECG, serum potassium	Sodium bicarbonate, magnesium

3. **Garlic** (*Allium sativum*)—Garlic has been used as a food and a medicine since ancient times. As a herb, it is used for treatment of infections, hypertension, colic, and cancer.[80] The intact cells of garlic contain the odorless, sulfur-containing amino acid derivative (+)-*S*-allyl-L-cysteine sulfoxide, also known as *alliin*. When crushed, alliin is converted to allicin (diallyl thiosulfinate), which has antibacterial and antioxidant activity and gives the herb its characteristic odor and flavor. Side effects of garlic extracts include contact dermatitis, gastroenteritis, nausea, and vomiting. Several constituents of garlic, such as ajoene, possess antiplatelet effects.

Consequently, garlic may increase the risk of bleeding in individuals who are also taking antiplatelet agents or anticoagulants.[80]

4. **Ginkgo** (*Ginkgo biloba*)—This herb contains ginkgo flavone glycosides, known as *ginkgolides*, that are reputed to have antioxidant properties, inhibit platelet aggregation, and increase circulation. It is a popularly used to treat or prevent both Alzheimer disease and peripheral vascular disease. However, two studies in 2002 and 2008 failed to demonstrate any improvement in cognitive function in healthy elderly subjects without cognitive impairment.[67,180] In appropriate doses ginkgo appears to be safe, although it may

TABLE 43–2. Selected Herbal Preparations, Popular Use, and Potential Toxicities

Herbal Preparation	Scientific Name	Other Common Names	Traditional and Popular Usage	Active/Toxic Ingredient(s)	Adverse Effects
Aconite	*Acontium napellus* *Acontium kusnezoffi* *Acontium carmichaelii*	Monkshood, wolfsbane caowu, chuanwu, bushi	Topical analgesic Neuralgia, asthma, heart disease	Aconite alkaloids (C19 diterpenoid esters) aconitine	GI upset, dysrhythmias
Agrimony	*Agrimonia eupatoria*	Cocklebur, stickwort, liverwort	Catarrh, gallbladder disease, astringent		Photodermatitis
Alfalfa	*Medicago sativa*		Arthritis, diabetes	l-canavanine	High doses: lupus, pancytopenia
Aloe	*Aloe vera* and other spp	Cape, Zanzibar, Socotrine, Curacao, Carrisyn	Heals wounds, emollient, laxative, abortifacient	Anthraquinones, barbaloin, isobarbaloin	GI upset, dermatitis, hepatitis
Apricot pits	*Prunus armeniaca*	–	(Laetrile) cancer remedy	Amygdalin	Cyanide poisoning
Aristolochia	*Aristolochia clematis* *Aristolochia reticulata* *Aristolochia fangchi*	Birthwort, heartwort, fangchi	Uterine stimulant, cancer treatment, antibacterial	Aristolochic acid	Nephrotoxin Renal cancer Retroperitoneal fibrosis
Artemisia	*Artemisia vulgaris* *Artemisia dracunculus* *Artemisia lactiflora*	Mugwort, felon herb, moxa, guizhou	Depression, dyspepsia, menstrual disorder, abortifacient	Lactones (sesquiterpenes)	GI upset, allergic reaction (skin, pulmonary)
Astragalus	*Astragalus membranaceus*	Huang qi, milk vetch root	Immune booster, AIDS, cancer, antioxidant, increase endurance	Astrogalasides, trigonoside, and flavonoid constituent	May alter effectiveness immunosuppressives (eg steroids, cyclosporine)
Atractylis	*Atractylis gummifera*	Piney thistle	Chewing gum, antipyretic, diuretic, gastrointestinal remedy	Potassium atractylate and gummiferin: mitochondrial toxin	Hepatitis, altered mental status, seizures, vomiting, hypoglycemia
Atractylodes	*Atractylodes macrocephala*	Baizhu, cangzhu	Appetite stimulant, diuretic, GI upset	Atractylon, atractylol, atractylenolides	None
Autumn crocus	*Colchicum autumnale*	Crocus, fall crocus, meadow saffron, mysteria, vellorita	Gout, rheumatism, prostate/hepatic disease, cancer, gonorrhea	Colchicine	GI upset, renal disease, agranulocytosis
Bee pollen, royal jelly	Derived from *Apis mellifera*	–	Increase stamina, athletic ability, longevity	Pollen mixture containing hyperallergenic plant pollen or fungi contamination	Allergic reactions, anaphylaxis
Bee venom	Derived from *Apis mellifera*	–	Immunomodulator	Phospholipase A2 and mellitin, hyaluronidases	Allergic reactions, anaphylaxis
Betel nut	*Areca catechu*	Areca nut, pinlang, pinang	Stimulant	Arecoline	Possible bronchospasm, chronic use associated with leukoplakia and oropharyngeal squamous cell carcinoma
Bilberry	*Vaccinium myrtillus*	Whortleberry, black whortles	Diarrhea, night vision, varicose veins	Anthocyanosides	None reported
Bitter orange	*Citrus aurantia*	Changcao, Fructus auranti, green orange, kijitsu, Seville orange, sour orange, Zhi shi	Dyspepsia, increase appetite Weight loss	Synephrines	Cardiovascular toxicity, ephedrine-like effects
Bitter melon	*Momordica charantia*	Balsam pear	Abortifacient, diabetes, GI disorder, cancer, HIV therapy	Polysaccharide MAP-30 (protein)	None reported
Black cohosh	*Cimicifuga racemosa*	Black snakeroot, squawroot, bugbane, baneberry	Abortifacient, menstrual irregularity, astringent, dyspepsia	Triterpene glycosides	Dizziness, nausea, vomiting, headache

TABLE 43–2. Selected Herbal Preparations, Popular Use, and Potential Toxicities (*Continued*)

Herbal Preparation	Scientific Name	Other Common Names	Traditional and Popular Usage	Active/Toxic Ingredient(s)	Adverse Effects
Black currant oil	*Ribes nigrum*	Quinsy berry, squinancy berry	Immunostimulant, premenstrual syndrome	GLA (γ-linolenic acid) ALA (α-linolenic acid)	None reported
Blue cohosh	*Caulophyllum thalictroides*	Squaw root, papoose root, blue ginseng	Abortifacient, dysmenorrhea, antispasmodic	*N*-methylcytisine (2.5% the potency of nicotine)	Nicotinic toxicity
Boneset	*Eupatorium perfoliatum*	Thoroughwort, vegetable antimony, feverwort	Antipyretic	Pyrrolizidine alkaloids	Possible hepatotoxicity, dermatitis, milk sickness
Borage	*Borago officinalis*	Bee plant, bee bread	Diuretic, antidepressant, antiinflammatory	Pyrrolizidine alkaloids, amabiline	Hepatotoxicity
Boron		Boron	Topical astringent, wound remedy	Boron	Dermatitis, GI upset, renal and hepatic toxicity, seizures, coma, death
Broom	*Cytisus scoparius*	Scotch broom, Bannal, broom top	Cathartic, diuretic, induce labor, drug of abuse	l-sparteine	Nicotinic toxicity
Buchu	*Agathosma betulina*	Bookoo, buku, diosma, bucku, bucco	Diuretic, stimulant, carminative, urine infections, insect repellent	Diosmin, hesperidin; pulegone	None reported
Buckthorn	*Rhamnus frangula*		Laxative	Anthraquinones	Diarrhea, weakness
Burdock root	*Arctium lappa* *Arctium minus*	Great burdock, gobo, lappa, beggar's button, hareburr, niu bang zi	Diuretic, cholerectic, induce sweating, skin disorders, burn remedy, diabetes treatment	Atropine (contamination with belladonna alkaloids during harvesting)	Anticholinergic toxicity
Calendula	*Calendula officinalis*	Marigold, garden marigold, pot marigold, gold bloom, holligold	Wounds, dysmenorrhea, "radiation" dermatitis		None reported
Cantharidin	*Cantharis vesicatoria* beetle	Spanish fly, blister beetles	Aphrodisiac, abortifacient, blood purifier	Terpenoid: cantharidin	GI upset, urinary tract and skin irritant, renal toxicity
Caraway	*Umbelliferae carvi*		Antispasmodic, carminative	d-carvone	
Carp bile (raw)	*Ctenopharyngodon idellus*	Grass carp	Improve visual acuity and health	? Cyprinol, C27 bile alcohol	Hepatitis, renal failure
	Cyprinus carpio	Common carp			
Cascara	*Rhamnus purshiana*	Cascara sagrada	Laxative	Anthraquinones	Diarrhea, weakness
Cat's claw	*Uncaria tomentosa* *Uncaria guianensis*	Uña de gato	AIDS, cancer, arthritis, ulcers, dysmenorrhea, wounds, contraceptives	Pentacyclic oxindole alkaloids, tetracyclic oxindole alkaloids	None reported
Catnip	*Nepeta cataria*	Cataria, catnep, catmint	Indigestion, colic, sedative, euphoriant, headaches, emmenagogue	Nepetalactone	Sedative
Ch'an Su	*Bufo bufo gargarizans* *Bufo bufo melanosticus*	Stone, lovestone, black stone, rock hard, chuan wu, kyushin	Topical anesthetic, aphrodisiac, cardiac disease	Bufodienolides, bufotenin	Dysrhythmias, hallucinations
Chamomile	*Matricaria recutita*, *Chamaemelum nobile*	Manzanilla	Digestive disorders, skin disorders, cramps	Allergens	Contact dermatitis, allergic reaction, anaphylaxis very rare
Chaparral	*Larrea tridentata*	Creosote bush, greasewood, hediondilla	Bronchitis, analgesic, anti-aging, cancer	Nondihydroguaiaretic acid (NDGA)	Hepatotoxicity (chronic)
Chestnut	*Chestnut*	Horse chestnut, California buckeye, Ohio buckeye, buckeye	Arthritis, rheumatism, varicose veins, hemorrhoids	Esculin, nicotine, quercetin, quercitrin, rutin, saponin, shikimic acid	Fasciculations, weakness, incoordination, GI upset, paralysis, stupor
Chuen-Lin	*Coptis chinensis*, *Coptis japonicum*	Golden thread, Huang-Lien, Ma-Huang	Infant tonic	Berberine: displaces bilirubin from protein	Neonatal hyperbilirubinemia

(*Continued*)

TABLE 43–2. Selected Herbal Preparations, Popular Use, and Potential Toxicities (*Continued*)

Herbal Preparation	Scientific Name	Other Common Names	Traditional and Popular Usage	Active/Toxic Ingredient(s)	Adverse Effects
Clove	*Syzygium aromaticum*	Caryophyllum	Expectorant, antiemetic, counterirritant, antiseptic, carminative euphoriant	Eugenol (4-allyl-2-methoxyphenol)	Pulmonary toxicity (cigarettes)
Coltsfoot	*Tussilago farfara*	Coughwort, horsehoof, kuandong hua	Throat irritation, asthma, bronchitis, cough	Pyrrolizidine alkaloids: tussilagin, senkirkine	Allergy, hepatotoxicity
Comfrey	*Symphytum officinale, Symphytum spp, S. x uplandicum*	Knitbone, bruisewort, blackwort, slippery root, Russian comfrey	Ulcers, hemorrhoids, bronchitis, burns, sprains, swelling, bruises	Pyrrolizidine alkaloids: symphytine, echimidine, lasiocarpine	Hepatic veno-occlusive disease
Compound Q	*Trichosanthes kirilowii*	Gualougen, GLQ-223, Chinese cucumber root	Fevers, swelling, expectorant, abortifacient, diabetes, AIDS	Trichosanthin	Pulmonary injury (ALI), cerebral edema, cerebral hemorrhage, seizures, fevers
Cordyceps {mushroom]	*Cordyceps sinensis*	Dong chong xia cao	General tonic, aphrodisiac, bronchitis, kidney disorders	Cordyceptic acid, Cordycepin	None reported
Damiana	*Turnera diffusa var aphrodisiaca*	–	Stimulant, purgative, aphrodisiac, antidepressant	Caryophyllene oxide, caryophyllene, δ-cadinene, elemene, 1,8-cineol	Genitourinary irritation
Dandelion	*Taraxacum officinale*		Diuretic, detoxifying remedy, bitter	Luteolin	None reported
Deer antler velvet			Erectile dysfunction, infertility immunostimulant, antiinflammatory, athletic performance	Small amounts of androstenedione, dihydroepiandrosterone, and testosterone	None reported
Dong Quai	*Angelica polymorpha*	Tang kuei, dang gui	Blood purifier, dysmenorrhea, improve circulation	Coumarin, psoralens, safrole in essential oil	Anticoagulant effects, photodermatitis, possible carcinogen in oil
Echinacea	*Echinacea angustifolia, Echinacea purpurea*	American cone flower, purple cone flower, snakeroot	Infections, immunostimulant	Echinacoside	CYP 1A2 inhibitor
Elder	*Sambucus spp*	Elderberry, sweet elder, sambucus	Diuretic, laxative, astringent, cancer	Isoquercitrin Cyanogenic glycoside: sambunigrin in leaves	GI upset, weakness if uncooked leaves ingested
Ephedra	*Ephedra spp*	Ma-huang, Mormon tea, yellow horse, desert tea, squaw tea, sea grape	Stimulant, bronchospasm	Ephedrine, pseudoephedrine	Headache, insomnia, dizziness, palpitations, seizures, stroke, myocardial infarction, death
Evening primrose	*Oenothera biennis*	Oil of evening primrose	Coronary disease, multiple sclerosis, cancer, diabetes rheumatoid arthritis, premenstrual syndrome	Cis-γ-linoleic acid	Lower seizure threshold
Fennel	*Foeniculum vulgare*	Common, sweet, or bitter fennel	Gastroenteritis, expectorant, emmenagogue, stimulate lactation	Volatile oils: transanethole, fenchone; estrogens: dianethole, photoanethole	Ingestion of volatile oils: vomiting, seizures, pulmonary injury (ALI), dermatitis, estrogen effects
Fenugreek	*Trigonella foenumgraecum*	Bird's foot, Greek hay seed	Expectorant, demulcent, antiinflammatory, emmenanogue, galactogogue, diabetes	4-hydroxyisoleucine	Hypoglycemia, Hypokalemia

TABLE 43–2. Selected Herbal Preparations, Popular Use, and Potential Toxicities (*Continued*)

Herbal Preparation	Scientific Name	Other Common Names	Traditional and Popular Usage	Active/Toxic Ingredient(s)	Adverse Effects
Feverfew	*Tanacetum parthenium*	Featherfew, altamisa, bachelor's button, featherfoil, febrifuge plant, midsummer daisy, nosebleed, wild quinine	Migraine headache, menstrual pain, asthma, dermatitis, arthritis, antipyretic, abortifacient		Oral ulcerations, "postfeverfew syndrome," rebound of migraine symptoms, anxiety, insomnia following cessation of chronic use
Fo-Ti	*Polygonum multiflorum*	Climbing knotwood, he shou-wu	Scrofula, cancer, constipation therapy, promote longevity	Anthraquinones: chrysophanol, emodin, rhein	Cathartic effects
Foxglove	*Digitalis purpurea, Digitalis lanata, Digitalis lutea, Digitalis* spp	Purple foxglove, throatwort, fairy finger, fairy cap, lady's thimble, scotch mercury, witch's bells, dead man's bells	Asthma, sedative, diuretic/cardiotonic, wounds and burns (India)	Cardioactive steroids (eg, digitoxin, gitoxin, digoxin, digitalin, gitaloxin)	Blurred vision, GI upset, dizziness, muscle weakness, tremors, dysrhythmias
Garcinia	*Garcinia cambogia*	Brindleberry, hydroxycitric acid	Weight loss	Hydroxycitric acid	May lower serum glucose concentration in diabetics
Garlic	*Allium sativum*	Allium, stinking rose, rustic treacle, nectar of the gods, da suan	Infections, coronary artery disease, hypertension	Alliin, Ajoene	Contact dermatitis, gastroenteritis, antiplatelet effects
Gentian	*Gentiana lutea, Gentiana* spp	Bitter root, gall weed Longdancao	Bitter, digestive stimulant, emmenagogue	–	None reported
Germander	*Teucrium chamaedrys*	Wall germander	Antipyretic, abdominal disorders, wounds, diuretic, choleretic	Furano neoclerodane diterpenes	Hepatotoxicity, hepatitis, cirrhosis
Ginger	*Zingiber officinale*		Carminative, diuretic, antiemetic, stimulant, motion sickness	Volatile oil, phenol	Possible increased risk of bleeding when taken with anticoagulants
Ginkgo	*Ginkgo biloba*	Maidenhair tree, kew tree, tebonin, tanakan, rokan, kaveri	Asthma, chilblain, digestive aid, cerebral dysfunction	Ginkgo flavone glycosides and terpene lactones (ginkgolides and bilobalide)	Extracts: GI upset, headache, skin reaction; whole plants: allergic reactions
Ginseng	*Panax ginseng Panax quinquefolius Panax pseudoginseng*	Ren shen	Respiratory illnesses, gastrointestinal disorders, impotence, fatigue, stress, adaptogenic, external demulcent	Ginsenosides: panaxin, ginsenin	Ginseng abuse syndrome
Glucomannan	*Amorphophallus konjac*	Konjac, konjac mannan	Weight-reducing agent: "grapefruit diet," increase viscosity, decrease gastric emptying	Polysaccharides	Esophageal and lower GI obstruction
Glucosamine	2-amino-2-deoxyglucose	Chitosamine	Wound-healing polymer, antiarthritic	Glucosamine	None reported
Goat's rue	*Galega officinalis*	French lilac, French honeysuckle	Antidiabetic	Galegine, paragalegine	Hypoglycemia
Goji	*Lycium barbarum, chinense*	Wolfberry, gou qi zi	Protect liver, improve eyesight, enhance immune system	Carotenoids, lutein, atropine	May inhibit warfarin metabolism
Goldenseal	*Hydrastis canadensis*	Orange root, yellow root, turmeric root	Astringent, GI disorders, dysmenorrhea	Berberine, hydrastine	GI upset, Very high doses: paralysis and respiratory failure

(*Continued*)

TABLE 43–2. Selected Herbal Preparations, Popular Use, and Potential Toxicities (*Continued*)

Herbal Preparation	Scientific Name	Other Common Names	Traditional and Popular Usage	Active/Toxic Ingredient(s)	Adverse Effects
Gordolobo yerba	Senecio longiloba Senecio aureu, Senecio vulgaris Senecio spartoides	Groundsel, liferoot	Gargle, cough, emmenagogue	Pyrrolizidine alkaloids	Hepatic veno-occlusive disease
Gotu Kola	Centella asiatica	Hydrocotyle, Indian pennywort, talepetrako	Wound healing, tonic, antibacterial	Asiaticoside, asiatic acid, madecassic acid	Contact dermatitis
Grape seed	Vitis vinifera		Antioxidant: antiaging, peripheral vascular disease	Proanthocyanidins	None reported
Green tea	Camillia sinensis	Green tea	Antioxidant, weight loss, reduce cholesterol	Polyphenols (catechins and epigallocatechin gallate)	Hepatotoxicity from green tea extracts
Hawthorn	Crataegus oxyacantha Crataegus laevigata Crataegus monogyna	English hawthorn, haw, maybush, whitethorn	Hypertension, CHF, dysrhythmias, antispasmodic, sedative	Hyperoside, vitexin, procyanidin	Hypotension, sedation
Heliotrope	Crotalaria specatabilis, Heliotropium europaeum	Rattlebox, groundsel, viper's bugloss, bush tea	Cancer	Pyrrolizidine alkaloids	Hepatic veno-occlusive disease
Henbane	Hyoscyamus niger	Fetid nightshade, poison tobacco, insane root, stinky nightshade	Sedative, analgesic, antispasmodic, asthma	Hyoscyamine, hyoscine	Anticholinergic toxicity
Holly	Ilex aquifolium Ilex opaca Ilex vomitoria	English holly, American holly, and yaupon	Tea, emetic, CNS stimulant, coronary artery disease	Saponins	GI upset
Hoodia	Hoodia gordonii	Xhooba, khoba, Ghaap, hoodia cactus, South African desert cactus	Weight loss, appetite suppressant	P57	None reported
Horny goat weed	Epimedium grandiflorum	Ying yang huo	Aphrodisiac	Icariin	None reported
Hydrangea	Hydrangea arborescens Hydrangea paniculata	Seven bark, wild hydrangea	Diuretic, stimulant, carminative, cystitis, renal calculi, asthma	Hydrangin, saponin	Dizziness, chest pain, GI upset
Iboga	Tabernanthe iboga	Ibogaine	Aphrodisiac, stimulant, hallucinogen, addiction treatment	Indole alkaloid: ibogaine	Hallucinations, cholinergic hyperactivity
Impila	Callipesis laureola		Zulu traditional remedy	Potassium atractylate–like compound	Vomiting, hypoglycemia, centrilobular hepatic necrosis
Jalap	Ipomoea purga	–	Cathartic	Convolvulin	Profuse watery diarrhea
Jimsonweed	Datura stramonium	Datura, stramonium, apple of Peru, Jamestown weed, thornapple, tolguacha	Asthma	Atropine, scopolamine, hyoscyamine, stramonium	Anticholinergic toxicity
Juniper	Juniperus communis Juniperus macropoda	Oil of sabinol	Tonic, diuretic, urinary antiseptic, emmenogogue, abortifacient	Monoterpenes (terpinen-4-ol)	Renal irritation

TABLE 43–2. Selected Herbal Preparations, Popular Use, and Potential Toxicities (*Continued*)

Herbal Preparation	Scientific Name	Other Common Names	Traditional and Popular Usage	Active/Toxic Ingredient(s)	Adverse Effects
Kava kava	*Piper methysticum*	Awa, kava-kava, kew, tonga	Relaxation beverage, uterine relaxation headaches, colds, wounds, aphrodisiac	Kava lactones Flavokwain A and B	Mild euphoria, muscle weakness Skin discoloration, hepatic failure
KH-3	Procaine HCl	Gerovital-H3, GH-3, Gero-vita	Cerebral atherosclerosis, dementia, arthritis, hair loss, hypertension	Procaine	Procaine toxicity
Khat	*Catha edulis*	Qut, kat, chaat, Kus es Salahin, Tchaad, Gat	CNS stimulant, depression, fatigue, obesity, ulcers	Cathine, cathinone	Euphoria, dysphoria, stimulation, sedation, psychological dependence leukoplakia
Kola nut	*Cola acuminata*	Botu cola, cola nut	Digestive aid, tonic, aphrodisiac, headache, diuretic	Caffeine, theobromine, kolanin	CNS stimulant
Kombucha	Mixture of bacteria and yeast	Kombucha tea, kombucha mushroom, Manchurian tea	Memory loss, premenstrual syndrome, cancer	—	Hepatotoxicity/metabolic acidosis
Levant berry	*Anamirta cocculus*	Fish killer, fishberry, hockle elderberry, Indian berry, louseberry, poisonberry	Vermifuge, malaria	Picrotoxin	CNS stimulant, GI upset
Licorice	*Glycyrrhiza glabra*	Spanish licorice, Russian licorice, gancao	Gastric irritation	Glycoside glycyrrhizin	Flaccid weakness, dysrhythmias, hypokalemia, lethargy
Lipoic acid		α-lipoic acid, thioctic acid	Antioxidant, diabetes, neuropathy, AIDS	Lipoic acid	Hypoglycemia
Lobelia	*Lobelia inflata*	Indian tobacco	Antispasmodic, respiratory stimulant, relaxant	Pyridine-derived alkaloids (lobeline)	Nicotine toxicity
Mace	*Myristica fragrans*	Mace, muscade, seed cover of nutmeg	Diarrhea, mouth sores, insomnia, rheumatism	Myristicin (methoxysafrole)	Hallucinations
Mandrake	*Mandragora officinarum*		Hallucinogen	Atropine, scopolamine, hyoscyamine	Anticholinergic toxicity
Mate	*Ilex paraguayensis*	Paraguay tea	Stimulant	Caffeine	Caffeine toxicity
Milk thistle	*Carduus marianus* *Silybum marinaum*	Mary thistle	Liver disease, antidepressant, HIV	Silymarin	None
Mistletoe	*Viscum album* *Phoradendron leucarpum*	Iscador	Antispasmodic, calmative, cancer, HIV	Viscotoxins, lectins	GI upset, bradycardia, delirium
Morinda	*Morinda citrifolia*	Noni, Indian mulberry, nonu/nono, mengkudu, bajitian	Antioxidant, stress, depression	Polysaccharides, anthraquinone: damnacanthal	None
Morning glory	*Ipomoea purpurea* *I. violacea*	Heavenly blue, blue star, flying saucers	Hallucinogen	Lysergic acid lamide Ergine	LSD-like toxicity
Myrrh	*Commiphora molmol*	Mulmul, ogo, heerabol	Astringent, antiseptic, emmenagogue, antispasmodic, cancer	Sesquiterpenes	None
Nutmeg	*Myristica fragrans*	Mace, rou dou kou	Hallucinogen, abortifacient, aphrodisiac, GI disorders, emmenogogue	Myristicin	Hallucinogen, GI upset

(*Continued*)

TABLE 43–2. Selected Herbal Preparations, Popular Use, and Potential Toxicities (*Continued*)

Herbal Preparation	Scientific Name	Other Common Names	Traditional and Popular Usage	Active/Toxic Ingredient(s)	Adverse Effects
Oleander	*Nerium oleander*	Adelfa, laurier rose, rosa laurel, rose bay, rose francesca	Cardiac disorders, asthma, corns, cancer, epilepsy	Oleandrin, neriin, Gentiobiosyloeandrin, odoroside A	GI upset, diarrhea, dysrhythmias
Olive leaf extract	*Olea europaea*		Immunostimulant	Oleuropein	
Ostrich fern	*Matteuccia struthipteris*	–	Laxative	–	GI upset if eaten undercooked
Parsley	*Petroselinum crispum*	Rock parsley, garden parsley	Diuretic, uterine stimulant, abortifacient	Myristicin, apiol, furocoumarin, psoralen	Uterine stimulant, photosensitization
Passion flower	*Passiflora incarnata*	Passiflora, maypop	Insomnia, analgesic stimulant	Harmala alkaloids	Sedation
Pau d'Arco	*Tabebuia* spp	Ipe roxo, lapacho, taheebo tea	Tonic, "blood builder," cancer, AIDS	Napthoquinone derivative: lapachol	GI upset anemia, bleeding
Pennyroyal oil	*Hedeoma pulegioides* *Mentha pulegium*	American pennyroyal, Squawmint, mosquito plant	Abortifacient, regulate menstruation, digestive tonic	Cyclohexanone: pulegone	Hepatotoxicity
Periwinkle	*Catharanthus roseus*	Red periwinkle, Madagascar or Cape periwinkle, old maid, church-flower, ram-goat rose, "myrtle," magdalena	Hallucinogen, ocular inflammation, diabetes, hemorrhage, insect stings, cancers	Vincristine, vinblastine Indole alkaloid	Vincristine/vinblastine toxicity
Podophyllum	*Podophyllum peltatum* *Podophyllum hexandrum* *Podophyllum emodi*	Mandrake, mayapple, American podophyllum Indian podophyllum guijiu	Cathartic, purgative	Podophyllin	Podophyllin toxicity
Pokeweed	*Phytolacca americana* *Phytolacca decandra*	American nightshade, Cancer jalap, inkberry, poke, scoke	Arthritis, emetic, purgative	Saponins: phytolaccigenin, jaligonic acid, phytolaccagenic acid, pokeweed mitogen	Gastroenteritis, blurry vision, weakness, respiratory distress, seizures, leukocytosis
Pycnogenol (French maritime pine bark extract)	*Pinus pinaster*	Pine bark extract	Antioxidant, hypertension vascular disease, ADHD	Proanthocyanidins	None reported
Pygeum	*Prunus africana*	Pygeum africanum, African prune	Impotence, male infertility, prostate cancer, benign prostatic hypertrophy	β-sitosterol, pentacyclic terpenes, ferulic esters	None reported
Quinine	*Cinchona succirubra* *Cinchona calisya* *Cinchona ledgeriana*	Red bark, Peruvian bark Jesuit's bark, China bark Cinchona bark, quinaquina, fever tree	Malaria, fever, indigestion Cancer Hemorrhoids, varicose veins, abortifacient	Quinine	Cinchonism
Red bush tea	*Aspalathus linearis*	Rooibos tea	Anxiety, allergic dermatitis, indigestion	Aspalathin, isoorientin, orientin, rutin	None reported
Red clover	*Trifolium pratense*	Trefoil, purple clover, wild clover	Bronchitis, cough, eczema, acne, premenstrual syndrome	Isoflavones: biochanin A and formononetin	None reported
Rehmannia	*Rehmannia glutinosa*	Sheng di huang, Chinese foxglove root	Arthritis, asthma, kidney and liver tonic, aplastic anemia, hypopituitarism	Irodoids and iridoid glycosides	None reported
Reishi mushroom	*Ganoderma lucidum*	Ling zhi, lucky fungus	Hepatitis, promote longevity	Polysaccharide peptides, triterpenes (ganoderic acid)	None reported

TABLE 43–2. Selected Herbal Preparations, Popular Use, and Potential Toxicities (*Continued*)

Herbal Preparation	Scientific Name	Other Common Names	Traditional and Popular Usage	Active/Toxic Ingredient(s)	Adverse Effects
Rosavin	*Rhodiola rosea*	Golden root, crenulin	Weight loss, aphrodisiac, adaptogen, improve cognitive function	Loaustralin, rosavin, rosin, rosarin, salidroside	None reported
Rose hips	*Rosa canina*	Hip berry, rose haws, rose heps, wild boar fruit	Vitamin C supplement, Upper respiratory infection, diarrhea	Vitamin C, vitamin K	May interfere with warfarin
Rue	*Ruta graveolens*	Herb of grace, herb grass	Emmenagogue, antispasmodic, abortifacient	Fucocoumarins, bergapten, xanthoxanthin	Photosensitization
Sage	*Salvia officinalis*	Garden sage, true sage, scarlet sage, meadow sage	Antiseptic, astringent, hormonal stimulant, carminative, abortifacient	Camphor, thujone	Seizures
St. John's wort	*Hypericum perforatum*	Klamath weed, John's wort, goatweed, sho-rengyo	Anxiety, depression, gastritis, insomnia, promote healing, AIDS	Hyperforin, Hypericin	Occasional photosensitization, drug interaction: CYP3A4
Salvia	*Salvia divinorum* *Salvia miltiorrhizae*	Sierra mazateca, diviners sage, magic mint, Maria pastora	Hallucinogen, renal disease	Salvinorum A Lithospermate B	Hallucinations
SAM-e	*S*-adenosyl-L-methionine		Antidepressant, osteoarthritis, liver disease	*S*-adenoysl-L-methionine,	None reported
Sassafras	*Sassafras albidum*	Lauraceae	Stimulant, antispasmodic, purifier	sassafras oil (80% Safrole)	Hepatotoxicity, carcinogen (?)
Saw palmetto	*Serenoa repens*	Sabal, American dwarf palm tree, cabbage palm	Genitourinary disorders, increase sperm production, sexual vigor	5-α reductase inhibitor	Diarrhea
Schisandra	*Schisandra chinensis*	Wu zei zi, five flavored seed	Tonic, aphrodisiac, liver treatment, sedative	Schisandrins, nigranoic acid	None reported
Scullcap	*Scutellaria lateriflora*	Skullcap, helmetflower, hood wort	Tranquilizer, tonic, antispasmodic	Flavone glucuronides and flavanone glucuronides	None reported
Senna	*Cassia acutifoli* *Cassia angustifolia*	Alexandrian senna	Stimulant, laxative, diet tea	Anthraquinone, glycosides (sennosides)	Diarrhea, CNS effects
Shark cartilage	*Squalus acanthias* *Sphyrna lewini*	–	Cancer: inhibit tumor angiogenesis	Chondroitin sulfate	None reported
Siberian ginseng	*Eleutherococcus senticos*	Devil's shrub, eleuthra, eleutherococ	Adaptogens, hypertension, immunomodulator	Ginsenosides	None reported
Slippery elm	*Ulmus rubra* *Ulmus fulva*	Elm, elm bark, red elm	Acne, boils, indigestion, abortifacient	Polysaccharide mucilage Oleoresin	Contact dermatitis
Soapwort	*Saponaria officinalis*	Bruisewort, bouncing bet, dog cloves, fuller's herb, latherwort	Acne, psoriasis, eczema, boils, natural soaps	Saponins	IV: highly toxic PO: None
SOD	Superoxide dismutase	Orgotein, ormetein, palosein	Improve health, lengthen lifespan, chronic bladder disease, paraquat poisoning	Superoxide dismutase	None reported
Soy isoflavone	*Glycine max*		Menopausal symptoms, heart disease	Phytoestrogens: genistein, daidzein, glycitein	Cancer
Squill	*Urginea maritima* *Urginea indica*	Sea onion Red Squill	Diuretic, emetic, cardiotonic, expectorant	Cardioactive steroid, scillaren A	Emesis, dysrhythmias

TABLE 43–2. Selected Herbal Preparations, Popular Use, and Potential Toxicities (*Continued*)

Herbal Preparation	Scientific Name	Other Common Names	Traditional and Popular Usage	Active/Toxic Ingredient(s)	Adverse Effects
Stephania	*Stephania tetranda*	Han fang ji	Fever, pain, inflammation, decrease water retention	–	None (misidentification of this herb with aristolochia [Guang fang ji] resulted in cases of Chinese herb nephropathy)
Stevia	*Stevia rebaudiana*	Sweet leaf of Paraguay	Sugar-free sweetener, diabetes, hypertension, weight-loss aid	Stevioside	None reported
T'u-san-chi	*Gynura segetum*	–	Tea	Pyrrolizidine alkaloids	Hepatic veno-occlusive disease
Tonka bean	*Dipteryx odorata, Dipteryx oppositifolia*	Tonquin bean, cumaru	Food, cosmetics	Coumarin	Anticoagulant effect
Tung seed	*Aleurites moluccana A. fordii*	Tung, candlenut, candleberry, barnish tree, balucanat, otaheite	Wood preservative (oil), purgative (oil), asthma treatment (seed)	Saponins, phytotoxins	GI upset, hyporeflexia, death; latex: dermatitis
Valerian	*Valeriana officinalis*	Radix valerianae, Indian Valerian, red valerian	Anxiety, insomnia, antispasmodic	– Valepotriates, valerenic acid	Sedation
Vitex	*Vitex agnus-castus*	Chasteberry, chaste tree, agnus castus	Premenstrual syndrome, female infertility	–	None reported
White cohosh	*Actaea alba, Actaea rubra*	Baneberry, snakeberry, doll's eyes, coralberry	Emmenagogue	Protoanemonin	Headache, GI upset, delirium, circulatory failure
White willow bark	*Salix alba*	Common willow, European willow	Fever, pain astringent	Salicin	Salicylate toxicity
Wild lettuce	*Lactuca virosa Lactuca sativa*	Lettuce opium, prickley lettuce	Sedative, cough suppressant, analgesic	–	None reported
Woodruff	*Galium odoratum*	Sweet woodruff	Wound healing, tonic, varicose veins, antispasmodic	Coumarin	None reported
Wormwood	*Artemisia absinthium*	Absinthes	Sedative, analgesic, antihelminthic	Thujone	Psychosis, hallucinations, seizures
Yarrow	*Achillea millefolium*	Bloodwort, carpenter's grass, dog daisy, nosebleed	Heal wounds, viral symptoms, digestive disorder, diuretic	–	Contact dermatitis
Yew	*Texus baccata*	Yew	Antispasmodic, cancer remedy	Taxine (Sodium channel blocker)	Dizziness, dry mouth, bradycardia, cardiac arrest
Yohimbe	*Pausinystalia yohimbe*	Yohimbi, yohimbehe	Body building, aphrodisiac, stimulant	Alkaloid yohimbine from bark	Hypertension, abdominal pain, weakness

increase the risk of bleeding in individuals who are also taking antiplatelet agents or anticoagulants.[77,136,151]

5. **Saw palmetto** (*Serenoa repens*)—Saw palmetto is a popular remedy for benign prostatic hypertrophy. Saw palmetto inhibits 5-α-reductase. However, a recent study observed that saw palmetto did not improve symptoms or objective measures of benign prostatic hypertrophy.[15] Saw palmetto appears to be safe in appropriate doses.[136,151]

6. **Echinacea** (*Echinacea purpurea, angustifolia*)—Echinacea is a reputed immunostimulant and is a popular herbal remedy for cold symptoms. However, a NCCAM-funded study was unable to detect any improvement in preventing these symptoms.[192] Echinacea appears to be safe in appropriate doses.[87] Rare individuals develop allergic reactions when taking echinacea.[141]

7. **Black cohosh** (*Cimicifuga racemosa*)—Black cohosh is a popular remedy for treatment of premenstrual syndrome and as alternative estrogen replacement therapy for relief of perimenopausal symptoms. It also is used as a treatment for arthritis and as a mild sedative. Black cohosh appears to be safe in appropriate doses.[18,98]

8. **Milk thistle** (*Silybum marianum*)—Milk thistle contains silymarin and is a popular remedy for treatment of liver dysfunction. It appears to be safe.

TABLE 43–3. Constituent Psychoactive Xenobiotics in Herbal Preparations

Labeled Ingredient	Scientific Name	Usage	Active Ingredients	Effects
Broom	*Cytisus scoparius*	Smoke for relaxation	L-Sparteine	Sedative-hypnotic
California poppy	*Eschscholtzia californica*	Smoke as marijuana substitute	Alkaloids and glucosides	Euphoriant
Catnip	*Nepeta cataria*	Smoke or tea as marijuana substitute	Nepetalactone	Euphoriant
Ch'an Su	*Bufo bufo gargarizans* *Bufo bufo melanosticus*	Smoke or lick for hallucinations	Bufotenin	Hallucinogen
Cinnamon	*Cinnamomum camphora*	Smoke with marijuana	?	Stimulant
Clove	*Syzgium aromaticum*	Smoke in cigarette/"kreteks"	Eugenol	Euphoriant
Damiana	*Turnera diffusa*	Smoke as marijuana substitute	?	Stimulant/hallucinogen
Goldenseal	*Hydrastis canadensis*	Ingest to mask detection of opioid, marijuana, or cocaine in urinary drug screen	–	No evidence
Hops	*Humulus lupulus*	Smoke or tea as sedative and marijuana substitute	Humulone, lupulone → methylbutenol	Sedative (mild)
Hydrangea	*Hydrangea paniculata*	Smoke as marijuana substitute	Hydrangin, saponin	Stimulant
Ibogaine	*Tabernanthe iboga*	Stimulant, hallucinogen	Ibogaine	Hallucinogen
Juniper	*Juniperus macropoda*	Smoke as hallucinogen	?	Hallucinogen
Kava kava	*Piper methysticum*	Smoke or tea as marijuana substitute	Kava lactones	Hallucinogen
Kola nut	*Cola acuminata*	Smoke, tea, or capsules as stimulant	Caffeine, theobromine, kolanin	Stimulant
Lobelia	*Lobelia inflata*	Smoke or tea as marijuana substitute	Lobeline	Euphoriant
Mandrake	*Mandragora officinarum*	Tea as hallucinogen	Atropine, scopolamine	Hallucinogen
Mate	*Ilex paraguayensis*	Tea as stimulant	Caffeine	Stimulant
Mormon tea	*Ephedra nevadensis*	Tea as stimulant	Ephedrine	Stimulant
Morning glory	*Ipomoea violacea*	Seeds have hallucinogens	D-lysergic acid amide (ergine)	Hallucinogen
Nutmeg	*Myristica fragrans*	Tea as hallucinogen	Myristicin	Hallucinogen
Passion flower	*Passiflora incarnata*	Smoke, tea, or capsules as marijuana substitute	Harmala alkaloids	Stimulant (mild)
Periwinkle	*Catharanthus roseus*	Smoke or tea as euphoriant	Indole alkaloids	Hallucinogen
Prickly poppy	*Argemone mexicana*	Smoke as euphoriant	Protopine, bergerine, isoquinolones	Analgesic
Salvia	*Salvia divinorum*	Smoked, chewed	Salvinorum A	Hallucinogen
Snakeroot	*Rauwolfia serpentina*	Smoke or tea as tobacco substitute	Reserpine	Tranquilizer
Thorn apple	*Datura stramonium*	Smoke or tea as tobacco substitute or hallucinogen	Atropine, scopolamine	Hallucinogen
Tobacco	*Nicotiana* spp	Smoke as tobacco	Nicotine	Stimulant
Valerian	*Valeriana officinalis*	Tea or capsules	Chatinine, velerine alkaloids	Tranquilizer
Wild lettuce	*Lactuca sativa*	Smoke as opium substitute	Unknown	Analgesic (mild)
Wormwood	*Artemisia absinthium*	Smoke or tea as relaxant	Thujone	Analgesic
Yohimbe	*Pausinystalia yohimbe*	Smoke or tea as stimulant	Yohimbine	Hallucinogen (mild)

9. **Ginseng** (*Panax ginseng*)—Ginseng is the common name for deciduous, perennial plants of the genus *Panax. Panax ginseng* is native to Korea, China, Japan, and Russia. *Panax quinquefolius* is the common ginseng species in North America and grows abundantly throughout the central and eastern regions of Canada and the United States. Ginseng preparations have been used in China for treatment of respiratory illnesses, gastrointestinal disorders, impotence, fatigue, and stress ("adaptogenic effect"). It is regarded as a tonic and panacea (hence the name *Panax*, meaning "all healing"). Its only recognized use in the United States is as an external demulcent.[82,122,137] Ginseng provides a good example of the complexity of the biochemistry and pharmacologic effects of herbs. The active components of ginseng are called *ginsenosides* and include panaxin, panax acid, panaquilin, panacen, sapogenin,

and ginsenin. Its general metabolic effects include decreasing serum glucose and serum cholesterol concentrations; increasing erythropoiesis, hemoglobin production, and iron absorption from the gut; increasing blood pressure and heart rate; GI motility; and CNS stimulation. Ginseng abuse syndrome (GAS), which consists of hypertension, nervousness, sleeplessness, and morning diarrhea, has been described following long-term use of ginseng.[82,175,176] Ginseng use may reduce the anticoagulant effect of warfarin.[102,210]

10. **St. John's wort** (*Hypericum perforatum*)—St. John's wort is a popular herbal remedy for treatment of depression and is also used as a topical remedy for cuts, bruises, and wounds.[171] It has lost its popularity as an AIDS treatment because of the lack of clinical efficacy.[88] The active ingredients are hyperforin and hypericin. Its antidepressant properties likely derive from the ability of hyperforin to inhibit the reuptake of serotonin, dopamine, norepineprine, γ-aminobutyric acid, and glutamate.[30] A major study in 2002 demonstrated that St. John's wort is ineffective in treating depression.[101] Acute toxicity appears limited to photosensitization reactions. St. John's wort induces CYP3A4 and may interact with medications metabolized by this enzyme (eg, indinavir, oral contraceptives, cycloserine).[128,162] Hyperforin is a weak monoamine oxidase inhibitor, raising concerns about interactions with the selective serotonin reuptake inhibitors.[162]

11. **Green tea**—Green tea is a popular antioxidant used to prevent chronic disease as well as for weight reduction. It is also touted to protect against cancer and decrease cholesterol. A 2006 study in Japan observed that green tea consumption was associated with a decreased mortality from all causes of cardiovascular disease.[117] Polyphenols contained in green tea including catechins and epigallocatechin gallate (EGCG) are responsible for its antioxidant properties. Although green tea consumption is considered to be safe, recent case reports describing the development of acute hepatitis following ingestion of green tea extracts or infusions suggests that idiosyncratic hepatotoxicity may occur in rare individuals.[3,17,22,78,83,103,105,156,164,182,191,201]

12. **Evening primrose** (*Oenothera biennis*)—Evening primrose contain *cis*-γ-linoleic acid (GLA), a prostaglandin E_1 precursor. This herb is a popular remedy for treatment of premenstrual syndrome, diabetes, eczema, and rheumatoid arthritis. Evening primrose appears to be safe in appropriate doses. This herb may lower the seizure threshold in epilepsy.

13. **Valerian** (*Valeriana officinalis*)—Valerian is a popular remedy for treatment of anxiety and is also used as a sleeping aid. Valerian appears to be safe in appropriate doses. Valerian may potentiate sedation in patients taking sedative-hypnotics.[151]

TOXICITY OF SIGNIFICANT HERBAL PREPARATIONS

■ CARDIOVASCULAR TOXINS

Aconite Aconites (caowu, chuanwu, and fuzi) are the dried rootstocks of the *Aconitum* plant.[185] In China, aconite usually is derived from *Aconitum carmichaelii* (chuan wu) or *A. kuznezoffii* (caowu). In Europe and the United States, aconite is derived from *A. napellus*, commonly known as *monkshood* or *wolfsbane*. The tubers are the most toxic part of the plant. When ingested, both cardiac and neurologic toxicity occur. Aconite poisoning is far more common in Asia, especially China.[52] In Hong Kong, it is responsible for the majority of serious poisonings from Chinese herbal preparations.[47,50,52]

Aconite toxicity is caused by C19 diterpenoid-ester alkaloids, including aconitine, mesaconitine, and hypaconitine.[29] Aconitine increases sodium influx through the sodium channel, increasing inotropy while delaying the final repolarization phase of the action potential and promoting premature excitation.[94] Sinus bradycardia and ventricular dysrhythmias can occur.[51] Symptoms can occur from 5 minutes to 4 hours after ingestion. Paresthesias of the oral mucosa and entire body may be followed by nausea, vomiting, diarrhea, and hypersalivation, and then by progressive skeletal muscle weakness. Fatalities may occur with doses as low as 5 mL aconite tincture, 2 mg pure aconite, or 1 g dried plant. Atropine may be of value in treating bradycardia or hypersalivation.[186] Although no antidote is available, anecdotal reports suggest the use of amiodarone, flecainide, bretylium, lidocaine, and procainamide for ventricular tachydysrhythmias.[186,209] Pharmacologic principles support the use of these sodium channel blockers. One case of aconite-induced refractory tachydysrhythmias was successfully managed with a ventricular assist device.[73] In a case series of two aconite-poisoned patients, reversal of aconite-induced ventricular dysrhythmias was attributed to the use of charcoal hemoperfusion for aconitine removal.[124,125]

Ch'an Su Ch'an su is a traditional herbal remedy derived from the secretions of the parotid and sebaceous glands of the toad Bufo bufo gargarizans or Bufo melanosticus. This remedy is traditionally used as a treatment for congestive heart failure.[115] Ch'an su contains two groups of toxic compounds: digoxin-like cardioactive steroids consisting of bufadienolides and the hallucinogenic compound bufotenin. Clinical findings following ingestion are similar to cardioactive steroid poisoning, including gastrointestinal symptoms and dysrhythmias. It was also marketed as an aphrodisiac for its purported topical anesthetic effects and sold under names such as "Stone," "Love Stone," "Black Stone," and "Rock Hard." Between 1993 and 1996 in New York City, several fatalities were associated with the ingestion of Ch'an su marketed as a topical aphrodisiac.[35] Severe toxic reactions and death are reported after mouthing toads, "toad licking," or eating an entire toad, or ingesting toad soup, or toad eggs.[26] Assays for serum digoxin unpredictably cross-react with bufadienolides, but may qualitatively assist in making a presumptive diagnosis (Table 43-1). Digoxin-specific Fab was successfully used to treat Ch'an su poisoning and should be empirically administered for any suspected case of cardiotoxicity from Ch'an su or other cardioactive steroid[26,177] (Chap. 64).

■ CENTRAL NERVOUS SYSTEM TOXINS

Absinthe Wormwood (Artemisia absinthium) extract is the main ingredient in absinthe, a toxic liquor that was outlawed in the United States in 1912. This volatile oil is a mixture of α- and β-thujone (Table 43-3).[208] Both tetrahydrocannabinol and thujone have an affinity for a common CNS receptor binding site and for similar oxidative metabolic pathways.[208]

Chronic absinthe use caused "absinthism," characterized by psychosis, hallucinations, intellectual deterioration, and seizures. The most famous victim of absinthism may have been Vincent Van Gogh, who is thought to have suffered from this disorder in the later part of his life.[8] A thujone-free wormwood extract now is used for flavoring vermouth and pastis. A case of wormwood-induced seizures, rhabdomyolysis, and acute renal failure was described involving a patient who purchased from the Internet and consumed approximately 10 mL essential oil of wormwood, assuming it was absinthe liquor.[204] Treatment remains supportive.

Anticholinergic Agents: Henbane, Jimson Weed, Mandrake Many plants contain the belladonna alkaloids atropine (dl-hyoscyamine), hyoscyamine, and scopolamine (l-hyoscine). They may still be used

therapeutically for treatment of asthma and occasionally are mistakenly included in herbal teas.[46] Signs and symptoms of anticholinergic poisoning include mydriasis, diminished bowel sounds, urinary retention, dry mouth, flushed skin, tachycardia, and agitation. Mildly poisoned patients usually require only supportive care and sedation with intravenous benzodiazepines. Intravenous physostigmine reverses anticholinergic poisoning; however, its use should be limited to treatment of moderately to severely symptomatic patients because inappropriate use may cause seizures and dysrhythmias.

Ephedra Members of the genus *Ephedra* generally consist of erect evergreen plants resembling small shrubs.[190] Common names include sea grape, ma-huang, yellow horse, desert tea, squaw tea, and Mormon tea. *Ephedra* species have a long history of use as stimulants and for management of bronchospasm. They contain the alkaloids ephedrine and, in some species, pseudoephedrine.[167,190] In large doses, ephedrine causes nervousness, headache, insomnia, dizziness, palpitations, skin flushing, tingling, vomiting, anxiety, restlessness, mania, and psychosis. The treatment is similar to that for other CNS stimulants (Chap. 75). In a published review of 140 reports of adverse events associated with ephedra use submitted to the FDA, 62% of cases (82) were considered "probable" or "possibly" related to ephedra use. Hypertension was the most commonly reported adverse effect (17 cases), followed by palpitations or tachycardia (13 cases), strokes (10 cases), and seizures (7 cases). Ten reported cases resulted in death. Thirteen cases resulted in permanent disability.[91] In 2002, the FDA banned the sale of ephedra-containing dietary supplements.[195] However, other herbal preparations, such as bitter orange (*Citrus aurantia*), contain ephedralike alkaloids (synephrine) and are still widely available.[141,149] Exposures may result in cardiovascular toxicity.[142,150]

Khat A common form of drug abuse in East Africa involves chewing the leaves and stems of the khat (*Catha edulis*) plant and swallowing the juice.[69,126] Khat is used by herbalists to treat depression, fatigue, obesity, and gastric ulcers. The two active compounds in khat are cathine (norpseudoephedrine) and cathinone (α-aminopropiophenone), the more active stimulant (an extensive discussion is given in Chap. 75).

Nicotinic Agents: Betel Nut, Blue Cohosh, Broom, Chestnut, Lobelia, Tobacco Betel (*Areca catechu*) is chewed by an estimated 200 million people worldwide for its euphoric effect. As an herb, it used as a digestive aid and as a treatment for cough and sore throat. Its active ingredient is arecoline, a direct-acting nicotinic agonist. The betel leaf also contains a phenolic volatile oil and an alkaloid capable of producing sympathomimetic reactions. Arecoline is a bronchoconstrictor, although weaker than methacholine, and may exacerbate bronchospasm in asthmatic patients chewing betel nut.[189] Treatment for betel nut toxicity is supportive. Long-term use of betel nut is associated with leukoplakia and squamous cell carcinoma of the oral mucosa.[148]

Many other herbal preparations have nicotinic effects. Examples of plants and their nicotinic ingredient include blue cohosh,[18] methylcytisine; broom, l-sparteine; chestnut, esculin; lobelia, lobeline; and tobacco/nicotine.

Other herbs that have CNS activity include valerian (sedation), kava kava (sedation), Japanese star anise (seizures), nutmeg (hallucinations),[205] mace (hallucinations), and iboga (hallucinations).

■ GASTROINTESTINAL TOXINS

Goldenseal Goldenseal (*Hydrastis canadensis*) originally was used by the Cherokees and other Native Americans as a dye and an internal remedy.[84] Today, it is used as an astringent, as a remedy for mucous membranes or gastrointestinal tract disorders, and as treatment for menorrhagia. Goldenseal is reputed to mask the presence of illicit

drugs on urinary drug screens, although multiple studies indicate goldenseal does not affect the results of urinary drug screens.[56,144,153] This myth originated in the murder-mystery *Stringtown on the Pike* (1900), which was written by the internationally known plant pharmacist Uri Lloyd. In this novel, one of the major characters is accused of murder by poisoning with strychnine but is posthumously exonerated with evidence that hydrastine (the active alkaloid in goldenseal) and morphine cross-react to produce a positive color assay for strychnine.[76] Appropriate usage of this herb is thought to be safe, but ingestion of large amounts can cause vomiting, diarrhea, convulsions, paralysis, and respiratory failure. In cases of large ingestions, the patient should receive supportive and symptomatic care.

■ HEPATOTOXINS

Pennyroyal Pennyroyal oil is a volatile oil extract from the leaves of Mentha pulegium and Hedeoma pulegioides plants. Herbalists use pennyroyal oil as an abortifacient and to regulate menstruation. It is also used as a flea/mosquito repellant and as a fragrance. The abortive effect is thought to be caused by irritation and contraction of the uterus.[185] Pennyroyal usually is ingested as a strong tea prepared from the leaves or as the oil itself. It is cited as the causative agent in several well-documented cases of hepatic failure following ingestion of as little as 15 mL of the oil.[5,11] The postulated mechanism is direct hepatotoxicity following glutathione depletion from the cyclohexanone pulegone and its cytochrome P450 (CYP1A2, CYP2E1, CYP2C19)-dependent toxic metabolites that include menthofuran.[112] On autopsy, vacuolization of the white matter of the midbrain was reported in both a fatal human exposure and in animal models.[10,152] Because pulegone depletes hepatic glutathione stores, N-acetylcysteine treatment may be beneficial[5,27] (A4: *N*-Acetylcysteine). In an animal model, pretreatment with cytochrome P450 inhibitors cimetidine (CYP1A2, CYP2C19) and disulfiram (CYP2E1) reduced pulegone-induced hepatotoxicity.[184] It may be reasonable to consider use of cytochrome P450 inhibitors in the treatment of pennyroyal-poisoned patients; however, evidence of clinical benefit in humans currently is lacking.

Pyrrolizidine Alkaloids Pyrrolizidine alkaloids are hepatotoxins found in many plants, including *Heliotropium*, *Senecio*, *Crotalaria*, and *Symphytum*.[161,166] Examples of other plants and products containing pyrrolizidine alkaloids include borage (*Borago officinalis*), coltsfoot (*Tussilago farfara*), and T'u-san-chi'i (*Gynura segetum*).[99,116,167]

The alkaloids undergo metabolism to pyrroles, which serve as biologic alkylating agents.[99] The pyrroles cause hepatic sinusoidal hypertrophy and venous occlusion, resulting in hepatic veno-occlusive disease, hepatomegaly, cirrhosis, and possibly hepatic carcinoma. Chronic low doses may cause pulmonary toxicity resulting in pulmonary artery hypertension and right ventricular hypertrophy. Consumption of "bush" tea, prepared from the leaves of the *Crotalaria* plant, is considered an endemic problem in Jamaica. Epidemics have also occurred in Afghanistan and India, where ingestion of contaminated cereals containing *Heliotropium* and *Crotalaria* seeds resulted in reports of 1632 and 60 cases of veno-occlusive disease, respectively.[138,188] In western countries, ingestion of herbal products containing *Senecio* and comfrey have led to several cases of hepatic veno-occlusive disease.[161] Treatment of hepatic veno-occlusive disease is supportive but may require liver transplantation in severe cases.

Several other herbal preparations are associated with hepatotoxicity.[119] These preparations include chaparral (*Larrea tridentata*),[34,85] germander (*Teucrium chamaedrys*),[120] impilia (*Callilepsis laureola*),[116] atractylis (*Atractylis gummifera*), sassafras (*Sassafras albidum*),[175] and kava kava (*Piper methysticum*).[197]

METALS

Poisonings by metals, including arsenic, cadmium, lead, and mercury, may occur following consumption of various types of herbal preparations[39,41,60,167] (Chaps. 88, 90, 94, and 96). Treatment consists of ceasing consumption of the herbal product and use of an appropriate chelating agent when indicated.

Hai-ge-ten (clamshell powder) contamination with copper, chromium, arsenic, or lead is described in several case reports.[93,129] Pay-loo-ah, a red and orange powder used by the Hmong people as a fever and rash remedy, was contaminated with lead.[36] Ayurvedic remedies are either herbal only or *rasa shastra* which, based upon ancient traditional healing of India, deliberately combines metals such as gold, silver, copper, zinc, iron, lead, tin, and mercury and are used by the majority of the Indian population.[40,163,165,173] Ghasard, Bola Goli, Kandu, and Moha Yogran Guggulu, traditional Indian remedies for abdominal pain, are associated with lead poisoning.[39,174] One fatality from lead poisoning from Ghasard, Bola Goli, and Kandu is reported from the United States.[39] In one study, 20% of surveyed Ayurvedic products produced in South Asia and sold on a nonprescription basis in stores in the Boston area contained potentially harmful concentrations of lead, mercury, or arsenic.[172] A followup study determined that a similar percentage 21% of Ayurvedic products sold over the unit also contained potentially harmful levels of lead, mercury, or arsenic irrespective of whether manufacture occurred in the United States or India.

These same investigators recently studied the lead, mercury and arsenic concentrations in US and Indian manufactured Ayurvedic medicines sold via the Internet demonstrating that 20% of these were contaminated with one of these metals, all exceeding one or more standards for acceptable daily intake of a toxic metal.[173] Azarcon (lead tetroxide) and greta (lead oxide) are used by an estimated 7.2%–12.1% of Mexican-Hispanic families for treatment of *empacho*. In Spanish, *empacho* means "blocked intestine," but it refers to any type of chronic digestive problem, including such diverse symptoms as constipation, diarrhea, nausea, vomiting, anorexia, apathy, and lethargy.[42,45] Azarcon and greta are fine powders with total lead contents varying from 70% to >90%.[23,43]

Herbal balls, hand-rolled mixtures of herbs and honey produced in China, are often associated with arsenic and mercury contamination.[72] Examples include An Gong Niu Huang Wan, Da Huo Luo Wan, and Niu Huang Chiang Ya Wan.

RENAL TOXINS

Aristolochia An epidemic of renal failure in Belgium was linked to the substitution of Aristolochia fangchi, also known as birthwort, heartwort, and fangchi, for another Chinese herbal, Stephania tetranda, in the formulation of a weight-loss regimen.[198,199] Of 70 identified cases of renal fibrosis, 30 patients developed chronic renal failure. Aristolochic acid in Aristolochia causes renal fibrosis which typically becomes clinically apparent 12 to 24 months after the initial injury. Patients with Aristolochia-induced nephropathy also have an increased risk for developing urothelial cancer.[147]

MISCELLANEOUS

Chamomile Tea Chamomile tea is a popular herbal drink made from chamomile flower heads. Anaphylactic reactions can occur in patients allergic to ragweed, asters, chrysanthemums, or other members of the Compositae family.[14,31] Such reactions are rare but can be life threatening. The patient need not have severe allergies or be highly atopic to experience a cross-reaction.

Rattlesnake Capsules Rattlesnake capsules are a common Mexican folk remedy used to treat cancer, arthritis, and skin disorders. These capsules contain dried, pulverized rattlesnake powder and are sold under various names, such as vibora de cascabel, polvo de vibora, and carne de vibora, without prescriptions. Infection with Salmonella arizonae is described following ingestion.[16,57,149,169,203]

CHINESE PATENT MEDICATIONS

Chinese patent medicines, a component of traditional Chinese medicine, contain traditional herbals, formulated into tablets, capsules, syrups, powders, ointments, and plasters, for easy use. They are produced by poorly regulated Chinese pharmaceutical agencies and are highly susceptible to adulteration or contamination. They are often sold by nonherbalists at convenience stores in packages with incomplete documentation of ingredients, and, typically, they are not labeled in English. In 1998, the California Department of Health Services investigated 260 Asian patent medications for adulterants and determined that 32% contained undeclared pharmaceutics or heavy metals.[114] A similar study in Taiwan determined that 24% of 2609 samples collected were contaminated by at least one adulterant.[96] In 2007, 90 Chinese patent medicines randomly purchased in New York City's Chinatown identified five samples containing nine western medications including chlormethiazole, chlorpheniramine, diclofenac, chlordiazepoxide, hydrochlorothiazide, triamterene, diphenhydramine, and sildenafil citrate.[135]

Jin Bu Huan is a traditional Chinese preparation used as a sedative and analgesic.[206] The active ingredient, an isoquinoline alkaloid l-tetrahydropalmatine (l-THP), is responsible for the morphine-like properties of Jin Bu Huan. In two case reports, three pediatric patients developed life-threatening bradycardia and seven adult patients developed hepatitis while using Jin Bu Huan.[37,38] Hepatotoxicity may be related to L-THP, which is structurally similar to the hepatotoxic pyrrolizidine alkaloids.[206] Although the package insert for Jin Bu Huan in these cases indicated that *Polygala chinensis* was the plant source for L-THP, *P. chinensis* does not contain L-THP. Plants from the genera *Stephania* and *Corydalis* are also known as Jin Bu Huan and contain appreciable amounts of L-THP. The product implicated in the case reports may have been simply mislabeled by the manufacturer.

Nan Lien Chiu Fong Toukuwan (now withdrawn from the market) was found to variably contain aminopyrine, phenacetin, phenylbutazone, indomethacin, mefenamic acid, diazepam, hydrochlorothiazide, dexamethasone, mercuric sulfide, lead, and cadmium, depending on the manufacturer.[50] Several cases of agranulocytosis were reported following ingestion of this preparation.[168] Dr. Tong Shap Yee's asthma pills were found to contain theophylline.[50] Leng Pui Kee cough pills were found to contain bromhexine.[50]

Tung Shueh (black ball) contains diazepam and mefenamic acid and is associated with acute interstitial nephritis.[65] Gan Mao Tong Pian, an herbal cold remedy, contains phenylbutazone and caused aplastic anemia in one child.[145] Chui Feng Su Ho Wan, which contains *Glycyrrhiza glabra*, was associated with hypokalemia-induced torsade de pointes in an elderly woman.[50]

Several Chinese patent medicines contain the mercurials cinnabar (mercuric sulfide) and calomel (mercurous chloride). Tse Koo Choy and Qing Fen, which contain calomel, are associated with several cases of mercury poisoning.[108]

Many Chinese medicated oils contain oil of wintergreen, which is methylsalicylate. Although these oils are intended for external use, it is a common practice to ingest a few drops undiluted or in a hot drink as a general tonic or specific remedy. Examples of medicated oils include White Flower Medicine Oil (40% oil of wintergreen, 30% menthol, 6% camphor), Red Flower Oil (67% oil of wintergreen, 22% turpentine oil), and Kwan Loong Medicated Oil (menthol 25%, methylsalicylate 15%, camphor 10%).[50]

■ HERBAL PREPARATIONS AND AIDS THERAPIES

Many patients infected with human immunodeficiency virus (HIV) have turned to alternative treatments in the hope of finding less toxic therapy than the conventional modalities currently available. In a study of 114 HIV-positive patients in a university-based AIDS clinic, 22% used one or more herbal products in a 3-month period.[109] Twenty-four percent of these patients were unable to state which herbs they were taking. Adverse effects included dermatitis, nausea, vomiting, diarrhea, thrombocytopenia, coagulopathies, altered mental status, hepatotoxicity, and electrolyte imbalances. Twenty percent of patients stated their physicians were unaware of their use of herbs. A more recent study reported that more than two thirds of AIDS patients were taking alternative medicines, and 24% of AIDS patients were taking Chinese herbs or other botanicals.[86]

Current popular herbal preparations and dietary supplements for treatment of AIDS or AIDS-related illnesses include *Lactobacillus acidophilus*, adrenal cortex, aloe vera, *Artemisia*, *Astragalus*, bitter melon, bioperine, blue-green algae, cat's claw, *Chlorella*, coenzyme Q10, colloidal silver, curcumin, dehydroepiandrosterone (DHEA), echinacea, elderberry, evening primrose oil, flaxseed oil, garlic, germanium, ginger, *Ginkgo biloba*, glucosamine, glutamine, glutathione, glycyrrhizin, grapeseed, green tea, lipoic acid, *N*-acetylcysteine, saw palmetto, Siberian ginseng, and silymarin, and are used for treatment of HIV infection.[146]

TREATMENT

A specific treatment strategy should emphasize identification of the specific herbal preparation(s) used by the patient, concurrent medication(s), and medical illness(es). Because herbal preparation toxicity varies greatly depending on the preparation used, careful examination may be aided by knowledge of the herbal preparation. In most cases, supportive care and discontinuation of the herbal preparation(s) are sufficient. Some herbal toxicities require specific laboratory analysis and therapy (Table 43-1).

All adverse events associated with herbal preparations should be reported to the local poison control center or to FDA MedWatch by phone at 1-800-FDA-1088 or online at https://www.fda.gov/ medwatch.

SUMMARY

Herbal preparation usage is a popular type of "complementary" or alternative medicine. Although most herb users will suffer no ill effects, both herb users and clinicians should be aware that these preparations are pharmacologically active, have the potential for toxicity, and are not as closely regulated by the FDA (or any governmental agency) as pharmaceuticals. They may interact with prescription medications to increase the toxicity of the medication or decrease its therapeutic effect. Patients with specific medical conditions may have increased risk for toxicity when using herbal preparations.

Herb users should be aware that these preparations are poorly studied with scientific proof of efficacy lacking for most preparations. No standards exist for their manufacture, quality, or control and many herbal products do not contain the purported amount of the active ingredient. Some herbal products do not even contain the correct active ingredient. Some herbal products are reported to be adulterated with prescription medications or contain contaminants such as heavy metals.

Many herbal stores are staffed by untrained personnel who may dispense incorrect medical advice and unfounded claims concerning their products.[160] Herbalists (eg, Chinese herbalists) may dispense traditional remedies with the potential for serious toxicity as the result

of improper identification of the correct herb or improper preparation of the herbal product by the herbalist or herb user.[50] Most herb users and many herbalists may be unaware of the potential for toxicity of their product.

Clinicians should be familiar with herbal preparations and their potential for drug interactions and adverse effects. This is especially important because standard herbal reference texts may lack sufficient information on the management of poisoning or other adverse effects.[90] Every patient history should include questions assessing the concurrent or recent past use of herbal preparations.

CHAPTER 44
ATHLETIC PERFORMANCE ENHANCERS

Susi U. Vassallo

Public interest in extraordinary athletic achievement fuels the modern-day science of performance enhancement in sports. The desire to improve athletic performance in a scientific manner is a relatively recent development; at one time, the focus on maximizing human physical and mental potential centered on the importance of manual work and military service. The role of sport was inconsequential, except for its potential in improving military preparedness.[105] Today, "sports doping" refers to the use of a prohibited xenobiotic to enhance athletic performance. The word *doping* comes from the Dutch word *doop,* a viscous opium juice used by the ancient Greeks.[30]

HISTORY AND EPIDEMIOLOGY

Controversy surrounding the systematic use of performance-enhancing xenobiotics by the participating athletes has marred many sporting events. Since the International Olympic Committee (IOC) began testing for xenobiotics during the 1968 Olympic games, prominent athletes have been sanctioned and stripped of their Olympic medals because they tested positive for banned xenobiotics. However, from a public health perspective, the use of performance-enhancing xenobiotics among athletes of all ages and abilities is a far more serious concern than the highly publicized cases involving world-class athletes. The majority of studies on the epidemiology of performance-enhancing xenobiotics have investigated androgenic anabolic steroid use. *Androgenic* means masculinizing and *anabolic* means tissue building. An *anabolic process* stimulates protein synthesis, promotes nitrogen deposition in lean body mass, and decreases protein breakdown.[250] Studies of high school students document that 6.6% of male seniors have used anabolic steroids, and 35% of these individuals were not involved in organized athletics.[32] Other studies find rates of androgenic steroid use in adolescent athletes ranging from 3% to 19%.[114,127,182,246,251,250]

PERFORMANCE ENHANCEMENT AND SUDDEN DEATH IN ATHLETES

Many unexpected deaths in certain groups of young competitors have occurred in the absence of obvious medical or traumatic cause. In some cases, the use of performance-enhancing drugs is linked to the deaths. The use of erythropoietin (EPO), introduced in Europe in 1987, may have contributed to the large number of deaths in young European endurance athletes over the subsequent few years.[67,89,149,173,239] In young healthy athletes experiencing cerebrovascular events or myocardial infarction, the temporal link between the use of cocaine, ephedrine, or performance enhancers such as anabolic androgenic steroids suggests a role for these xenobiotics as precipitants of these adverse events[147] (Chap. 76). Nevertheless, the leading cause of nontraumatic sudden

death in young athletes is most often associated with congenital cardiac anomalies.[146] In autopsy studies of athletes in the United States with sudden death, hypertrophic cardiomyopathy is the most common structural abnormality, accounting for more than one-third of the cardiac arrests, followed by coronary artery anomalies.[147] Medical causes of sudden death other than cardiac causes include heat stroke (Chap. 15), sickle cell trait, and asthma.[75,119,132]

PRINCIPLES

Performance enhancers can be classified in several ways for the purposes of study. Some categorize performance enhancers according to the expected effects. For example, some xenobiotics increase muscle mass, whereas others decrease recovery time, increase energy, or mask the presence of other drugs. However, one xenobiotic may have several expected effects. For example, diuretics may be used to mask the presence of other xenobiotics by producing dilute urine, or they may be used to reduce weight. Clenbuterol is an anabolic xenobiotic, but it also is a stimulant because of its β_2-adrenergic agonist effects. Bromantan is another stimulant, but it is used as a masking agent. Depending on the xenobiotic, it is used either during training to improve future performance or during competition to improve immediate results.[30]

According to the World Anti-Doping Agency (WADA) World Anti-Doping Code 2008, a xenobiotic or method constitutes doping and can be added to the prohibited list if it is a masking xenobiotic, or if it meets two of the following three criteria: it enhances performance; its use presents a risk to the athlete's health; and it is contrary to the spirit of sport[248] (Table 44–1).

◼ THERAPEUTIC USE EXEMPTION

Some of the Prohibited Substances and Methods on the WADA 2008 Prohibited List are used to treat legitimate medical conditions encountered in athletes.[247] Athletes with documented medical conditions requiring the use of a prohibited substance or method may request a Therapeutic Use Exemption (TUE). In the Olympics, use of inhaled β_2-adrenergic agonists requires a TUE. Nevertheless, a high salbutamol concentration (free salbutamol concentration plus glucuronide level >1000 ng/mL) is considered a positive test and an adverse finding unless the athlete proves that the abnormal value results from therapeutic use of the drug.[45,247] Many athletes have sought to explain a positive doping test by claiming the substance was prescribed for a medical condition, such as the use of modafinil, a stimulant, for the sleep disorder narcolepsy.

ANABOLIC XENOBIOTICS

◼ ANDROGENIC STEROIDS

Androgenic anabolic steroids (AAS) increase muscle mass, lean body weight, and cause nitrogen retention.[157] Testosterone is the prototypical androgen, and most androgenic anabolic steroids are synthetic testosterone derivatives. The androgenic effects of steroids are responsible for male appearance and secondary sexual characteristics such as increased growth of body hair and deepening of the voice.

In the 1970s and 1980s, federal regulation of anabolic steroids was under the direction of the Food and Drug Administration (FDA). Because of increasing media reports on the use of anabolic steroids in sports, particularly by high school students and amateur athletes, Congress enacted the Anabolic Steroid Control Act of 1990, which

TABLE 44–1. Abbreviated Summary of World Anti-Doping Agency 2008 Prohibited List[247]

Substances (S) and Methods (M) Prohibited at All Times (In- and Out-of-Competition)

S1. Anabolic Androgenic Agents

    Clenbuterol

    Selective androgen receptor modulators (SARMS)

S2. Hormones and Related Substances

S3. β_2-Adrenergic Agonists

    Exceptions require Therapeutic Use Exemption

S4. Hormone Antagonists and Modulators

    Myostatin inhibitors

S5. Diuretics and Other Masking Agents

M1. Enhancement of Oxygen Transfer

M2. Chemical and Physical Manipulation

M3. Gene Doping

Substances and Methods Prohibited In Competition

In addition to S1 to S5 and M1 to M3 above, the following categories are prohibited in competition:

    S6. Stimulants

    S7. Narcotics

    S8. Cannabinoids

    S9. Glucocorticosteroids except topically unless TUE

Substances Prohibited in Particular (P) Sports

    P1. Alcohol

    P2. β-Adrenergic Antagonists

Specified substances[a]

    Ephedrine

    Cannabinoids

    All inhaled β_2-adrenergic agonists, except Clenbuterol

    Probenecid

    All glucocorticosteroids

    All β-adrenergic antagonists

    Alcohol in competition only

[a] In certain circumstances, a doping violation involving specified substances may result in a reduced sanction, provided the athlete establishes that the use was not intended to enhance performance.

TUE = therapeutic use exemption

TABLE 44–2. Synthetic Testosterone Derivatives/ Anabolic Androgenic Steroids

Generic Nomenclature		
17α-Alkyl Derivatives (Oral)	17β-Ester Derivatives (Parenteral)	Transdermal Testosterone Preparations
Ethylestrenol	Boldenone	Buccal gel, sublingual
Fluoxymesterone	Nandrolone decanoate	Dermal gel, ointment
Methandrostenolone	Nandrolone	Transdermal reservoir
Methyltestosterone	phenpropionate	patch
Oxandrolone	Testosterone esters	
Oxymetholone	Testosterone	
Stanozolol	cypionate	
	Testosterone enanthate	
	Testosterone ester	
	combination	
	Testosterone propionate	
	Trenbolone	

amended the Controlled Substances Act and placed anabolic steroids on schedule III. Schedule III states that a xenobiotic has a currently accepted medical use in the United States and has less potential for abuse than the xenobiotics categorized as schedule I or II. The Anabolic Steroid Control Act of 2004 adds certain steroid precursors, such as androstenedione and dihydrotestosterone, to the list of controlled substances that are considered illegal without a prescription. Possession of androstenedione or other metabolic precursors called *prohormone drugs* is considered a federal crime. Nevertheless, anabolic steroids are still available illicitly over the Internet from international marketers, veterinary pharmaceutical companies, and some legitimate US manufacturers.

■ PHYSIOLOGY AND PHARMACOLOGY

The Leydig cells of the testis produce 95% of endogenous male testosterone; the remainder comes from the adrenal glands. Normally 4–10 mg testosterone and 1–3 mg androstenedione are produced daily in men. Women secrete approximately 0.04–0.12 mg testosterone and 2–4 mg androstenedione daily from their ovaries and adrenal glands.[219]

Testosterone is rapidly degraded in the liver, with a plasma half-life of less than 30 minutes. Therefore, in order to create a medication that is useful clinically, testosterone is esterified at the 17-hydroxy position, forming a hydrophobic compound that can be administered in an oil vehicle for gradual release.[14] Most of these esters of testosterone must be injected intramuscularly to avoid extensive first-pass hepatic metabolism associated with oral administration.[14] Alternatively, alkylation at the 17-hydroxy position produces androgens that can be administered orally because they are more resistant to hepatic metabolism. These agents, more commonly used by athletes, are responsible for the majority of complications associated with AAS use[14] (Table 44–2).

■ ANTIESTROGENS AND ANTIANDROGENS

In male athletes using androgens, avoiding the unwanted side effects of feminization such as gynecomastia, or in the case of female athletes avoiding masculinization and features such as facial hair and deepening voice, requires manipulation of the metabolic pathways of androgen metabolism. Creating a xenobiotic that completely dissociates the desired from the unwanted effects has not been possible. However, xenobiotics with properties capable of manipulating metabolic pathways associated with undesirable side effects are divided into four main groups, all on the prohibited list: (1) Aromatase inhibitors such as anastrozole and aminoglutethimide prevent the conversion of androstenedione and testosterone into estrogen. (2) The antiestrogen clomiphene blocks estrogen receptors in the hypothalamus, opposing the negative feedback of estrogen, causing an increase in gonadotropin releasing hormone, thereby increasing testosterone release. (3) Selective estrogen receptor modulators (SERMs) such as tamoxifen and raloxifene bind to estrogen receptors and exhibit agonist or antagonist effects at the estrogen receptors. By indirectly increasing gonadotropin

release, SERMs restore endogenous testosterone production upon discontinuation of androgenic anabolic steroids.[190] (4) Selective androgen receptor modulators (SARMs) are nonsteroidal tissue-selective anabolic agents that are not yet commercially available. They are not aromatized and are not substrates for 5α-reductase, nor do they undergo the same metabolic pathways to testosterone. Therefore, they have fewer unwanted androgenic side effects.[82,223]

ADMINISTRATION

Approximately 50% of AASs are taken orally. The remainder is administered by intramuscular injection, with one-fourth of intramuscular AAS users sharing needles.[62,163] One-third of the needles and syringes exchanged in a needle-exchange program in Wales were used for anabolic steroids.[171] Unlike therapeutically indicated regimens, which consist of fixed doses at regular intervals, athletes typically use AASs in cycles of 6 to 8 weeks.[14] For example, the athlete may use steroids for 2 months and then abstain for 2 months. Cycling is based on the athlete's individual preferences and not on any validated protocol. *Stacking* implies combining the use of several AASs at one time, often with both oral and intramuscular administration. To prevent *plateauing,* or developing tolerance, to any one drug, some athletes use an average of five different AASs simultaneously. The doses used are frequently hundreds of times in excess of scientifically based therapeutic recommendations.[3,245] *Pyramiding* implies starting the AAS at a low dose, increasing the dose many times, and then tapering once again. Fat-soluble AASs may require several months to be totally eliminated, whereas water-soluble steroids may require only days to weeks to be cleared by the kidney. Water-soluble testosterone esters are used for bridging therapy. *Bridging* refers to the practice of halting the administration of long-lasting alkylated testosterone formulations so that urine analyses at a specific time offer no evidence of use, while injections of shorter-acting testosterone esters are used to replace the orally administered alkylated formulations. This strategy, which was used extensively in the German Democratic Republic, is documented in a review of the subject based on extensive research of previously classified records.[74] Clearance profiles for testosterone congeners were determined for each athlete. In general, the daily injection of testosterone esters was used when termination of the more readily detectable synthetic alkylated testosterone derivatives was necessary to avoid a positive doping test. These daily injections of testosterone propionate were halted 4–5 days before competition. Corrupt officials involved in doping were sure that the values would decrease to acceptable concentrations in time for the event, based on the science of athletes' clearance of testosterone esters.[74]

CLINICAL MANIFESTATIONS OF ANDROGENIC ANABOLIC STEROID USE

Musculoskeletal Supraphysiologic doses of testosterone, when combined with strength training, increase muscle strength and size.[24] The most common musculoskeletal complications of steroid use are tendon and ligament rupture.[76,102,133,138]

Hepatic Hepatic subcapsular hematoma with hemorrhage is reported.[203] Peliosis hepatis, a condition of blood-filled sinuses in the liver that may result in fatal hepatic rupture, occurs most commonly with alkylated androgens and may not improve when androgen use is stopped.[15,104,211,241] This condition is not associated with the dose or duration of treatment.[14,112,214] Cyproterone acetate is a chlorinated progesterone derivative that inhibits 5α-reductase and reportedly causes hepatotoxicity.[14,79,84]

Infectious Local complications from injection include infected joints,[70] cutaneous abscess,[148,187] and *Candida albicans* endophthalmitis.[244]

Injection of steroids using contaminated needles has led to transmission of infectious diseases such as HIV and hepatitis B and C.[163,167,185,186,205,210] Severe varicella is reported in long-term AAS users.[114]

Dermatologic/Gingiva Cutaneous side effects are common and include keloid formation, sebaceous cysts, comedones, seborrheic furunculosis, folliculitis, and striae.[206] Acne is associated with steroid use and sometimes is referred to as "gymnasium acne."[44,174] A common triad of acne, striae, and gynecomastia occurs. The production of sebum is an androgen-dependent process, and dihydrotestosterone is active in sebaceous glands.[14] Gingival hyperplasia is reported.[165]

Endocrine Conversion of AAS to estradiol in peripheral tissues results in feminization of male athletes. Gynecomastia may be irreversible. AAS use causes negative feedback inhibition of gonadotropin-releasing hormone, luteinizing hormone, and follicle-stimulating hormone from the hypothalamus. This process results in testicular atrophy and decreased spermatogenesis, which may be reversible. In females, menstrual irregularities and breast atrophy may occur. AAS use causes virilization in females.[219]

Cardiovascular Cardiac complications include acute myocardial infarction and sudden cardiac arrest.[9,73,100,110,140,142,153] Autopsy examination of the heart may reveal biventricular hypertrophy, extensive myocardial fibrosis, and contraction-band necrosis. Myofibrillar disorganization and hypertrophy of the interventricular septum and left ventricle are present.[140] Intense training and use of AAS impair diastolic function by increasing left ventricular wall thickness. Animal models and in vitro myocardial cell studies show similar pathologic changes.[54,126,154,221,230,231] Doppler echocardiography shows that several years after strength athletes discontinue using AAS, concentric left ventricular hypertrophy remains, compared to similar strength athletes not using AAS.[231] Growth hormone may potentiate the effects of AAS and further increase concentric remodeling of the left ventricle.[118] In addition to direct myocardial injury, vasospasm or thrombosis may occur.[154] Alkylated androgens lower the concentration of high-density lipoprotein (HDL) cholesterol and may increase platelet aggregation.[3,73] Thromboembolic complications include pulmonary embolus,[59,81] stroke,[122,123,209] carotid arterial occlusion,[132] cerebral sinus thrombosis, poststeroid balance disorder,[28,130] and popliteal artery entrapment.[137]

Neuropsychiatric Distractibility, depression or mania, delirium, irritability, insomnia, hostility, anxiety, mood lability, and aggressiveness ("roid rage") may occur.[18,178,179,220] These neuropsychiatric effects do not appear to correlate with plasma AAS concentrations.[209,220] Withdrawal symptoms from AAS include decreased libido, fatigue, and myalgias.[121,250]

Cancer An association between AAS use and development of cancer has been observed in experimental animals.[192] Testicular and prostatic carcinomas are reported in more frequent users of AAS.[80,191] Hepatocellular carcinoma,[71,113,164] cholangiocarcinoma,[14,91] Wilms tumor, and renal cell carcinoma are also reported in young AAS users.[33,181] The relationship between the dose of AAS and cancer is unknown.

SPECIFIC ANABOLIC XENOBIOTICS

Dehydroepiandrosterone Dehydroepiandrosterone (DHEA) is a precursor to testosterone (Fig. 44–1). Although banned by the FDA in 1996, this drug subsequently was marketed as a nutritional supplement and is available for purchase without a prescription.[219] DHEA is converted to androstenedione and then to testosterone by the enzyme 17β-hydroxysteroid dehydrogenase.[108,139,143] Administration of androstenedione in dosages of 300 mg/d increases testosterone and estradiol concentrations in some men and women.[136] Women with
FIGURE 44–1. Metabolic pathways of dehydroepiandrosterone (DHEA).

adrenal insufficiency given DHEA replacement at a dose of 50 mg/d orally for 4 months demonstrated increased serum concentrations of DHEA, androstenedione, testosterone, and dihydrotestosterone. Serum total and HDL cholesterol concentrations simultaneously decreased. Some women experienced androgenic side effects, including greasy skin, acne, and hirsutism.[12] Sense of well-being and sexuality increased in men and women after 4 months of treatment.[12,158,159] The neuropsychiatric effects of DHEA have been demonstrated in animals. Increased hypothalamic serotonin, anxiolytic effects, antagonism at the γ-aminobutyric acid type A (GABA$_A$) receptor, and agonism of the N-methyl-D-aspartate receptor are demonstrated.[12,144,155]

Clenbuterol Clenbuterol is a β$_2$-adrenergic agonist that decreases fat deposition and prevents protein breakdown in animal models.[7,42] Clenbuterol is also a potent *nutrient partitioning agent,* a term implying it can increase the amount of muscle and decrease the amount of fat produced per pound of feed given to cattle and other animals.[77,189] Use of clenbuterol in cattle farming is illegal in many countries. Nevertheless, the consumption of veal liver contaminated with clenbuterol has resulted in sympathomimetic symptoms and positive urine tests in affected individuals.[195] Clenbuterol increases the glycolytic capacity of muscle and causes hypertrophy, enhancing the growth of fast-twitch fibers.[145,253] β$_2$-Adrenergic receptors are present in skeletal muscle and may mediate the anabolic effect of this class of drugs. Athletes typically use doses of 60–100 μg/d clenbuterol and in some cases as much as 600 μ/d. Clenbuterol overdose is characterized by the typical symptoms of sympathomimetic overdose [41,51,106] (Chap. 65).

PEPTIDES AND GLYCOPROTEIN HORMONES

◼ CREATINE

Creatine is an amino acid formed by combining the amino acids methionine, arginine, and glycine. It is synthesized naturally by the liver, kidneys, and pancreas. Creatine is found in protein-containing foods such as meat and fish. In its phosphorylated form it is involved in the rapid resynthesis of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) by acting as a substrate to donate phosphorous.[218] Because ATP is the immediate source of energy for muscle contraction, creatine is used by athletes to increase energy during short, high-intensity exercise.[234] More than 2.5 million kg of creatine is consumed annually in the United States.[5] Exceptional athletes have admitted to using creatine as part of their training nutritional regimen, leading to interest by athletes at all levels. Numerous studies demonstrate improved performance with creatine supplementation, particularly in sports requiring short, high-intensity effort.[27,34,97,129,152,234] Creatine is found in skeletal muscle and in the heart, brain and kidney. Two-thirds of creatine is stored primarily as phosphorylated creatine (PCr) and the remainder as free creatine (Cr).[16] Consuming carbohydrates with creatine supplements increases total creatine and PCr stores in skeletal muscle.[94] This process explains why creatine is marketed in combination with carbohydrate. Human endogenous creatine production is 1 g/d, and normal diets containing meat and fish offer another 1–2 g/d as dietary intake. One to two grams of creatine is eliminated daily by irreversible conversion to creatinine.[240]

Creatine supplementation is most commonly accomplished with creatine monohydrate. A dose of 20–25 g/d can increase the skeletal muscle total creatine concentration by 20%.[97,111] Creatine stores do not increase in some individuals despite creatine supplementation. Creatine uptake in skeletal muscle occurs via the creatine transporter proteins at the sarcolemma. Creatine transporter expression and activity, as well as exercise and training, influence the uptake of creatine and the effect of creatine loading on athletic performance.[212,213,215]

One adverse effect of creatine supplementation is weight gain, which is thought to result primarily from water retention.[97,152] However, evidence indicates that net protein increase is partially responsible for the weight gain associated with long-term creatine use.[116] Diarrhea was the most commonly reported side effect of creatine use in one study of 52 male college athletes. Other complaints were muscle cramping and dehydration, although many subjects had no complaints.[117]

Creatine supplementation increases urinary creatine and creatinine excretion and may increase serum creatinine concentrations by 20%.[97,116] Long-term and short-term creatine supplementation does not appear to have an adverse effect on renal function.[176,177] One patient who had been taking creatine 5 g/d for 4 weeks developed interstitial nephritis that improved with cessation of creatine use. Whether ingestion of creatine caused the nephritis is unknown.[128] A young man with focal segmental glomerular sclerosis developed an elevated creatinine concentration and a decreased glomerular filtration rate (GFR) when creatine supplementation was started. The values returned to baseline upon cessation of creatine supplementation.[11] The possibility of developing decreased renal function is a theoretical concern. Ingestion of large amounts of creatine may result in formation of the carcinogenic substance N-nitrososarcosine, which induces esophageal cancer in rats.[10,11]

HUMAN GROWTH HORMONE

Human growth hormone (hGH) is an anabolic peptide hormone secreted by the anterior pituitary gland. It causes its anabolic effect by stimulating protein synthesis and increasing growth and muscle mass in children. Recombinant human growth hormone has been available since 1984. It is commonly used therapeutically for children with growth hormone deficiency in daily doses of 5–26 μg/kg body weight.[235]

Growth hormone secretion is stimulated by growth hormone–releasing hormone and is inhibited by somatostatin. Growth hormone receptors occur in many tissues, including the liver. Binding of hGH to hepatic receptors causes secretion of insulin-like growth factor-1 (IGF-1), which has potent anabolic effects and is the mediator responsible for many of the actions of hGH.

Human growth hormone is released in a pulsatile manner, mainly during sleep. Exercise stimulates hGH release, and more intense exercise causes proportionately more hGH release.[29,50,219] Amino acids such as ornithine, l-arginine, tryptophan, and L-lysine increase hGH release through an unknown mechanism and often are ingested for this purpose.[50,99]

Human growth hormone stimulates protein synthesis and tissue growth by nitrogen retention and increased movement of amino acids into tissue. The effects on increasing muscle mass and size are well proven in growth hormone–deficient individuals, but some studies do not support a resultant increase in strength related to the increase in muscle size in athletes.[48,141] In a more recent study, lean body mass, strength, and power increased.[93] Human growth hormone improves muscle and cardiac function, increases red cell mass and oxygen-carrying capacity, stimulates lipolysis, normalizes serum lipid concentrations, and decreases subcutaneous fat. It also improves mood and sense of well-being.[48,49,101,197,219,235]

Growth hormone is used by athletes for its anabolic potential. As a xenobiotic of abuse, it is particularly attractive because laboratory detection is difficult. In one survey, 12% of people in gyms used hGH for body building.[69] In another survey of adolescents, 5% of 10th-grade boys had used hGH.[188] Human growth hormone may be illicitly sold as recombinant growth hormone on the black market.

Human growth hormone administration may cause myalgias, arthralgias, carpal tunnel syndrome, and edema.[235] The effects of hGH on skeletal growth depend on the user's age. In preadolescence, excessive hGH may cause increased bony growth and gigantism. In adults, excessive hGH may cause acromegaly.[235] Growth hormone may cause glucose intolerance and hyperglycemia. Skin changes such as increased melanocytic nevi and altered skin texture occur.[175] Lipid profiles may be adversely affected. HDL concentrations are decreased, a change associated with increased risk of coronary artery disease.[254] Because hGH must be given parenterally, there is risk of transmission of infection.[141] The illicit sale of cadaveric human pituitary–derived growth hormone is associated with a risk of Creutzfeldt-Jakob disease.[58] Long-term users of hGH may be at increased risk for prostate cancer because of the complications associated with IGF-1[90] (see next section).

INSULIN-LIKE GROWTH FACTOR

IGF-1 is a peptide chain structurally related to insulin. A recombinant form is available.[188] Parenteral administration of IGF-1 is approved for clinical treatment of dwarfism and insulin resistance. Children who develop antibodies to recombinant growth hormone may respond to IGF-1.

Human growth hormone is the primary stimulus for release of IGF-1, although insulin, DHEA, and nutrition play a role.[194] The actions of IGF-1 can be classified as either anabolic or insulin-like.[194] The effects of growth hormone are primarily mediated by IGF-1. IGF-1 is produced in the liver and many other cell types. IGF-1 binds principally to the type I IGF receptor, which has 40% homology with the insulin receptor and a similar tyrosine kinase subunit.[225] IGF-1 also binds to insulin receptors, but it has only 1% of insulin's affinity for the insulin receptor. IGF-1 increases glucose utilization by causing the movement of glucose into cells, increasing amino acid uptake and stimulating protein synthesis.

Side effects are similar to those associated with use of growth hormone and include acromegaly. Other effects include headache, jaw pain, edema, and alterations in lipid profiles. A potentially serious side effect of IGF-1 is hypoglycemia. High endogenous plasma IGF-1 levels are associated with an increased risk for prostate cancer.[39]

Few studies on the efficacy of IGF-1 in improving the conditioning of athletes are available. IGF-1 is attractive to female athletes because it does not cause virilization.[219]

INSULIN

Insulin is used by body builders for its anabolic properties. Of 20 self-identified anabolic androgenic steroid users in one gym, five (25%) who had no medical reason to take insulin reported using it to increase muscle mass.[184] These individuals stated that they had injected insulin from 20 to 60 times over the 6 months prior to the study.[184] Their practice was to inject 10 U regular insulin and then eat sugar-containing foods after injection. Hypoglycemia has been reported in body builders using insulin.[66,183]

Insulin inhibits proteolysis and promotes growth by stimulating movement of glucose and amino acids into muscle and fat cells. It increases the synthesis of glycogen, fatty acids, and proteins[53] (Chap. 48).

HUMAN CHORIONIC GONADOTROPIN

Human chorionic gonadotropin (hCG) is a glycoprotein that stimulates testicular steroidogenesis in men. In women, hCG is secreted by

the placenta during pregnancy. Human chorionic gonadotropin may be used by male athletes to prevent testicular atrophy during and after androgen administration.[124] Analysis of hCG in 740 urinary specimens of male athletes revealed abnormal concentrations in 21 individuals. This finding prompted the IOC ban on hCG use in 1987. Presently, distinguishing exogenous hCG administration from hCG production in early pregnancy is not possible, so the urine samples of women are not tested.[124]

Very small amounts of hCG are normally present in men and non-pregnant women. Currently measurement is made by immunoassay. The decision limit, the concentration at which the test is considered positive, is set at 5 IU/mL urine. Trophoblastic tumors and nontro-phoblastic tumors can increase hCG concentrations, and this possibility must be considered in the evaluation of elevated urinary hCG concentration.[57]

Administration of hCG causes an increase in the total testosterone and epitestosterone produced.

OXYGEN TRANSPORT

■ ERYTHROPOIETIN (EPO)

Human erythropoietin (hEPO) is a hormone that, through a receptor-mediated mechanism, induces erythropoiesis by stimulating stem cells. Erythropoietin has been available since 1988 as recombinant human erythropoietin (rhEPO), and its use in international competition has been prohibited since 1990. While hEPO is produced primarily by the kidneys, rhEPO is produced in hamsters; this results in differing gly-cosylation patterns, an important piece in the laboratory detection of EPO in sports doping (see Laboratory Detection).[61]

Because EPO increases exercise capacity and hemoglobin produc-tion, it is used by athletes, often with additional iron supplementation. The clinical effects of increased hematocrit occur several days after administration.[78,168] EPO increases maximal oxygen uptake by 6%–7%, an effect that lasts approximately 2 weeks after rhEPO administration is completed.[65]

Two EPO analogs exist. Darbopoietin, also known as *new erythropoiesis-stimulating protein* (NESP), differs from EPO by five amino acids. It has a much longer half-life and can be injected weekly.[169] Another protein known as synthetic erythropoiesis protein (SEP) has a similar protein structure to EPO. The protein polymers created in this molecule have less immunogenicity, fewer biologic contaminants, and more predict-able pharmacokinetics.[169]

Human erythropoietin is secreted primarily by the kidney, although some is produced by other tissues, including the liver. The mean half-life of rhEPO is 4.5 hours following IV administration and 25 hours after subcutaneous administration.[196]

In patients with renal failure who are on dialysis, a typical dose is approximately 50 U/kg body weight given three times per week.[103,196] EPO enhances endothelial activation and platelet reactivity and increases systolic blood pressure during submaximal exercise.[23,217] These effects, in addition to the increase in hemoglobin, increase the risk for thromboembolic events, hypertension, and hyperviscosity syndromes.[23,151,168] Nineteen Belgian and Dutch cyclists died of uncer-tain causes between 1987 and 1990.[63] Increases in hematocrit subse-quent to EPO use are believed to have contributed to these deaths. The 1998 Tour de France was marred by the discovery of widespread EPO use by members of several different cycling teams.

An EPO overdose occurred in a patient who self-administered 10,000 U/d for an unknown period of time as a result of a dosing error. The patient presented to the hospital with confusion, a pletho-ric appearance, blackened toes, decreased pulses, and a hematocrit of 72%. Emergent erythropheresis was performed and resulted in rapid reduction of hematocrit and improvement in the patient's condition.[252] Another report of deliberate daily self-administration of an unknown dose of rhEPO resulted in a hematocrit of 70%. The patient was treated emergently with phlebotomy and intravenous hydration and improved.[32]

■ ARTIFICIAL OXYGEN CARRIERS

Artificial oxygen carriers are blood substitutes that supplement the oxygen-carrying capacity of RBCs.[204] Artificial oxygen carriers fall into two categories: hemoglobin-based oxygen carrier (HBOC) and perfluorocarbon (PFC) emulsions. Athletes may experiment with these substances to increase endurance.

Hemoglobin can be genetically engineered or obtained from cattle or outdated blood. Bovine hemoglobin may serve as a source for human HBOC products. Hemoglobin is composed of four subunits, two α-chains and two β-chains. When removed from erythrocytes, hemoglobin is unstable and dissociates into dimers. The life of HBOCs is much shorter than that of RBCs. In a meta-analysis of 16 trials of HBOCs, there is a 30% statistically significant increased risk of death and 2.7 times greater risk of myocardial infarction, regardless of the product.[162]

The differences in molecular weights of native hemoglobin and sta-bilized hemoglobin can be determined by size-exclusion high-performance liquid chromatography, which is one of the primary methods of doping analysis for HBOCs.[236]

■ PERFLUOROCARBONS

Perfluorocarbons are synthetic oxygen-carrying compounds that can be used as RBC substitutes. These liquids, which are composed of eight to ten carbon atoms with fluorine substitution for hydrogen, serve as excellent solvents for gases.[92] In 1966, it was shown that mice could sur-vive when fully submerged in PFCs infused with oxygen.[43] Compared to RBC transfusions, PFCs are without risk of infection, require no cross-matching, and do not increase the viscosity of blood. PFCs are stable at room temperature and have a shelf life of greater than 1 year, attributes that make them convenient to use.

Perfluorocarbons increase vascular tone, which may cause hyperten-sion. Both systemic and pulmonary vascular resistance is increased.[92] For unclear reasons, intravenous infusion of these emulsions can cause cardiac arrest.[227]

Because PFCs are perceived by the immune system as foreign sub-stances, they are rapidly cleared by the reticuloendothelial system. The plasma half-life is approximately 12 hours. PFCs accumulate in the liver and spleen and are slowly transported to the lung. Over a period of months to years, the PFCs are eliminated unchanged in the expired air and can be measured in expired air by thermal conductance or in blood by using gas chromatography-mass spectrometry.[204,227]

■ AUTOTRANSFUSION

Infusion of autologous blood (the athletes' own) or homologous blood (from a donor, also called *allogeneic* transfusion) for the purpose of increasing the hematocrit is known as *blood doping*. Blood doping was used in the Olympic Games as early as 1972 by a Finnish steeple-chaser. During subsequent summer and winter Olympics, distance runners, cyclists, and skiers acknowledged their use of this practice. The US cycling team admitted to using blood transfusions in the 1984 Olympics. Subsequently, the IOC banned the practice.

Blood doping is beneficial in endurance athletes. Infusion of 400 mL packed RBCs into distance runners increased the total RBC concentration

and substantially improved performance in 10-km races.[31] Blood doping also increases the speed performance of cross-country skiers.[22] The preparatory technique involves the removal of 1000 mL blood, the immediate replacement of plasma volume, and the freezing and storage of RBCs. After 5–6 weeks (the time needed to return to normocythemia), reinfusion of frozen RBCs resulted in increased hematocrit values from 45% to 49%, 5% increase in oxygen utilization, and increased endurance capacity.[64] Reinfusion of packed RBCs resulted overnight in an increase in maximal exercise work time of 23% and increased maximal oxygen uptake by 9%. These improvements correlated with the increase in hemoglobin concentration.[64]

Detection of homologous blood transfusion is possible based on red blood cell surface antigen typing. The surface of the erythrocyte contains genetically determined complex oligosaccharides and rhesus (Rh) polypeptides. Using flow cytometry complemented by enhanced separation of RBCs using signal amplification, histograms are created which visually represent distinct cell populations. In this way, the blood of one individual athlete may be discriminated from that of a donor.[223,238] Transplantation, transfusion, or a rare event in which an individual known as a chimera has a mixed red blood cell population are reported reasons for the presence of mixed populations of RBCs not due to doping; additionally, RBC agglutination may make interpretation of histograms uncertain. [87]

STIMULANTS

■ CAFFEINE

Caffeine is a CNS stimulant that causes a feeling of decreased fatigue and increases endurance performance[68,170] (Chap. 65). These changes may occur through several different mechanisms, including increased calcium permeability in the sarcoplasmic reticulum and enhanced contractility of muscle, phosphodiesterase inhibition and subsequent increased cyclic nucleotides, adenosine blockade leading to blood vessel dilation, and inhibited lipolysis. Caffeine is no longer on the 2008 WADA Prohibited List.[247]

■ AMPHETAMINES

The beneficial effects of amphetamines in sports result from their ability to mask fatigue and pain.[55] Initial studies of soldiers showed they could march longer and ignore pain when they took amphetamines.[228] In one study of college students, resting and maximal heart rates, strength, acceleration, and anaerobic capacity increased. However, although the perception of fatigue decreased, lactic acid continued to accumulate and maximal oxygen consumption was unchanged.[40] Other studies have shown no significant effects on exercise performance[120] (Chap. 75).

■ SODIUM BICARBONATE

Sodium bicarbonate loading, known as *soda loading,* has a long history of use in horse racing.[17] Sodium bicarbonate may buffer the lactic acidosis caused by exercise, thereby delaying fatigue and enhancing performance.[88]

During high-intensity exercise, metabolism becomes anaerobic and lactic acid is produced. Intracellular acidosis is said to contribute to muscle fatigue by reducing the sensitivity of the muscle contractile apparatus to calcium.[172] Several studies demonstrated improved running performance when sodium bicarbonate was ingested 2–3 hours before competition.[46,193] The study dose was 0.2–0.3 g/kg body weight of sodium bicarbonate, approximately 160 mEq NaHCO$_3$ per day. The

effects of sodium bicarbonate are greatest when periods of exercise last longer than 4 minutes because anaerobic metabolism contributes more to total energy production and energy from aerobic metabolism diminishes.[86,88] Adverse effects of bicarbonate loading include diarrhea, abdominal pain, and possible hypernatremia.[86]

An animal model demonstrated that intracellular acidosis, occurring as a consequence of lactate production, reversed muscle fatigue.[4,172] Previously, intracellular acidosis was thought to contribute to muscle fatigue by reducing the sensitivity of the muscle contractile apparatus to calcium, decreasing the force of muscle contraction. However, the mechanism of excitation–contraction is complex. Because it permeates membranes easily, chloride is an ion important for maintaining and stabilizing the muscle fiber resting membrane potential at normal pH. Because of this characteristic, a large sodium current is needed to overcome membrane stabilization and produce an action potential. In intracellular acidosis, membrane permeability to the chloride ion is reduced, the resting membrane potential is no longer stabilized, and less inward sodium influx is needed to produce an action potential. The excitability of the muscle T-tubule system is therefore increased by acidosis, protecting against muscle fatigue.[172]

DIURETICS

The World Anti-Doping Agency bans nonmedical diuretic use.[247] Diuretics are used in sports in which the athlete must achieve a certain weight to compete in discrete weight classes. In addition to weight loss, body builders find that diuretic use gives greater definition to the physique as the skin draws tightly around the muscles.[2] In one report a professional body builder attempted to lose weight using diuretics including bumetanide and spironolactone, and potassium supplements. He presented with hyperkalemia and hypotension[2] (Chap. 62). Diuretics also result in increased urine production, thereby diluting the urine and making more difficult the detection of other banned xenobiotics.[35,56]

MISCELLANEOUS XENOBIOTICS

■ CHROMIUM PICOLINATE

Chromium acts as a cofactor to enhance the action of insulin.[96] It is found naturally in meats, grains, raisins, apples, and mushrooms.[218] It is sold as chromium picolinate because picolinic acid is thought to enhance chromium absorption.[218] In people who are chromium deficient, chromium supplementation results in increased glycogen synthesis and glucose tolerance. Studies have not shown an increase in strength or a change in body composition or glucose metabolism when chromium is administered in a controlled fashion.[6,52] Anemia may result from chromium picolinate doses greater than 200 μg/d.[47] A 24-year-old body builder developed rhabdomyolysis after ingesting 1200 μg chromium picolinate, 6–24 times the daily recommended dose of 50–200 μg, over 48 hours.[150] Renal failure developed in one patient who took chromium picolinate 600 mcg/d for 6 weeks for weight reduction, which is 12–45 times the usual intake of dietary chromium and 3 times the recommended supplementation dose.[242] Another individual who took 1200–2400 μg/d chromium picolinate for the previous 4–5 months for weight loss presented with renal failure, liver dysfunction, anemia, thrombocytopenia, and hemolysis. Serum chromium concentrations were 2–3 times normal (Chap. 91). Other causes of the abnormalities were excluded, and laboratory parameters improved with cessation of chromium ingestion.[38]

LABORATORY DETECTION

Enormous amounts of energy and money are expended to determine the presence or absence of performance-enhancing substances. Analysis of samples on the international level is performed by a limited number of accredited laboratories. The majority of tests are performed on urine, with careful procedural requirements regarding handling of samples. Attention must be paid to proper storage of specimens, because bacterial metabolism may increase urinary steroid concentrations.[26,60] Upon the sample's arrival at the testing laboratory, the integrity of the sample is checked, including the code, seal, visual appearance, density, and pH. Registration of the sample is completed, and the sample is divided into two aliquots. All testing is done on the first aliquot, and any positive results are confirmed on the second aliquot. The aliquots are commonly referred to as sample A and sample B. Sample preparation is difficult and time consuming.

The complexity of the laboratory testing and continuous attempts to evade detection is illustrated in the discovery of an AAS previously undetectable by standard sport doping tests of urine. In the following situation, there was no preexisting reference data for the unknown xenobiotic. In the summer of 2003, a used syringe was provided anonymously to the United States antidoping authority. Through a painstaking process of analyses, an impurity in the substance in the syringe was identified as a derivative of the AAS norbolethone, a known reference compound, leading to the discovery, synthesis, and detection of tetrahydrogestrinone (THG), a new chemical previously unknown as a pharmaceutical or veterinary compound.[37] Since the discovery of THG, the identity of another designer steroid, madol, or desoxymethyltestosterone (DMT) was similarly discovered and the structure synthesized.[207]

■ CAPILLARY GAS CHROMATOGRAPHY/ MASS SPECTROMETRY

Capillary gas chromatography allows the determination of approximately 95% of all doping positive results. Gas chromatography typically is combined with mass spectrometry for detection of the majority of substances.[161] Analysis of the urine by gas chromatography-mass spectrophotometry (GC-MS) is the current standard for detection of anabolic androgenic steroids.[35] Such analysis relies on a large amount of previously derived reference data.[37]

■ TESTOSTERONE-TO-EPITESTOSTERONE (T/E) RATIO

Gas chromatography-mass spectrophotometry cannot distinguish endogenous testosterone from pharmaceutically derived exogenous testosterone. Therefore, other methods of detection are needed. One way of detecting the use of exogenous testosterone is to measure the ratio of testosterone to epitestosterone (T/E). Epitestosterone is not a metabolite of testosterone, but its 17-α epimer, differing from testosterone only in the configuration of the hydroxyl group on C-17. Men produce 30 times more testosterone than epitestosterone; however, 1% of testosterone and 30% of epitestosterone is excreted unchanged in the urine. Therefore, the normal T/E ratio in the urine is about 1:1.[216] A T/E ratio less than 4:1 is considered acceptable; a T/E ratio >greater than 4:1 is considered evidence of doping using testosterone. In order to maintain a normal T/E ratio, an athlete may self-administer both testosterone and epitestosterone.[36]

The overall pattern of the T/E ratio over time is important. Athletes subjected to testing will have previous measurements of their T/E ratios on record with antidoping authorities, or additional tests may be obtained to establish a pattern of T/E ratios. These results are plotted against time. The mean, standard deviation, and confidence values are calculated.[36] The confidence values of three or more samples taken over months will be less than 60% unless the athlete is using testosterone.[36] Sudden variations in an athlete's pattern of T/E ratios over time is a cause for further testing.

In one high-profile doping case where the T/E ratio was elevated, the athlete suggested that ethanol consumption the previous night had caused the elevated T/E ratio. In this regard, there is evidence that at very high doses, for example, 2 g/kg, ethanol increases the T/E ratio, although the T/E ratio did not exceed 6:1.[72] This effect of ethanol is more pronounced in females and is limited to 8 hours postingestion of ethanol. The mechanism of this effect of ethanol may be that it increases the NADH to NAD^+ ratio and many steroid oxidation–reduction reactions are dependent on the relative abundance of NADH to NAD^+.[72] Ketoconazole inhibits testosterone synthesis and may cause a decrease in the T/E ratio within 6 hours of administration.[125]

■ ISOTOPE RATIO MASS SPECTROMETRY (IRMS)

Carbon is made up of six protons and six neutrons, giving it an atomic weight of 12 (^{12}C). Sometimes carbon has an extra neutron, giving it an atomic weight of 13 (^{13}C). Carbon is derived from carbon dioxide in the atmosphere. Warm-climate plants, such as soy, process carbon dioxide differently than other plants, using different photosynthetic pathways for carbon dioxide fixation, causing the depletion of ^{13}C.[198] Pharmaceutical testosterone is made from plant sterols, primarily soy plants, and therefore has less ^{13}C isotope than endogenous testosterone, made in the body from a typical human diet based in corn and not soy. This difference in isotope ratios is measured by IRMS. An athletes' natural carbon makeup is determined by analysis of an endogenous reference compound such as the testosterone precursor cholesterol. Cholesterol may be called an "autostandard" because it represents the athlete's $^{13}C/^{12}C$ ratio.[21] Finally, it is the difference between the ratio of the athlete's $^{13}C/^{12}C$ ratio and an international standard ratio that is measured and reported.[1] Values are negative because both endogenous and pharmaceutical testosterone contain less ^{13}C than the international standard.[98]

■ GROWTH HORMONE

Growth hormone testing is plagued by the difficulties inherent in testing for exogenous peptide doping in general; the identical amino acid sequences of both rhGH and hGH; and the fluctuating, pulsatile secretion, short half-life, and variation in normal level depending on sleep, stress, and exercise status, to name a few. Unlike the ability to use the differing pattern of *N*-linked glycosylation in hEPO produced in the human kidney to distinguish it from rhEPO produced in the hamster, hGH has no *N*-linked glycosylation sites.

There are currently two approaches to detection of hGH; the marker approach and the isoform approach.[107] The marker approach uses an immunoassay to measure growth hormone–dependent factors through which growth hormone exerts its effect, such as insulin-like growth factor 1 (IGF-1) and insulin-like growth factor binding proteins (IGFBP), and other markers of bone growth and turnover, such as the N-terminal extension peptide of procollagen type III (PIIIP).[25,180] The isoform approach refers to the measurement of the various forms of growth hormone. Recombinant hGH is primarily a 22-kDa monomeric form; pituitary hGH contains multiple isoforms. In athletes using rhGH, endogenous hGH with its multiple isoforms is suppressed through negative feedback on the pituitary. Therefore, the 22-kDa form characteristic of rhGH becomes predominant. The ratio of isoforms changes, as measured by immunoassay.

ERYTHROPOIETIN

Erythropoietin is directly measured by a monoclonal anti-EPO antibody test, which does not distinguish between endogenously produced and exogenously administered recombinant EPO. Therefore, indirect methods of EPO detection are used, such as measurement of hemoglobin or hematocrit.

Previously, some sports-governing bodies, such as the International Cycling Federation and the International Skiing Federation, selected a hematocrit of 50% in men and 47% in women as the action level above which an athlete may be disqualified for presumed EPO use. However, normal hematocrit values vary greatly among athletes. Several studies have shown that hematocrits above the action values of 50% in men and 47% in women are common in athletes. From 3% to 6% of athletes who did not use EPO had hematocrits greater than 50%.[237] Of those athletes living and training at altitudes between 2000 m and 3000 m above sea level, 20.5% had hematocrit values greater than 50%.[237] Other studies confirm the increased hematocrits of athletes training at altitudes from 1000 m to 6000 m.[20,199,200,237]

Although many endurance athletes may have increased blood volume, the hematocrit may be lowered because of the increased plasma volume, which exceeds the RBC volume. This dilutional pseudoanemia is sometimes called *sports anemia*.[208] Additionally, hematocrit measurements are affected by hydration status, upright versus supine posture, and nutrition, and they demonstrate an approximately 3% diurnal variation.[201] Because of natural variations among individuals, postural effects, and the ease of manipulation through saline infusion, indirect detection of EPO use by hematocrit measurement is fraught with potential for error.[168]

Several methods have been studied to detect the use of recombinant EPO by athletes. The ratio between serum soluble transferrin receptors (sTfr) and ferritin was used as an indirect method for detection of EPO use. Soluble transferrin receptor is released from RBC progenitors. EPO stimulates erythropoiesis and causes an increase in sTfr and a decrease in ferritin.[83] Individuals with other causes of polycythemia or accelerated erythropoiesis also can exhibit increased ratios and be falsely accused of EPO use. An increased hematocrit with sTfr greater than 10 μg/mL and sTfr-to-serum protein ratio greater than 153 has been proposed as an indirect measurement of EPO use.[13]

At the 2000 Olympics in Sydney, Australia, a combination of multiple indirect markers was developed for detection of altered erythropoiesis of rhEPO use.[168] Current EPO use, known as the "ON-model," and recent, but not current, use of EPO, known as the "OFF-model," were identified by measured laboratory values. For example, five variables predict current rhEPO use: reticulocyte count, serum EPO concentration, sTfr, hematocrit, and percentage of macrocytes. The three-variable combination of hematocrit, reticulocyte count, and serum EPO concentration was the best mechanism for detecting recent rhEPO use.[168] A major drawback to this method is the instability of these variables in whole blood so that confirmatory testing of the split blood sample is impossible.[169]

State-of-the-art detection of EPO doping is accomplished with isoelectric focusing and immunoblotting performed on urine samples. The two isoforms of EPO, recombinant and endogenous, have different glycosylation patterns and glycan sizes resulting in differing molecular charges.[169] An immunoblotting procedure takes advantage of these different net charges, and the proteins can be separated by their charges when they are placed in an electric field.[135] Subsequently, isoelectric focusing obtains an image of EPO patterns in the urine.[134] WADA considers a positive urine test result definitive using this method, even without the blood testing of indirect markers.[169] Because of darbopoietin's structural similarity to EPO, these detection techniques also are effective for darbopoietin.[169]

INSULIN

Insulin laboratory detection methods are not yet standardized and accredited by WADA; therefore, athletes are not currently tested for insulin use. The technology for testing for insulin uses immunoaffinity purification followed by liquid chromatography-tandem mass spectrometry to identify analytes including urinary metabolites of insulin.[224] When insulin is modified to improve its receptor selectivity or give it other favorable properties, the change in molecular weight or amino acid profile from human insulin makes it detectable by GCMS.[224]

MASKING XENOBIOTICS

Any chemical or physical manipulation done with the purpose of altering the integrity of a urine or blood sample is prohibited by WADA.[247] For example, use of intravenous fluids for dilution of the sample, or urine substitution, is prohibited. Some agents are added to the urine available for the sole purpose of interfering with urine testing and are easily detected. Examples include Klear, which is 90% methanol, and Golden Seal tea, which produces colored urine.[30] Other commercially available products include Xxtra Clean, which contains pyridinium chlorochromate, and Urine Luck, which contains glutaraldehyde.

Niacin has been used to alter urine test results, although there is no evidence it is effective for this purpose. There are reports of niacin toxicity, including skin reactions such as itching, flushing, and burning, when niacin is used for this purpose.[8,156] More serious symptoms including nausea, elevated liver enzymes, hypoglycemia, and anion gap acidosis are reported as a result of ingesting niacin in large amounts, such as 2.5–5.5 grams over 1–2 days.[8,156]

A significant issue in the analysis of urine for the presence of prohibited peptides such as rhEPO is the masking potential of proteases surreptitiously added to urine specimens slated for doping analysis. The proteases are packaged in grains known as protease granules or "rice grains" and placed in the urethra.[223] Upon urination for the purpose of providing a specimen for doping analysis, the grain flows with urine into the specimen cup. The proteases, including trypsin, chymotrypsin, and papain, will quickly degrade renally excreted peptides, most notably erythropoietin, making them undetectable. By the process of autolysis, proteases may themselves become undetectable over time. In one report, urine with elevated protease concentrations greater than 15 μg/mL underwent further analysis to identify normal urinary proteins such as albumin.[223] Normally, the presence of urinary proteins creates the image of a visible band by gel electrophoresis. However, the urine with elevated protease activity may demonstrate something called *trace of burning*, a term used to describe the appearance of a blank lane with no bands, indicating an absence of proteins.[222] In this report, suspicious specimens were subjected to further testing using liquid chromatography–mass spectrometry (LC-MS). After further molecular sequencing of derived proteins, human proteases can be distinguished from nonhuman proteases, such as bovine chymotrypsin or papain. The addition of a protease inhibitor to urine samples immediately after collection may be a future strategy to control the effectiveness of protease addition as a masking method.[222]

Although a small amount of hEPO is most commonly found in urine, in approximately 15% of urine specimens, hEPO is undetectable. This is due in part to circumstances unrelated to doping, such as physiological variation in EPO production and very low or very high urine-specific gravity. However, doping with exogenous rEPO and inhibition of endogenous hEPO production is another possible cause. In any case, a urine deemed as suspicious based on low urinary proteins or the absence of hEPO may ultimately not result in a positive doping test result.[131,223]

The list of prohibited masking agents includes diuretics, epitestosterone, probenecid, plasma expanders such as albumin, dextran,

and hydroxymethyl starch, and α-reductase inhibitors such as finasteride and dutasteride.[247] Probenecid blocks urinary excretion of the glucuronide conjugates of AAS.

GENE DOPING

The discovery of the genetic codes for some diseases has made gene therapy of medical conditions, such as muscular dystrophy, a reality. It is now conceivable that this technology can be used to enhance athletic performance. Gene doping is included on the WADA 2008 Prohibited List. Gene doping is defined as "the non-therapeutic use of cells, genes, genetic elements, or of the modulation of gene expression, having the capacity to enhance athlete performance."[247] For example, insertion of a gene sequence could produce a desired effect, such as large muscles or increased body production of potentially advantageous substances such as testosterone or growth hormone. In animal models, genes for EPO lead to erythropoiesis, and genes for IGF-1 produce increased muscle size and strength.[19] Myostatin, which belongs to a family of proteins that control growth and differentiation of tissues in the body, inhibits skeletal muscle growth.[115,202] Mutations of the myostatin gene may result in muscle hypertrophy. In dogs, the athletic performance of racing whippets is enhanced in those animals with a myostatin gene mutation.[160] In humans, a report of an extremely muscular baby born with a mutation in the myostatin gene illustrates the potential effect of gene alterations on athletic performance. The mother of this infant was a professional athlete, and other members of the family were known for their strength.[202] Monoclonal antibodies capable of inhibiting myostatin gene activity may be useful in the treatment of muscular dystrophy. Several studies associate an increased frequency of polymorphism in the angiotensin-converting enzyme (ACE) gene, particularly the insertion (I-allele) of a 287 base-pair sequence, with increased endurance and power in athletes and high-altitude mountaineers.[85,226] The increased frequency of a single nucleotide change in the α actinin 3 (ACTN3) gene encoding for fast-twitch myofibrils in skeletal muscle is found in Greek Olympic-level power-oriented track and field athletes.[166,249]

Gene doping requires the transfer of genetic material into the athlete by the use of a vector. These vectors include viruses or nonviral synthetic vectors, known as *plasmids*.[229] Plasmid DNA vectors are grown alongside other proteins in bacterial cultures and later purified of contaminants. Gene transfer may take place outside of the body by taking cells from the individual, subsequently genetically altering the cells in culture, and then returning the altered cells to the individual.[243] This is known as *ex vivo* gene transfer and it is the basis of therapy for certain diseases, such as severe combined immunodeficiency.[95] In vivo gene transfer directly delivers the genetic information into the body using a vector. One of the difficulties in applying gene doping has been the dose of vector particles required to treat a human currently exceeds the production capacity of most laboratories. Other limitations to the practical application of gene doping in athletes include the risks of the vectors themselves, the uncontrolled expression of genes, the activation of the immune response to vectors, oncogenesis, and the adverse effects associated with the end product.[243] An example of the latter is the description of autoimmune anemia in macaques genetically altered to increased erythropoietin production.

SUMMARY

Although the press spotlights a few world-class athletes, the vast majority of individuals using performance-enhancing substances are not in the public view. Some individuals suffer adverse consequences. The knowledgeable clinician will identify these health effects when they occur and educate susceptible individuals on the risks of using performance-enhancing substances.

CHAPTER 45
FOOD POISONING

Michael G. Tunik

There are approximately 76 million cases of food poisoning in the United States every year, resulting in 325,000 hospitalizations and 5000 deaths.[39] Worldwide food distribution, large-scale national food preparation and distribution networks, limited food regulatory practices, and corporate greed place everyone at risk. Food poisoning causes morbidity and mortality by one or more of the following mechanisms: Infectious agents (eg, bacteria, viruses) can be transmitted in food; toxins, produced by organisms can be consumed in food; toxins or chemicals can inadvertently or purposefully contaminate food and be ingested.

This chapter is organized into four major types of food poisoning: foodborne poisoning with neurologic symptoms, foodborne poisoning with gastrointestinal symptoms, foodborne poisoning anaphylaxis-like symptoms, and foodborne poisoning used for bioterrorism.

HISTORY AND EPIDEMIOLOGY

In recent years in the United States *Salmonella* spp and *Escherichia coli* have become the major causes of food poisoning responsible for epidemics that worry millions, poison and hospitalize hundreds, and kill many unsuspecting innocent people.

The most common causes of foodborne disease include bacteria—*Salmonella* spp, *Campylobacter* spp, *Shigella* spp, and *E. coli*.[123] (Table 45–1). In the last decade, large numbers of people have also suffered from food poisoning due to purposeful placement of chemicals in food,[41] and staphyloccal toxin.[154]

FOODBORNE POISONING WITH NEUROLOGIC SYMPTOMS

The differential diagnosis of patients with foodborne poisoning presenting with neurologic symptoms is vast (Tables 45–2 and 45–3). The sources of many of these cases are ichthyosarcotoxic involving toxins from the muscles, viscera, skin, gonads, and mucous surfaces of the fish; rarely, toxicity follows consumption of the fish blood or skeleton. Shellfish poisoning also must be considered. Most episodes of poisoning are not species specific, although particular forms of toxicity from Tetraodontiformes (puffer fish), Gymnothoraces (moray eel), and newts (*Taricha* and other species) are recognized.

In cases of ciguatera poisoning, the major symptoms usually are neurotoxic, and the gastrointestinal (GI) symptoms are minor. Scombroid poisoning, which is exceptionally common, is not associated with focal neurologic manifestations, but facial flushing, headache, and dysphagia are its major signs and symptoms.

Knowing where the fish was caught often helps establish a diagnosis, but refrigerated transport of foods and rapid worldwide travel can complicate that assessment. Travelers to Caribbean and Pacific islands, as well as those traveling within the United States, have suffered from ciguatera poisoning.[94] In geographically disparate regions of Canada,[130] individuals have suffered from domoic acid poisoning due to ingestion of cultivated mussels from Prince Edward Island.

In the differential diagnosis of foodborne poisons presenting with neurologic symptoms, activities other than eating must always be considered. In particular, sport divers often perform their activities in high-risk areas such as Florida, California, and Hawaii, and often during the high-risk periods from May through August. In the process, they may sustain sting from a stingray tail, or laceration (from a deltoid or pectoral fin spine of a lionfish or stonefish) that can cause consequential marine toxicity (Chap. 120).

■ CIGUATERA POISONING

Ciguatera poisoning is one of the most commonly reported forms of vertebrate fishborne poisonings in the United States accounting for almost half of the reported cases.[123] Ciguatera poisoning is endemic to warm-water, bottom-dwelling shore reef fish living around the globe between 35° north and 35° south latitude, which includes tropical areas such as the Indian Ocean, the South Pacific, and the Caribbean. Hawaii and Florida report 90% of all cases occurring in the United States, most commonly from May through August.[98]

More than 500 fish species have caused human cases of ciguatera poisoning, with the barracuda, sea bass, parrot fish, red snapper, grouper, amber jack, kingfish, and sturgeon the most common sources. The common factor is the comparably large size of the fish involved.

Large fish (4–6 lb or more) become vectors of ciguatera poisoning in accordance with complex feeding patterns inherent in aquatic life. Ciguatoxin can be found in blue-green algae, protozoa, and the free algae dinoflagellates. These plankton members of the phylum Protozoa are single-celled, motile, flagellated, pigmented organisms thriving through photosynthesis. Photosynthetic dinoflagellates such as *Gambierdiscus toxicus* and bacteria within the dinoflagellates are the origins of ciguatoxin.[50,76,102] Dinoflagellates are the main nutritional source for small herbivorous fish which in turn are the major food source for larger carnivorous fish thereby increasing the ciguatoxin concentrations in the flesh, adipose tissue, and viscera of larger and larger fish.[11]

Ciguatoxin is heat stable, lipid soluble, acid stable, odorless, and tasteless. When purified, the toxin is a large (molecular weight 1100 Da) complex ester that does not harm the fish but is stored in its tissues.[98,103] The molecule binds to voltage-sensitive sodium channels in diverse tissues and increases the sodium permeability of the channel.[10,158] The ciguatoxins cause hyperpolarization and a shift in the voltage dependence of channel activation, which opens the sodium channels. Ciguatoxins bind selectively to a particular binding site on the neuron's voltage-sensitive sodium channel protein.[101]

Multiple ciguatoxins are identified in the same fish, perhaps explaining the variability of symptoms and differing severity.[102] People can be afflicted after eating fresh or frozen fish that was prepared by all common methods: boiling, baking, frying, stewing, or broiling. The appearance, taste, and smell of the ciguatoxic fish are usually unremarkable. The majority of symptomatic episodes begin 2–6 hours after ingestion, 75% within 12 hours, and 96% within 24 hours.[11] Symptoms include acute onset of diaphoresis; headaches, abdominal pain with cramps, nausea, vomiting; profuse watery diarrhea; and a constellation of dramatic neurologic symptoms.[175] A sensation of loose, painful teeth may occur. Typically, peripheral dysesthesias and paresthesias predominate. Watery eyes, tingling, and numbness of the tongue, lips, throat, and perioral area occur. A strange metallic taste is frequently reported as is a reversal of temperature discrimination, the pathophysiology of which remains to be elucidated.[28] Myalgias, most often in the lower extremities, arthralgias, ataxia, and weakness are commonly experienced.[11]

Dysuria[63] and symptoms of dyspareunia and vaginal and pelvic discomfort may occur in women after sexual intercourse with men who are ciguatoxic.[93] Vertigo, seizures, and visual disturbances of blurred vision, scotomata, and transient blindness) are reported.

TABLE 45–1. Epidemiology[36] of Foodborne Poisoning Reported to the CDC (1993–1997)

Etiology	Cases	Outbreaks	Deaths
Salmonella *spp*	32,610	357	13
Escherichia coli[a]	3,260	84	8
Clostridium perfringens	2,772	57	0
Other parasitic	2,261	13	0
Other viral	2,104	24	0
Shigella *spp*	1,555	43	0
Staphylococcus aureus	1,413	42	1
Norwalk virus	1,233	9	0
Hepatitis A virus	729	23	0
Bacillus cereus	691	14	0
Other bacterial	609	6	1
Campylobacter *spp*	539	25	1
Scombrotoxin	297	69	0
Ciguatoxin	205	60	0
Streptococcus, group A	122	1	0
Listeria monocytogenes	100	3	2
Clostridium botulinum	56	13	1
Glardia lamblia	45	4	0
Vibrio parahaemolyticus	40	5	0
Other chemical	31	6	0
Yersinia enterocolitica	27	2	1
Mushroom poisoning	21	7	0
Brucella	19	1	0
Trichinella spiralis	19	2	0
Heavy metals	17	4	0
Streptococcus, other	6	1	0
Shellfish	3	1	0
Vibrio cholerae	2	1	0
Monosodium glutamate	2	1	0

[a]The fatality rate of *E. coli* 0157:H7 increased dramatically in the late 1990s.

TABLE 45–2. Differential Diagnosis of Possible Foodborne Poisoning Presenting with Neurologic Symptoms

Anticholinergic poisoning
Bacterial food poisoning
Botulism
Eaton-Lambert syndrome
Metals
MSG (monosodium glutamate)
Organic phosphorous compounds
Plant ingestions (poison hemlock, buckthorn)
Tick paralysis

Bradycardia and orthostatic hypotension are described.[59] The GI symptoms usually subside within 24–48 hours; however, cardiovascular and neurologic symptoms may persist for several days to weeks, depending on the amount of toxin ingested. Delayed symptoms may include protracted itching and hiccoughs. Although internationally deaths are reported, none have been documented in the United States.[123] When it occurs, mortality is a result of respiratory paralysis and seizures not managed with adequate life support. Ciguatoxin may be transmitted in breast milk[20] and can cross the placenta.[128]

Laboratory analysis using an enzyme-linked immunosorbent assay (ELISA) test for ciguatera toxin can be performed; alternatively, high-pressure liquid chromatography (HPLC) is accurate. A dipstick immunobead assay test being developed for field use will allow testing of fish without laboratory processing of the toxin-containing tissues.[10,74,127] A useful approach to diagnosis and management using laboratory testing to exclude other diagnostic possibilities and determine the need for, or extent of, specific therapeutic interventions.

Initial treatment for victims of ciguatoxin poisoning includes standard supportive care for a toxic ingestion.[175] In most patients, elimination of the toxin is accelerated if vomiting (40%) and diarrhea (70%) have occurred. Administration of activated charcoal may be of some benefit. In patients with significant GI fluid loss through vomiting and/or diarrhea, intravenous fluid and electrolyte repletion are essential. The orthostatic hypotension may respond to intravenous fluids and α-adrenergic agonists. Bradycardia may be treated with atropine.[56]

Intravenous mannitol may alleviate neurologic and muscular dysfunctional symptoms associated with ciguatera; however, GI symptoms are not ameliorated.[126,129] In one randomized controlled trial, mannitol failed to produce any greater improvement in symptoms than did IV 0.9% sodium chloride solution.[147] Mannitol should be used with caution because it may cause hypotension. Vascular reexpansion and cardiovascular stability should be initial treatment priorities.

Admission to the hospital for cautious supportive care is essential when the diagnosis is uncertain or when volume depletion or any consequential manifestations are present (Tables 45–2 and 45–3). The etiology of the symptoms must be rapidly identified to provide specific therapy, if available. Diaphoresis is a common clinical finding and an important factor in the differential diagnosis. Late in the course of ciguatera poisoning, amitriptyline 25 mg orally twice daily may alleviate symptoms,[23] which may persist up to 1 year. Victims recovering from ciguatera should avoid alcohol for 3–6 months if exposure exacerbates symptoms.

■ CIGUATERA-LIKE POISONING

Moray, conger, and anguillid eels carry a ciguatoxin-like neurotoxin in their viscera, muscles, and gonads that does not affect the eel itself. The toxin is a complex ester that may be structurally very similar to ciguatoxin and is heat stable.[122] These same eels also possess an ichthyohemotoxin that is resistant to drying but can be destroyed by heating to >149°F (65°C). Individuals who eat these eels may manifest neurotoxic symptomatology similar to ciguatoxin or may show signs of cholinergic toxicity, such as hypersalivation, nausea, vomiting, and diarrhea. Shortness of breath, mucosal erythema, and cutaneous eruptions may occur. These findings may be present in addition to the neurotoxic symptoms.[69] Management is supportive. Mortality is related to the complications of neurotoxicity, such as seizures and respiratory paralysis.

■ SHELLFISH POISONING

Healthy mollusks living between 30° north and 30° south latitude ingest and filter large quantities of dinoflagellates. These dinoflagellates are the

TABLE 45–3. Common Toxicologic Foodborne Neurologic Diseases (Primary Presenting Symptoms)

	Onset/Duration*	Symptoms	Toxin Source/Toxin*/Mechanism**	Diagnosis/Therapy*
Ciguatera	2–30 h *Months to years	t, p, n, v, d	Large reef fish: amber jack, barracuda, snapper, parrot, sea bass, moray (dinoflagellate, source) *Ciguatoxin **Increased sodium channel permeability	Clinical, mouse bioassay, immunoassay *Supportive, mannitol, isotonic saline, amitriptyline
Tetrodotoxin	Minutes to hours *Days	p, r, ↓bp	Puffer fish, *fugu,* blue-ringed octopus, newts, horseshoe crab *Tetrodotoxin **Blocks sodium channel	*Clinical *Respiratory support
Neurotoxic shellfish poisoning	15 min to 18 h *Days	b, t, n, v, d, p	Mussels, clams, scallops, oysters, *P. brevis:* "red tide" *Brevetoxin **Increased sodium channel permeability	Clinical, mouse bioassay of food, HPLC
Paralytic shellfish poisoning	30 min *Days	r, p, n, v, d	Mussels, clams, scallops, oysters, *P. catanella, P. tamarensis* *Saxitoxin **Decreases sodium channel permeability	Clinical, mouse bioassay of food, HPLC *Respiratory support
Amnestic shellfish poisoning	15 min to 38 h *Years	a n, v, d, p, r	Mussels, possibly other shellfish; *N. pungens;* *Domoic acid **Glutamate analog	Clinical, mouse bioassay of food, HPLC *Respiratory support
Botulism	12–73 h	v, d, r, w	Home-canned foods, honey, corn syrups, *C. botulinum* *Botulinum toxin **Binds presynaptically, blocks acetylcholine release	Clinical immunoassay *Antitoxin, respiratory support

a = amnesia; b = bronchospasm; d = diarrhea; n = nausea; p = paresthesias; r = respiratory depression; t = temperature reversal sensation; v = vomiting; w = weakness; ↓bp = hypotension.

major source of available ocean food during the "non-R" months (May through August) in the northern hemisphere. During this time, these dinoflagellates are responsible for the "red tides" that may be seen from California to Alaska, from New England to the St. Lawrence, and across the west coast of Europe.[109] The number of toxic dinoflagellates may be so overwhelming that birds and fish die, and humans who walk along the beach may suffer respiratory symptoms caused by aerosolized toxin.[111]

Ingestion of shellfish, including oysters, clams, mussels, and scallops, contaminated by dinoflagellates or algae may cause neurotoxic, paralytic, and amnestic syndromes. The dinoflagellates most frequently implicated are *Karenia brevis* (originally named *Gymnodinium breve* in 1948, renamed *Ptychodiscus brevis* in 1979, and reclassified again to the current nomenclature in 2000). The diatoms causing neurotoxic shellfish poisoning include *Protogonyaulax catanella* and *Protogonyaulax tamarensis*, which cause paralytic shellfish poisoning; and *Nitzschia pungens*, the diatom implicated in amnestic shellfish poisoning. Proliferation of these diatoms may cause a red tide, but shellfish poisoning may occur even in the absence of this extreme proliferation.

Paralytic shellfish poisoning is caused by saxitoxin. Saxitoxin blocks the voltage-sensitive sodium channel in a manner identical to tetrodotoxin (see later). The shellfish implicated usually are clams, oysters, mussels, and scallops, but poisoning has occurred through consumption of crustaceans, gastropods, and fish.

The higher the number of shellfish consumed the more severe the symptoms. Symptoms usually occur within 30 minutes of ingestion. Neurologic symptoms predominate and include paresthesias and numbness of the mouth and extremities, a sensation of floating, headache, ataxia, vertigo, muscle weakness, paralysis, and cranial nerve dysfunction manifested by dysphagia, dysarthria, dysphonia, and transient blindness. GI symptoms are less common and include nausea, vomiting, abdominal pain, and diarrhea. Fatalities may occur as a result of respiratory failure, usually within the first 12 hours after symptom onset. Muscle weakness may persist for weeks.

Treatment is supportive. Early intervention for respiratory failure is indicated. Orogastric lavage and cathartics were used to remove unabsorbed toxin from the GI tract but probably are not necessary or efficacious.[26,99,115,152] Activated charcoal may be given. Antibodies against saxitoxin have reversed cardiorespiratory failure in animals,[14] but this therapy is not yet available for humans. Assays for saxitoxin include a mouse bioassay, ELISA, and HPLC. High-pressure liquid chromatography has good interlaboratory accuracy,[170] but the differences in saxitoxin derivatives make standardization of an analytic test difficult.[9,95]

Neurotoxic shellfish poisoning (NSP) is caused by brevetoxin. Brevetoxin, which is produced by *Karenia brevis* (previously *Gymnodium brevis*, and subsequently *Ptychodiscus brevis*), is a lipid-soluble, heat-stable polyether toxin similar to ciguatoxin. It acts by stimulating sodium flux through the sodium channels of both nerve and muscle.[6,29] NSP is characterized by gastroenteritis with associated neurologic symptoms. GI symptoms include abdominal pain, nausea, vomiting, diarrhea, and rectal burning. Neurologic features include paresthesias, reversal of hot and cold temperature sensation, myalgias, vertigo, and ataxia. Other symptoms may include headache, malaise,

tremor, dysphagia, bradycardia, decreased reflexes, and dilated pupils. Paralysis does not occur. The combination of bradycardia and mydriasis is unusual. The incubation period is 3 hours (range 15 minutes to 18 hours). GI and neurologic symptoms appear simultaneously. Other manifestations of brevetoxin poisoning include mucosal irritation, cough, and bronchospasm, which occur when *P. brevis* is aerosolized by wave action during red tides. Duration of symptoms averages 17 hours (range 1–72 hours).[115]

Brevetoxins can be assayed using mouse bioassay, ELISA, and, more recently, antibody radioimmunoassay (RIA) and reconstituted sodium channels.[132,167] Treatment is supportive, and severe respiratory depression is very uncommon. Therapy includes removal of the patient from the environment and the administration of bronchodilators. Neurotoxic shellfish poisoning is not fatal.

Amnestic shellfish poisoning is caused by domoic acid, a structural analogue of glutamic and kainic acids produced by the diatom *N. pungens*. The most extensively documented human outbreak occurred in Canada in 1987, when 107 individuals who had consumed mussels harvested from cultivated river estuaries on Prince Edward Island were affected.[130] Other human outbreaks may have occurred due to a similar diatom—*Pseudonitzschia australis*—which has been isolated in shellfish from other areas.[57] Pelican deaths caused by domoic acid–laden anchovies were reported in 1991 and Canada instituted monitoring for domoic acid after this outbreak.[163] The death of 400 sea lions in California in 1998 was linked to domoic acid from the diatom *N. pungens f multiseries*.[148]

Amnestic shellfish poisoning is characterized by GI symptoms of nausea, vomiting, abdominal cramps, diarrhea, and by neurologic symptoms of memory loss and, less frequently, coma, seizures, hemiparesis, ophthalmoplegia, purposeless chewing, and grimacing. Other signs and symptoms include hemodynamic instability and cardiac dysrhythmias. Symptoms typically begin 5 hours (range 15 minutes to 38 hours) after ingestion of mussels. The mortality rate is 2%, with death most frequently occurring in older patients, who suffer more severe neurologic symptoms. Ten percent of victims may suffer long-term antegrade memory deficits, as well as motor and sensory neuropathy. Postmortem examinations have revealed neuronal damage in the hippocampus and amygdala.[162]

TETRODON POISONING

This type of fish poisoning involves only the order Tetraodontiformes. Although this order of fish is not restricted geographically, it is eaten most frequently in Japan, California, Africa, South America, and Australia.[69] Cases have also occurred in Florida and New Jersey. Approximately 100 freshwater and saltwater species exist in this order, including a number of puffer-like fish such as the globe fish, balloon fish, blowfish, and toad fish.[117] Tetrodotoxin (TTX) found in these fish is also isolated from the blue-ringed octopus[54] and the gastropod mollusk,[177] and has also been responsible for fatalities from ingestion of horseshoe crab eggs.[79] Certain tetrodotoxin-containing newts (*Taricha, notophthalmus, triturus,* and *cynops*), particularly *Taricha granulosa*, found in Oregon, California, and southern Alaska, can be fatal when ingested. Most newts and salamanders with bright colors and rough skins contain toxins.[24] In Japan, *fugu* (a local variety of puffer fish) is considered a delicacy, but special licensing is required to prepare this exceedingly toxic fish. In 1989, the FDA legalized the importation of puffer fish. However, prior to exportation from Japan, the fish must be laboratory tested and certified by two Japanese organizations to be tetrodotoxin free.

Tetrodotoxin is a heat-stable (except in alkaline milieu), water-soluble nonprotein, found mainly in the fish skin, liver, ovary, intestine, and possibly muscle.[69,143] The ovary has a high concentration of the toxin and is most poisonous if eaten during the spawning season. Tetrodotoxin is detected by mouse bioassay. It is unstable when heated to 212°F (100°C) in acid, distinguishing it from saxitoxin. Tetrodotoxin from fish can be detected using fluorescent spectrometry[9] or from the urine of poisoned patients using a combination of immunoaffinity chromatography and fluorometric HPLC.[82]

Tetrodotoxin and saxitoxin are produced by marine bacteria and likely accumulate in animals higher on the food chain that consume these bacteria.[121] Accumulation of toxins, primarily in the skin, of two species of asian puffer fish has been documented. Whether this accumulation of toxin is simply an evolutionary adaptation, to remove a toxic substance, or one that has evolutionary advantages of protection is unclear.[120]

Neurotoxicity is produced by inhibition of sodium channels and blockade of neuromuscular transmission.[118] The sodium channel is blocked from the external surface of the neuron, by the TTX molecule which contains a guanidinium group that fits into the external orifice of sodium channel. This causes external "plugging" of the sodium channel, though the gating mechanism is functional.[119]

Symptoms of tetrodon poisoning typically occur within minutes of ingestion. Headache, diaphoresis, dysesthesias, and paresthesias of the lips, tongue, mouth, face, fingers, and toes evolve rapidly. Buccal bullae and salivation may develop. Dysphagia, dysarthria, nausea, vomiting, and abdominal pain may ensue. Generalized malaise, loss of coordination, weakness, fasciculations, and an ascending paralysis (with risk of respiratory paralysis) occur in 4–24 hours. Other cranial nerves may be involved. In more severe toxicity, hypotension is present. In some studies, mortality has approached 50%.[155]

Therapy is supportive. Removal of the toxin and prevention of absorption are the essential measures. Supportive respiratory care emphasizing airway protection, including intubation, if necessary, is extremely important.

LESS COMMON POISONINGS: ECHINODERMS

The sea urchin usually causes toxicity by contact with its spinous processes, but this Caribbean delicacy also is toxic upon ingestion. When the sea urchin is prepared as food, the venom-containing gonads should be removed because they contain an acetylcholine-like substance that causes the cholinergic syndrome of profuse salivation, abdominal pain, nausea, vomiting, and diarrhea. The sea star is considered edible by some individuals, although an asteriotoxin with saponin-like activity that produces nausea and vomiting is reported.

PREVENTION OF MARINE FOODBORNE DISEASE

Careful evaluation of the symptoms and meticulous reporting to local and state health departments, as well as to the Centers for Disease Control and Prevention (CDC), will allow for more precise analysis of epidemics of poisoning from contaminated or poisonous food or fish. Many states and countries have developed rigorous health codes with regard to harvesting certain species of fish in certain areas at certain times.

Some examples of actions taken by state and foreign health agencies in controlling epidemics of seafood-borne food poisoning are the following: A 3230-km stretch of Massachusetts coastline was noted to be unsafe for shellfish harvesting due to a red tide bloom. The state declared a health emergency and confiscated shellfish harvested in this area, and prohibited the marketing, export, and serving of shellfish.[109] The health code of Miami, Florida prohibits the sale of barracuda and warns against eating fillets from large and potentially toxic fish

containing ciguatoxin. The Japanese closely regulate preparation and selling of the puffer fish (fugu), requiring that preparers receive special training and licensing. The sale of fugu is now also permitted under strict control in the United States as well. The Canadian government marks the location and time of harvesting of mussels, and mussels are tested for the presence of domoic acid.[57,130]

FOODBORNE POISONING ASSOCIATED WITH DIARRHEA

The initial differential diagnosis for acute diarrhea involves several etiologies: infectious (bacterial, viral, parasitic, and fungal), structural (including surgical), metabolic, functional, inflammatory, toxin induced, and food induced. The differential diagnosis is described in greater detail in Chap. 25.

An elevated temperature may be caused by invasive organisms, including *Salmonella* spp, *Shigella* spp, *Campylobacter* spp, invasive *E. coli*, *Vibrio parahaemolyticus*, and *Yersinia* spp, as well as some viruses. Episodes of acute gastroenteritis not associated with fever can be caused by organisms producing toxins, including *Staphylococcus*

aureus, Bacillus cereus, Clostridium perfringens, enterotoxigenic *E. coli,* and viruses.[3]

Fecal leukocytes typically are found in patients with invasive shigellosis, salmonellosis, Campylobacter enteritis, typhoid fever, invasive *E. coli* colitis, *V. parahaemolyticus*, *Yersinia enterocolitica*, and ulcerative colitis. In all of these conditions, except typhoid fever, the leukocytes are primarily polymorphonuclear; in typhoid fever, they are mononuclear. No stool leukocytes are noted in cholera, viral diarrhea, noninvasive *E. coli* diarrhea, or nonspecific diarrhea.[73]

The timing of diarrhea onset after exposure or the incubation period can be useful in differentiating the cause. Extremely short incubation periods of less than 6 hours are typical for *Staphylococcus, B. cereus* (type I), enterotoxigenic *E. coli*,[3,106,161] and pre-formed enterotoxins, as well as roundworm larvae ingestions. Intermediate incubation periods of 8–24 hours are found with *C. perfringens*, *B. cereus* (type II enterotoxin), enteroinvasive *E. coli*,[48,113] and salmonella. Longer incubation periods are seen in other bacterial causes of acute gastroenteritis (Table 45–4).

The three most likely etiologies of diarrhea are infectious, xenobiotics, and foodborne. These three etiologies are not mutually exclusive. The differential diagnosis must be made among these groups. When

TABLE 45–4. Common Foodborne Disease: Gastrointestinal (Primary Presenting Symptom)

Etiology	Symptoms						Source	Pathogenesis	Therapy
	Onset	A	V	Di	Dy	F			
Staphylococcus spp	2–6 h	+	+	+	–	–	Prepared foods: meats, pastries, salads	Heat-stable enterotoxin	Supportive, Volume expansion
Bacillus cereus									
Type I	1–6 h	+	+	+	–	–	Fried rice	Heat-labile toxins	Supportive, Volume expansion
Type II	12 h	+	–	+	–	–	Meats, vegetables	Heat-labile toxins	
Anisakiasis	1–12 h	+	+	–	–	–	Raw fish, sushi, Eustrongyloides, minnows, salmon, cod, herring, squid, tuna	Intestinal larvae	Endoscopy Laparotomy Removal
Clostridium perfringens	8–24 h	+	±	+	±	–	Poultry, heat-processed meats	Heat-labile enterotoxin	Volume expansion
Salmonella spp	8–24 h	±	±	+	±	+	Poultry, egg Pets (turtles, lizards, chicks)	Bacteria, endotoxin (bactermia)	Antibiotics
E. coli	24–72 h						Water, food	Enterotoxin, heat stable	Volume expansion
Enterotoxigenic	<6h	+	±	+	–	+	Enteric contact		Electrolytes
Invasive		+	–	+	+	+	Raw produce	Bacteria (invasive)	Antibiotics
Hemorrhagic		+	+	+	+	±	Under cooked beef Unpasteurized milk	Shigalike toxin	Renal, hematologic support
Vibrio cholera	24–72 h	±	±	+	–	±	Water, food Enteric contact	Enterotoxin Heat labile	Electrolyte replacement, antibiotics
Shigella spp	24–72 h	+	±	+	+	±	Institutional food handler Household, preschool, enteric contact	Bacteria Endotoxin	Antibiotics
Campylobacter jejuni	1–7 d	+	+	+	±	+	Milk, poultry Unchlorinated water	Bacteria, Heat-labile enterotoxin	Antibiotics
Yersinia spp	1–7 d	+	+	+	±	+	Pork, milk, pets	Bacteria, Enterotoxin	Antibiotics

A = abdominal pain; Di = diarrhea; Dy = dysentery; F = fever; V = vomiting.

the time from exposure to onset of symptoms is brief, all of the nonbacterial infectious etiologies (viral, parasitic, fungal, and algal) except for upper GI invasion by roundworm larvae can be eliminated. The possibility of a bacterial etiology with enterotoxin production should be considered (Table 45–4).[3,21]

EPIDEMIOLOGY

Epidemiologic analysis is of immediate importance, particularly when GI diseases strike more than one person in a group. The questions raised in Table 45–5 must be answered.[142] If available, an infectious disease consultant or infection control officer should be called for assistance. Alternatively, assistance from state and local health departments should be sought. Often, only the CDC or state health department has the resources to investigate and confirm a presumptive diagnosis in an outbreak. Sophisticated techniques such as toxin detection, matching the organism in the food by phage type with a food handler, matching an organism by phage type with other persons, isolating 10 or more organisms per gram of implicated food,[48,52] or PCR identification of bacterial or plasmid DNA are potentially useful, although generally not possible using the laboratory and personnel available in most hospitals.[27,32,64] Structural, metabolic, and functional causes often can be eliminated. As in these diseases, neither a significant grouping of cases nor a limited clinical history is characteristic. Foodborne parasites such as *Trichinella spiralis* (trichinosis), *Toxoplasma gondii* (toxoplasmosis), and *G. lamblia* (giardiasis) must be considered, although acute GI symptoms are not usually prominent.

■ *SALMONELLA* SPECIES

Salmonella enteritidis infections are of great concern in the United States. Two particular outbreaks define very special problems. In the 1980s, recurrent outbreaks associated with grade A eggs or food containing such eggs occurred. In the past, such outbreaks of salmonella enteritis were attributed to infection of the egg with salmonella (from the chicken's GI tract) through cracks in the shell. More recently,

outbreaks have involved noncracked, nonsoiled eggs.[114] In these cases, presumably the salmonella has infected the eggs before the shell was formed. In either case, people who consume raw or undercooked eggs are at most risk for salmonella enteritis. Raw eggs can be found as ingredients of chocolate mousse, hollandaise sauce, eggnog, caesar salads, and homemade ice cream. Whole, partially cooked eggs are eaten sunny side up or poached.[37] The second group of outbreaks was associated with raw milk,[133] which has become very popular in certain communities. Inadequate microwave cooking may cause small outbreaks.[52] These outbreaks are of great concern because they frequently involve multiple drug-resistant salmonella infections.[45] Drinking pasteurized milk may not be protective. An outbreak of salmonellosis resulting in more than 16,000 culture-proven cases was traced to one Illinois dairy. The probable cause of the outbreak was a transfer line connecting raw and pasteurized milk containment tanks.[139]

The contamination of food that is widely distributed places thousands at risk. A recent outbreak of salmonella food poisoning from peanut butter caused 529 confirmed illnesses in 48 states and Canada, 116 hospitalizations, and possibly 8 deaths.[40] The CDC estimates that the proportion of salmonella infections that are confirmed by laboratory testing is 3% of the total, so the estimated number of infected people affected by this contamination incident may be more than 15,000. News reports state that the peanut butter contamination with salmonella was known, and that the peanut butter was retested for contamination, until no salmonella was reported. The peanut butter was then distributed nationally.[72]

Additional concern has developed over the widespread use of antibiotics in animal feed, responsible for meats, poultry, and manure-fertilized vegetables now frequently containing resistant bacterial strains to which virtually the entire population may be exposed.[45,139] "Household" pets such as chicks, turtles, and iguanas carry salmonella and frequently transmit the organism to household contacts, including infants, who are at particular risk for invasive diseases, as well as other family members.[1]

FOODBORNE POISONING ASSOCIATED WITH GASTROENTERITIS, ANEMIA, THROMBOCYTOPENIA, AND AZOTEMIA

The hemolytic uremic syndrome (HUS) is frequently caused by a bacterial gastroenteritis. The most commonly responsible organism is *E. coli* O157:H7.[66] Other bacteria producing a Shigalike toxin can cause the same findings, and other xenobiotics also implicated in causing HUS include estrogen-containing oral contraceptives, mitomycin C, cyclosporin A, and radiation therapy.[131] Nontoxicologic causes of this same clinical picture include autoimmune disease, Kawasaki syndrome, and bacterial enteritis/sepsis leading to disseminated intravascular coagulopathy and shock.

Laboratory findings typically include microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. Hyperkalemia, metabolic acidosis, hyponatremia, and hypocalcemia also are found. Hepatic aminotransferase concentrations may be elevated, and pancreatic involvement may produce hyperamylasemia, elevated lipase concentration, and hyperglycemia.

Most children with HUS are younger than 6 years, and many are younger than 2 years. HUS begins with a prodrome of diarrhea 90% of the time. The diarrhea lasts for 3–4 days and frequently becomes bloody. Abdominal pain due to colitis is common, and vomiting, altered mental status (irritability or lethargy), pallor, and low-grade fever frequently occur. At the time of presentation, many children have oliguria or anuria. Approximately 10% of children present with a generalized seizure at the onset of HUS.[151]

TABLE 45–5. Epidemiologic Analysis of Gastrointestinal Disease

1. Is the occurrence of the disease in a large group significant enough to be consistent with foodborne disease (two or more cases)?
2. Is the symptomatology in affected individuals well defined and similar?
3. Is the onset, time, and duration of illness similar among affected group members (incubation)?
4. What are the possible modes of transmission (ie, contact, food, water)?
5. Is there a relationship between the time of exposure of the group and the mode of transmission?
6. Do attack rates differ for age, gender, or occupation?
7. Can it be determined which foods were served and to whom? Can the items which were not eaten by those who did not become ill be identified?
8. What is the food-specific attack rate?
9. How was the food procured? How was it stored?
10. Was cooking technique adequate?
11. Was personal hygiene acceptable?
12. Was there animal contamination?

Postdiarrheal HUS is endemic in Argentina.[105] Frequent epidemics occur in North America, and many of these reports describe the association of enterohemorrhagic *E. coli* (EHEC) or *E. coli* O157:H7 with postdiarrheal HUS.[25,108,124,125,137,172] Postdiarrheal HUS occurs most frequently during the summer months, matching the peak incidence of positive stool cultures in cattle (the most common source of the organism).[70] Food products from cattle (ground beef, milk, yogurt, cheese) and water contaminated with fecal material are common sources.[47,70,110] Contaminated water used in gardens and unpasteurized apple cider have caused bloody diarrhea and HUS as a result of EHEC.[16,44]

Enterohemorrhagic *E. coli*, including *E. coli* O157:H7, produces a toxin similar to the toxin produced by *Shigella dysenteriae* type I, referred to as Shigalike toxin (SLT) or verotoxin.[21] The proposed mechanism for SLT damage is intestinal absorption, bloodstream access to renal glomerular endothelium, intracellular adsorption via glycolipid receptors, ribosomal inactivation, and cell death.[160] In animal models, organ damage is more severe if endothelial cells have high concentrations of globotriaosylceramide receptors, which have a high binding affinity for shiga toxin. Other organs with these receptors include the renal, GI, and central nervous systems, which may explain the pattern of organ damage in children with HUS. Endothelial cell damage and other pathologic processes, including platelet and leukocyte activation, triggering of the coagulation cascade, and the production of cytokines, occur.[81,169] More than one type of SLT exists; SLT-1, SLT-2, and variants of SLT-2 structure have been identified.[17]

Detection of *E. coli* O157:H7 through stool culture early in the course of disease is useful. The recovery decreases after the first week of illness.[131,160] *E. coli* O157:H7 almost always produces SLT; therefore, if stool cultures are negative, enzyme immunoassay (EIA) and polymerase chain reaction (PCR) tests can be used to detect SLT in the stool when *E. coli* can no longer be identified by culture.[27]

Treatment of HUS should focus on meticulous supportive care, with fluid and electrolyte balance the priority. Peritoneal dialysis or hemodialysis should be instituted early for azotemia, hyperkalemia, acidosis, and fluid overload. Red blood cells transfusions maintain hemoglobin concentrations greater than 6 g/dL and platelet transfusion may be necessary to maintain hemostasis, especially important measures before invasive procedures are undertaken. Hypertension should be treated with short-acting calcium channel blockers (nifedipine 0.25–0.5 mg/kg/dose orally) and seizures with benzodiazepines. The many therapies used for HUS include heparin, fibrinolytics, IV immunoglobulin, fresh-frozen plasma, vitamin E, and antiplatelet agents. However, none has been obviously beneficial, and some have been deleterious.[165] Plasmapheresis has been used in nondiarrheal HUS and in recurrent HUS after renal transplants. In a controlled trial, antibiotics did not change the course or outcome for children with postdiarrheal HUS.[134] A meta-analysis also found no increased risk from antibiotic therapy.[140] Anti–SLT-2 antibodies have protected mice from SLT-2 toxicity, but IV immunoglobulin with SLT-2 activity has not improved outcome in children with HUS. A double-blind, placebo-controlled study on the use of synthetic SLT receptors attached to an oral carrier found that mortality or serious morbidity of HUS syndrome did not change as a result.[166]

The mortality from HUS with good supportive care is approximately 5%; another 5% of victims suffer end-stage renal disease or cerebral ischemic events and chronic neurologic impairment. Prolonged anuria (>1 week), oliguria (>2 weeks), or severe extrarenal disease may serve as markers for higher mortality and morbidity.[131]

Strategies to prevent the spread of *E. coli* O157:H7 and subsequent HUS include public education on the importance of thorough cooking of beef to a "well-done" temperature of 170°F (77°C), pasteurization of milk and apple cider, and thorough cleaning of vegetables. Public health measures include education of clinicians to consider *E. coli* O157:H7 in patients with bloody diarrhea and insuring the routine capability of microbiology laboratories to culture *E. coli* O157:H7 and provide for EIA or PCR determination of SLT. Public health departments should provide active surveillance systems to identify early outbreaks of *E. coli* O157:H7 infection.

■ *STAPHYLOCOCCUS* SPECIES

In cases of suspected food poisoning with a short incubation period, the physician should first assess the risk for staphylococcal causes. The usual foods associated with staphylococcal toxin production include milk products and other proteinaceous foods, cream-filled baked goods, potato and chicken salads, sausages, ham, tongue, and gravy. Pie crust can act as an insulator, maintaining the temperature of the cream filling and occasionally permitting toxin production even during refrigeration.[4] A routine assessment must be made for the presence of lesions on the hands or nose of any food handlers involved. Unfortunately, carriers of enterotoxigenic staphylococci are difficult to recognize because they usually lack lesions and appear healthy.[75] A fixed association between a particular food and an illness would be most helpful epidemiologically but rarely occurs clinically. Factors such as environment, host resistance, nature of the agent, and dose make the results surprisingly variable.

Although patients with staphylococcal food poisoning rarely have significant temperature elevations, 16% of 2992 documented cases in a published review had a subjective sense of fever.[75] Abdominal pain, nausea followed by vomiting, and diarrhea dominate the clinical findings. Diarrhea does not occur in the absence of nausea and vomiting. The mean incubation period is 4.4 hours with a mean duration of illness of 20 hours. Two staphylococcal enterotoxin food poisoning incidents involving large numbers of people have been reported. At a public event in Brazil in 1998, half of the 8000 people who attended suffered nausea, emesis, diarrhea, abdominal pain, and dizziness within hours of consuming food. Of the ill patients, 2000 overwhelmed the capacity of local emergency departments, 396 (20%) were admitted including 81 to intensive care units, and 16 young children and elderly participants died.[154] In another report, 328 individuals became ill with symptoms of diarrhea, vomiting, dizziness, chills, and headache after eating cheese or milk.[153] In both reports, staphylococcus enterotoxin was found in the food consumed.

Most enterotoxins are produced by *S. aureus* coagulase–positive species. The enterotoxins initiate an inflammatory response in GI mucosal cells and lead to cell destruction. The enterotoxins also may exert a sudden explosive effect on the emesis center in the brain and diverse other organ systems. Discrimination of unique *S. aureus* isolates from those found in foodborne outbreaks can be made using restriction fragment length polymorphism analysis by pulsed-field gel electrophoresis and PCR techniques.[173]

■ *CAMPYLOBACTER JEJUNI*

Campylobacter jejuni, a curved Gram-negative rod, is a major cause of bacterial enteritis. The organism is most commonly isolated in children younger than 5 years and in adults 20–40 years. Campylobacter enteritis outbreaks are more common in the summer months in temperate climates. Although most cases of *Campylobacter enteritis* are sporadic, outbreaks are associated with contaminated food and water. The most frequent sources of *Campylobacter* in food are raw or undercooked poultry products[53] and unpasteurized milk.[31,167] Birds are a common reservoir, and small outbreaks are associated with contamination of milk by birds pecking on milk-container tops.[156] Contaminated water supplies are also frequent sources of Campylobacter enteritis involving

large numbers of individuals.[19] *C. jejuni* is heat labile; cooking of food, pasteurization of milk, and chlorination of water will prevent human transmission.

The incubation period for *Campylobacter enteritis* varies from 1–7 days (mean 3 days). Typical symptoms include diarrhea, abdominal cramps, and fever. Other symptoms may include headache, vomiting, excessive gas, and malaise. The diarrhea may contain gross blood, and leukocytes are frequently present on microscopic examination.[73] Illness usually lasts 5–6 days (range 1–8 days). Rarely, symptoms last for several weeks. Severely affected individuals present with lower GI hemorrhage, abdominal pain mimicking appendicitis, a typhoid-like syndrome, reactive arthritis, or meningitis. The organism may be detected using PCR identification techniques.[61] Treatment is supportive, and consists of volume resuscitation, and possibly quinolone antibiotics for the more severe cases.[3]

■ GROUP A *STREPTOCOCCUS*

Bacterial infections not usually associated with food or food handling are nevertheless occasionally transmitted by food or food handling. Transmission of streptococcal pharyngitis in food prepared by an individual with streptococcal pharyngitis has been demonstrated.[46] A Swedish food handler caused 153 people to become ill with streptococcal pharyngitis when his infected finger wound contaminated a layer cake served at a birthday party.[7]

■ *CLOSTRIDIUM BOTULINUM*

In the last 3 decades, a median of 4 cases of foodborne botulism, 3 cases of wound botulism, and 71 cases of infant botulism have been reported annually to the CDC.[150] Home-canned fruits and vegetables, as well as commercial fish products, are among the common foods causing botulism. The incubation period usually is 12–36 hours; typical symptoms include some initial GI symptoms, followed by malaise, fatigue, diplopia, dysphagia, and rapid development of small muscle incoordination.[96] In botulism, the toxin is irreversibly bound to the neuromuscular junction, where it impairs the presynaptic release of acetylcholine.[90] A patient's survival depends on a rapidly diagnosing botulism and immediate initiation of aggressive respiratory therapy. Establishing the diagnosis early may make it possible to treat the "sentinel" patient and also others who consumed the contaminated food with antitoxin prior to their developing signs and symptoms (Chap. 46 and Antidotes in Depth A8: Botulinum Antitoxin). The differential diagnosis of botulism includes myasthenia gravis, atypical Guillain-Barré syndrome, tick-induced paralysis, and certain chemical ingestions (see Tables 46-1 and 46-2).

■ *YERSINIA ENTEROCOLITICA*

Yersinia enterocolitica is a Gram-negative coccobacillus that causes enteritis most frequently in children and young adults. Typical clinical features include fever, abdominal pain, and diarrhea, which usually contains mucus and blood.[8,159,171] Other associated symptoms include nausea, vomiting, anorexia, and weight loss. The incubation period may be 1 day to 1 week or more. Less common features include prolonged enteritis, arthritis, pharyngeal and hepatic involvement, and rash. Yersinia is a common pathogen in many animals, including dogs and pigs. Sources of human infection include milk products, raw pork products, infected household pets, and person-to-person transmission.[22,68,97] Diagnosis may be based on cultures of food, stool, blood, and, less frequently, skin abscesses, pharyngeal cultures, or cultures from other organ tissues (mesenteric lymph nodes, liver). Yersinia may be identified by PCR.[80] Patients receiving the chelator deferoxamine may

aquire yersinia infections due to the patients increased susceptibility. The deferoxamine-iron complex acts as a siderophore for the organism growth. Therapy is usually supportive, but patients with invasive disease (eg, bacteremia, bacterial arthritis) should be treated with IV antibiotics. Fluoroquinolones and third-generation cephalosporins are highly bacteriocidal against *Yersinia* spp.

■ *LISTERIA MONOCYTOGENES*

Listeriosis transmitted by food usually occurs in pregnant women and their fetuses, the elderly, and immunocompromised individuals using corticosteroids or with malignancies, diabetes mellitus, renal disease, or HIV infection.[15,34,36,146] Typical food sources include unpasteurized milk, soft cheeses such as feta, and undercooked chicken. Individuals at risk should avoid the usual sources and should be evaluated for listeriosis if typical symptoms of fever, severe headache, muscle ache, and pharyngitis develop. Treatment with IV ampicillin or trimethoprim–sulfamethoxazole is indicated for systemic listerial infections.

■ XENOBIOTIC-INDUCED DISEASES

In addition to the aforementioned saxitoxin tetrodotoxin, domoic acid, and ciguatoxin, many other xenobiotics contaminate our food sources. Careful assessment for possible foodborne pesticide poisoning is essential. For example, aldicarb contamination has occurred in hydroponically grown vegetables and watermelons contaminated with pesticides.[65] Eating malathion-contaminated chapatti and wheat flour resulted in 60 poisonings including a death in one outbreak[42] (Chap. 113). Insecticides, rodenticides, arsenic, lead, or fluoride preparations can be mistaken for a food ingredient. These poisonings usually have a rapid onset of signs and symptoms after exposure.

The possibility of unintentional acute heavy-metal ingestion must also be considered. This type of poisoning most typically occurs when very acidic fruit punch is served in metal-lined containers. Antimony, zinc, copper, tin, or cadmium in a container may be dissolved by an acid food or juice medium.

■ MUSHROOM-INDUCED DISEASE

Some species produce major GI effects. *Amanita phalloides,* the most poisonous mushroom, usually causes GI symptoms as well as hepatotoxic effects with a delay to clinical manifestations. The rapid onset of symptoms suggests some of the gastroenterotoxic mushrooms (Chap. 117).

■ INTESTINAL PARASITIC INFECTIONS

The popularity of eating raw fish, a popular form of Japanese cuisine, has led to an increase in reported intestinal parasitic infections. The etiologic agents typically are roundworms (*Eustrongyloides anisakis*) and fish tapeworms (*Diphyllobothrium* spp). Symptoms of anisakiasis, or eustrongylidiasis, that are localized to the stomach typically occur 1–12 hours after eating raw fish, whereas symptoms of lower intestinal involvement may be delayed for days or weeks. Typical gastric or intestinal symptoms include nausea, vomiting, and severe crampy abdominal pain that may mimic a gastric ulcer. Typical lower intestinal symptoms include abdominal cramping and, with perforation of the intestinal wall by the larvae, severe localized abdominal pain, rebound, and guarding, which may mimic an acute abdomen (appendicitis). In some cases, the symptoms include anaphylaxis with or without abdominal pain. Without an adequate dietary history of eating raw fish, the diagnosis may be almost impossible to establish and therapy might instead be directed toward the most likely diagnostic entity such as gastric ulcer or appendicitis. Diagnosis of parasitic infection usually

is established by visual inspection of the larvae (on endoscopy, laparo-tomy, or pathologic examination), which typically are pink or red. Raw fish that may contain *Eustrongyloides* include minnows (*Fundulus* spp) and other bait fish. *Anisakis simplex* and *Pseudoterranova decipiens* are Anisakidae that may be found in several types of frequently consumed raw fish, including mackerel, cod, herring, rockfish, salmon, yellowfin tuna, and squid. Reliable methods of preventing ingestion of live anisakid larvae are freezing –4°F (–20°C) for 60 hours or cooking at 140°F (60°C) for 5 minutes.[31,87,104,138,144,176]

Diphyllobothriasis (fish tapeworm disease) is caused by eating uncooked fish that harbor the parasite. Hosts include, but are not limited to, herring, salmon, pike, and whitefish. The symptoms are less acute than with intestinal roundworm ingestions and usually begin 1–2 weeks after ingestion.[30] Signs and symptoms include nausea, vomiting, abdominal cramping, flatulence, abdominal distension, diarrhea, and megaloblastic anemia. Diagnosis is based on a history of ingesting raw fish and on identification of the tapeworm proglottids in stool. Treatment with niclosamide, praziquantel, or paromomycin usually is effective.[35]

Yet another foodborne toxin with GI symptoms is associated with eating reheated fried rice. *Bacillus cereus* type I is the causative organism, and bacterial overgrowth and toxin production causes consequential early onset nausea and vomiting.[2] Infrequently this toxin causes liver failure.[107] *Bacillus cereus* type II has a delayed onset of similar GI symptoms, including diarrhea.[58]

■ MONOSODIUM GLUTAMATE

The so-called Chinese restaurant syndrome results from the ingestion of monosodium glutamate (MSG). Affected individuals present with a burning sensation of the upper torso, facial pressure, headache, flushing, chest pain, nausea and vomiting, and, infrequently, life-threatening bronchospasm[3] and angioedema.[157] Intensity and duration of symptoms are generally dose related but with significant variation in individual responses to the amount ingested.[145,178] MSG causes "shudder attacks" or a seizure-like syndrome in young children. Absorption

is more rapid following fasting, and the typical burning symptoms rapidly spread over the back, neck, shoulders, abdomen, and occasionally the thighs. GI symptoms are rarely prominent and symptoms can usually be prevented by prior ingestion of food. When symptoms do occur, they tend to last approximately 1 hour. The syndrome is a reaction to MSG, which had traditionally been commonly used in Chinese restaurants in the past but frequently used in many other restaurants. MSG is also marketed as an effective flavor enhancer.[13] Many sausages and canned soups contain heavy doses of MSG.

MSG (regarded as "safe" by the FDA) can cause other acute and bizarre neurologic symptoms. There is evidence that humans have a unique taste receptor for glutamate.[89] This explains its ability to act as a flavor enhancer for foods. Glutamate is also an excitatory neurotransmitter which can stimulate central nervous system neurons through activation of glutamate receptors, and may be the explanation for some of the neurologic symptoms described with ingestion.[179]

■ ANAPHYLAXIS AND ANAPHYLACTOID PRESENTATIONS

Some foods and foodborne toxins may cause allergic or anaphylacticlike manifestations,[83] also sometimes referred to as "restaurant syndromes"[149] (Table 45-6). The similarity of these syndromes complicates a patient's future approach to safe eating. Isolating the precipitant is essential so that the risk can be effectively assessed. Manufacturers of processed foods should provide an unambiguous listing of ingredients on package labels. Sensitive individuals (or in the cases of children their parents) must be rigorously attentive.[141,180] Those who experience severe reactions should make sure that epinephrine and antihistamines are always available immediately. Attempts to prevent allergic reactions to dairy products by avoiding dairy-containing foods may fail. Nondairy foods may still be processed in equipment used for dairy products or contain flavor enhancers of a dairy origin (eg, partially hydrolyzed sodium caseinate), both of which can cause morbidity and death in allergic individuals.[60] Individuals with known food allergies do not always carry prescribed autoinjectable spring-injected epinephrine

TABLE 45–6. Common Foodborne Disease Symptoms: Flushing, Bronchospasm, Headache (Primary Presenting Symptoms)

	Onset	Symptoms/Signs	Cause	Therapy
Anaphylaxis (anaphylactoid)	Minutes to hours	Urticaria, angioedema, bronchospasm, hypotension	Allergens–nuts, eggs, milk, fish, shellfish, peanuts, soy	Oxygen, epinephrine, β_2-adrenergic agonist, Corticosteroids, volume expansion, H_1, H_2 histamine blockers
MSG (monosodium glutamate)	Minutes	Flushing, hypotension, palpitations, facial pressure, headaches, bronchospasm, shivering (Children)	Flavor enhancer of foods	Oxygen, β_2-adrenergic agonists, volume expansion, avoidance
Metabisulfites	Minutes	Flushing, hypotension, bronchospasm	Preservative in wines, salad (bars), fruit juice, shrimp	See Anaphylaxis, Avoidance
Scombroid	Minutes to hours	Flushing, hypotension urticaria, headache, pruritis, GI symptoms	Large fish–poorly refrigerated; tuna, bonito, albacore, mackerel, mahi mahi (histidine)	See Anaphylaxis, Avoidance
Tyramine	Minutes to hours	Headache, hypertension (INH or MAOI) increases risk	Wines, aged cheeses	Avoidance for those with hypertension, migraines
Tartrazine	Hours	Urticaria, angioedema, brochospasm	Yellow coloring food additive	See Anaphylaxis, Avoidance

INH = isoniazid; MAOI = monoamine oxide inhibitor.

syringes, in some cases from a belief that the allergen is easily identifiable and avoidable.[83] Food additives that can cause anaphylaxis include antibiotics, aspartame, butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), nitrates or nitrites, sulfites, and paraben esters.[100] Regulation of these preservatives is limited, and agents such as sulfites are so ubiquitous that predicting which guacamole, cider, vinegar, fresh or dried fruits, wines, or beers contain these sensitizing agents may be impossible.

■ SCOMBROID POISONING

Scombroid poisoning originally was described with the Scombroidae fish (including the large dark-meat marine tuna, albacore, bonito, mackerel, and skipjack). However, the most commonly ingested vectors identified by the CDC are nonscombroid fish, such as mahi mahi and amber jack.[33] All of the implicated fish species live in temperate or tropical waters. Ingestion of bluefish in New Hampshire was the probable cause of scombroid poisoning in five people,[51] and mackerel was the likely offender in 28 cases reported from a prison.[50] The incidence of this disease is probably far greater than was originally perceived. This type of poisoning differs from other fishborne causes of illness in that it is entirely preventable if the fish is properly stored following removal from the water.

Scombroid poisoning results from eating cooked, smoked, canned, or raw fish. The implicated fish all have a high concentration of histidine in their dark meat. *Morganella morganii, E. coli,* and *Klebsiella pneumoniae,* commonly found on the surface of the fish, contain a histidine decarboxylase enzyme that acts on a warm (not refrigerated), freshly killed fish, converting histidine to histamine, saurine, and other heat-stable substances. Although saurine has been suggested as the causative toxin, chromatographic analysis demonstrates that histamine is found as histamine phosphate and saurine is merely histamine hydrochloride.[55,116] The term *saurine* originated from saury, a Japanese dried fish delicacy often associated with scombroid poisoning. The extent of spoilage usually correlates with histamine concentrations. Histamine concentrations in healthy fish are less than 0.1 mg/100 g fish meat. In fish left at room temperature, the concentration rapidly increases, reaching toxic concentrations of 100 mg/100 g fish within 12 hours.

The appearance, taste, and smell of the fish are usually unremarkable.[5] Rarely, the skin has an abnormal "honeycombing" character or a pungent, peppery taste that may be a clue to its toxicity (Chap. 20). Within minutes to hours after eating the fish, the individual experiences numbness, tingling, or a burning sensation of the mouth, dysphagia, headache, and, of particular significance for scombroid poisoning, a unique flush characterized by an intense diffuse erythema of the face, neck, and upper torso.[84] Rarely, pruritus, urticaria, angioedema, or bronchospasm ensues. Nausea, vomiting, dizziness, palpitations, abdominal pain, diarrhea, and prostration may develop.[43,62,84,112]

The prognosis is good with appropriate supportive care and parenteral antihistamines such as diphenhydramine. H_2-receptor antagonists such as cimetidine or ranitidine may also be useful in alleviating gastrointestinal symptoms.[18] The toxic substance should be removed or absorbed from the gut. Inhaled β_2-adrenergic agonists and epinephrine may be necessary if bronchospasm is prominent. Patients usually show significant improvement within a few hours.

Elevated serum or urine histamine concentrations can confirm the diagnosis, but are usually unnecessary. If any uncooked fish remains, isolation of causative bacteria from the flesh is suggestive, but not diagnostic. A capillary electrophoretic assay makes rapid histamine detection possible.[108] Histamine concentrations greater than 50 mg/100 g fish meat are considered hazardous by the US Food and Drug Administration (FDA). Isoniazid may increase the severity of the reaction to scombroid fish by inhibiting enzymes that break down histamine.[77,168]

Patients may be reassured that they are not allergic to fish if other individuals experience a similar reaction to eating the same fish at the same time, or if any remaining fish can be preserved and tested for elevated histamine concentrations. If this information is not available, an anaphylactic reaction to the fish must be considered. Table 45-4 lists the differential diagnosis of flushing, bronchospasm, and headache. Because many people often consume alcohol with fish, alcohol must be considered an independent variable.

The differential diagnosis of the scombrotoxic flush apart from a disulfiram-like reaction includes ingestion of niacin or nicotinic acid, and pheochromocytoma. The history and clinical evolution usually establish the diagnosis quickly.

■ GLOBAL FOOD DISTRIBUTION, ILLEGAL FOOD ADDITIVES

Xenobiotics are given to animals to increase their health and growth. Clenbuterol, a β_3 agonist, has been administered to cattle raised for human consumption. The substance can cause toxicity in humans who eat contaminated animal meat. Tachycardia, tremors, nausea, epigastric pain, headache, muscle pain, and diarrhea were present in 50 poisoned patients. Other findings included hypertension and leukocytosis.[136] No deaths have been reported. The use of antibiotics, β_3 agonists, and other growth enhancers continues, despite safety concerns and laws against their use, because these practices increase yield and profit.

The globalization of food supplies and international agricultural trade has created a new global threat, the apparent purposeful contamination of food for profit. In 2008, almost 300,000 children in China were affected by melamine contamination of milk. Of these 50,000 were hospitalized and 6 reported deaths occurred.

The melamine-contaminated milk was sold in China as powdered infant formula, with over 22 brands containing melamine. The contamination was not limited to China, as melamine has been found in candy, chocolate, cookies, and biscuits sold in the United States, likely due to the adulteration of milk used in preparation of these products.

Melamine is a non-nutritious nitrogen-containing compound, usually used in glues, plastics, and fertilizers. To increase profits, milk sold in China had previously been diluted, causing protein malnutrition in children. Because the nitrogen content of milk (a surrogate measure for protein content) is now carefully monitored to detect dilution and to prevent another episode of malnutrition, melamine was added to increase the measured nitrogen content and hide the dilution. This purposeful addition of melamine is suspected to be the cause of the melamine contamination of powdered milk in China.

Melamine and its metabolite cyanuric acid are excreted in the kidneys. Renal stones containing melamine and uric acid were found in 13 children with acute renal failure, who had consumed melamine containing milk formula.[67] Both melamine and cyanuric acid appear necessary to cause renal stones in animals. The combination alone caused renal crystals in cats.[135] Melamine found in wheat gluten that was added to pet food in 2007, and resulted in thousands of complaints, and dozens of suspected animal deaths in the United States.

The full extent of the melamine milk contamination, and the number of people affected is not yet known.[41,78]

Food products from all over the world find their way into our foods. Increased vigilance by the agencies responsible for food safety, both in countries where the food originates and in countries that import the food are needed to prevent other events such as the melamine contaminations.

■ VEGETABLES AND PLANTS

Plants, vegetables, and their diverse presentations often are involved in food poisonings.[71,85,86,91,92] Edible plants and plant products may be

poorly cooked or prepared, or they may be contaminated. Extensive discussion of this may be found in Chap. 118.

FOOD POISONING AND BIOTERRORISM

The threat of terrorist assaults has received increased attention and is discussed in Chaps. 131 and 132. The use of food as a vehicle for intentional contamination with the intent of causing mass suffering or death has already occurred in the United States.[38,88,164] In the first report, 12 laboratory workers suffered GI symptoms, primarily severe diarrhea, after consuming food purposefully contaminated with *Shigella. dysenteriae* type II[88] served in a staff break room. Four workers were hospitalized; none had reported long-term sequelae. This *Shigella* strain rarely causes endemic disease. Nevertheless an identical strain, identified by pulsed-field gel electrophoresis, was found in 8 of the 12 symptomatic workers, as well as in the pastries served in the break room, and in the laboratory stock culture of *S. dysenteriae*. This finding suggests purposeful poisoning of food eaten by laboratory personnel. The person responsible and the motive remain unknown.

The second case series describes a large community outbreak of food poisoning caused by *Salmonella typhimurium*.[164] The outbreak occurred in the Dalles, Oregon area during the fall of 1984; a total of 751 people suffered salmonella gastroenteritis. The outbreak was traced to the intentional contamination of restaurant salad bars and coffee creamer by members of a religious commune using a culture of *S. typhimurium* purchased before the outbreak of food poisoning. A criminal investigation found a salmonella culture on the religious commune grounds that contained *S. typhimurium* identical to the salmonella strain found in the food poisoning victims. It was identified by using antibiotic sensitivity, biochemical testing, and DNA restriction endonuclease digestion of plasmid DNA. Only after more than 1 year of investigation was this salmonella outbreak linked to terrorist activity. Reasons for the delay in identifying the outbreak as a purposeful food poisoning included (1) no apparent motive; (2) no claim of responsibility; (3) no pattern of unusual behavior in the restaurants; (4) no disgruntled restaurant employees identified; (5) multiple time points for contamination indicated by epidemic exposure curves, suggesting a sustained source of contamination and not a single act; (6) no previous event of similar nature as a reference; (7) the likeliness of other possibilities (eg, repeated unintentional contamination by restaurant workers); and (8) fear that the publicity necessary to aid the investigation might generate copycat criminal activity.

Publication of the event was delayed by almost 10 years out of fear of unintentionally encouraging copycat activity. On the other hand, use of biological weapons by the Japanese cult Aum Shinrikyo appears to have motivated authorities to release this publication in the hopes of quickly identifying similar deliberate food poisoning patters in the future.

A third report describes a disgruntled employee who contaminated 200 lb of meat at a supermarket with a nicotine-containing insecticide.[38] Ninety-two people became ill, and four sought medical care. Symptoms included vomiting, abdominal pain, rectal bleeding, and one case of atrial tachycardia.

In another case of human greed, a Chinese restaurant owner poisoned the food in his neighbor's restaurant with tetramine. Tetramine or tetramethylenedisulfotetramine is a highly lethal neurotoxic rodenticide, once used worldwide, now illegal in the United States. The snack shop owner caused hundreds to become ill and 38 deaths by spiking his competitors breakfast offerings (fried dough sticks, sesame cakes, and sticky rice balls). Tetramethylenedisulfotetramine is odorless and tasteless white crystal that is water soluble. The mechanism of action is noncompetitive irreversible binding to the chloride channel on the γ-aminobutyric acid receptor complex, which blocks the influx of chloride, and alters the neurons potential. It is referred to as a "cage convulsant" because of its globular structure. Severe intoxication presents with tachycardia, arrhythmias, agitation as well as status epilepticus and coma. Immediate or early treatment with sodium-(RS)-2,3-dimercaptopropane-1-sulfonate and pyridoxine (vitamin B6) appears to be effective in a mouse model.[12,49,174]

The capacity of foodborne xenobiotics that are easy to obtain and disburse to infect large numbers of people is clearly exemplified by two specific outbreaks: (1) the purposeful salmonella outbreak in Oregon, (2) the apparently unintentional salmonella outbreak that resulted in more than 16,000 culture-proven cases traced to contamination in an Illinois dairy. The probable cause of the outbreak was a contaminated transfer pipe connecting the raw and pasteurized milk containment tanks.[139] These events emphasize the vulnerability of our food supply and the importance of ensuring its safety and security.

SUMMARY

The diverse etiologies of food poisoning involve almost all aspects of toxicology. Our concerns center around the natural toxicity of plant or animal, the contamination of which can occur in the field, during factory processing, subsequent transport and distribution, or during home preparation or storage. Whether these events are intentional or unintentional, they alter our approaches to general nutrition and society. Issues in food safety include government's role in food preparation and protection, bacteria such as salmonella and *E. coli* 0157:H7, prions in Creutzfeldt-Jacob disease (bovine encephalopathy), and genetically altered materials such as corn. Future discussions of food poisonings and interpretations of the importance of these problems may dramatically alter our food sources and their preparation and monitoring.

CHAPTER 46
BOTULISM

Howard L. Geyer

Botulism, a potentially fatal neuroparalytic illness, has been recognized since the 18th century. It results from botulinum neurotoxin (BoNT), the most potent toxin known, which is produced by *Clostridium botulinum* and other *Clostridium* species. The toxin interferes with release of acetylcholine from presynaptic motor and autonomic nerve terminals, thereby disrupting neuromuscular transmission and autonomic synapses, resulting in flaccid paralysis and autonomic dysfunction. In adults, most cases are foodborne, resulting from ingestion of toxin, while most cases in infants result from ingestion of bacterial spores which proliferate and produce toxin in the gastrointestinal tract. Less common forms of botulism include wound botulism, in which spores are inoculated into a wound and locally produce toxin, and inhalational botulism due to aerosolized BoNT, potentially used as a weapon of bioterrorism. Therapeutic injections of BoNT may result in transient adverse effects, but serious sequelae are rare when BoNT is properly prepared and administered.

HISTORY AND EPIDEMIOLOGY

The earliest cases of botulism were described in Europe in 1735 and were attributed to improperly preserved German sausage; the name of the disease alludes to this association, *botulus* being Latin for *sausage*. Emile van Ermengem identified the causative organism in 1897 and named it *Bacillus botulinum*; it was later renamed *Clostridium botulinum*.[25] These Gram-positive, spore-forming bacteria produce seven serotypes of BoNT, denoted A through G. All clostridial species are ubiquitous, and the bacteria and spores are present in soil, seawater, and air.[130] Botulism outbreaks can occur anywhere in the world[118] and have been reported from such diverse areas as Iran,[106] Japan,[100] Thailand,[73] France,[1] Portugal,[77] and Canada.[94]

In 2007, a total of 144 cases of botulism were reported to the Centers for Disease Control and Prevention (CDC). Foodborne botulism constituted 18% of cases, infant botulism 63% of cases, and wound botulism 15%.[42] In this analysis, toxin type A accounted for the majority of cases of both foodborne (58%) and wound (82%) botulism, while infant botulism was due to toxin type A in 43% and to toxin type B in 56% of cases.[42] Six deaths were confirmed: three in patients with foodborne botulism and three in patients with wound botulism. The case fatality rate has improved for all botulism toxin types, probably due to increasing awareness of the problem and consequent earlier diagnosis, appropriate and early use of antitoxin, and better and more accessible life support techniques.

In the last 50 years, home-processed food has accounted for 65.1% of outbreaks, with commercial food processing constituting only 7% of reported cases; in the other 27.9% of outbreaks the origin remains unknown.[38] Common home-canning errors responsible for botulism include failure to use a pressure cooker and allowing food to putrefy at room temperature. Minimally processed foods such as soft cheeses may lack sufficient quantities of intrinsic barriers to BoNT production, such as salt and acidifying agents.[112] These foods become high-risk sources of botulism when refrigeration standards are violated. The US Food and Drug Administration (FDA) continuously reviews recommendations for appropriate measures to process such foods.[142,143]

Outbreaks of botulism have been associated with specialty foods consumed by different ethnic groups: chopped garlic in soy oil by Chinese in Vancouver, British Columbia;[94,136] uneviscerated salted fish—called *kapchunka*—eaten by Russian immigrants in New York City;[34,140] and the same fish—called *faseikh*—eaten by Egyptians in Egypt.[151] The incidence of botulism is high in Alaska where traditional foods include fermented fish and fish eggs, seal, beaver, and whale; between 1990 and 2000, 39% of cases of foodborne botulism occurred in Alaska.[133] Approximately 90% of toxin type E outbreaks have occurred in Alaska because of home-processed fish or meat from marine animals,[41,48,79,150] while one incident occurred in New Jersey.[35] In the 1990s, three cases of botulism involved members of a Native American church after they ingested a ceremonial tea made from the buttons of dried, alkaline-ground peyote cactus that were prepared in a water-covered refrigerated jar. The resultant alkaline and anaerobic milieu presumably fostered the growth of toxin from naturally occurring spores.[66] In 1996, eight cases of foodborne botulism in Italy were linked to mascarpone cream cheese eaten either alone or in tiramisu contaminated with BoNT type A.[14] In 2006, carrot juice was implicated in four cases in Georgia and Florida.[37] Ten cases in California, Indiana, Ohio, and Texas were linked to commercially processed chili sauce in 2007.[44] Awareness of evolving trends and unusual presentations or locations of botulism permits the establishment of preventive education programs.

Among cases attributed to commercial food processing, vegetables (peppers, beans, mushrooms, tomatoes, and beets, with or without meat) were thought to be the causative agents in approximately 70%, meat in 17%, and fish in 13% of cases.[38] Although only 4% of foodborne botulism is associated with food purchased in restaurants, restaurant-related outbreaks usually affect large numbers of individuals.[79]

Of 26 reported cases of botulism in 2007, 16 occurred in multicase outbreaks.[42] Among hundreds of outbreaks from 1975 to 1988 totaling more than 400 persons, approximately 70% involved only one person, 20% involved two persons, and only 10% involved more than two persons (mean 2.7 cases per outbreak).[155] Single affected patients were more severely ill, with 85% requiring intubation, compared to only 42% requiring intubation in multiperson outbreaks.[155] It may be that diagnosis in the index case leads to more rapid therapeutic intervention for associated cases.

Infant botulism is most common in certain geographic areas, presumably due to higher concentrations of botulinum spores in soil. Raw honey is a potential source of spores.[95] Most affected infants are younger than 6 months of age. Of 91 cases reported in 2007, most were from California (40%), Pennsylvania (14%), and New Jersey (11%). The median age was 15 weeks, and no deaths were reported.[42] With appropriate support and treatment, a favorable outcome is achieved in the majority of cases.

In 2007, 22 cases of wound botulism were reported; 20 of those cases occurred in California. Ages ranged from 23 to 58 years, with a median of 42 years. All but two were known to be injection drug users. Three patients died, and outcome information was unavailable for three others.[42]

Since 2001, concern about the use of inhalational BoNT as a biologic weapon has increased. In ways unimaginable when the first edition of this chapter was published, medical and public health realities associated with terrorism in the 21st century unfortunately have resulted in increased relevance of botulism to medical practitioners (Chap. 132). Concern regarding potential adverse consequences of therapeutic BoNT injections also has developed.[11]

BACTERIOLOGY

The genus *Clostridium* comprises a group of four spore-forming anaerobic Gram-positive bacillary species that produce seven different neurotoxic proteins: *C. botulinum,* which produces all BoNT serotypes A through G; *Clostridium baratii,* which produces toxin type F; *Clostridium butyricum,* which produces toxin type E; and *Clostridium argentinense,* which produces toxin type G.[67,124,129] Rare instances of both adult and infant botulism are attributed to *C. baratii* and *C. butyricum.*[65,88,101,108] The reported incidence of cases due to BoNT type F may be underestimated because of the only recent capacity of most laboratories to determine the presence of *C. baratii* and other clostridial species producing toxin type F.[65]

Toxin types A through G, with Cα and Cβ subtypes, have been identified to date. In the United States, toxin type A is found in soil west of the Mississippi,[81] type B is found east of the Mississippi, particularly in the Allegheny range, and type E is found in the Pacific northwest and the Great Lakes states.[36,130] Toxin types A and B typically are found in poorly processed meats and vegetables. Toxin type E is commonly found in raw or fermented marine fish and mammals. Toxin types C and D cause disease in birds and mammals. Toxin type G has not been associated with naturally occurring disease. Although botulinum toxins differ in the cellular molecules they target, the ultimate pathophysiology and clinical syndromes are identical.

All botulinum spores are dormant and highly resistant to damage. They can withstand boiling at 212°F (100°C) for hours, although they usually are destroyed by 30 minutes of moist heat at 248°F (120°C). Factors that promote germination of spores in food are pH greater than 4.5, sodium chloride content less than 3.5%, or a low nitrite concentration. Most viable organisms produce toxin in an anaerobic milieu with temperatures greater than 80.6°F (27°C), although some strains produce toxins even when conditions are not optimal. *C. botulinum* organisms can produce toxin type E at temperatures as low as 41°F (5°C). To prevent spore germination, acidifying agents such as phosphoric or citric acid are added to canned or bottled foods that have a low acid content, such as green beans, corn, beets, asparagus, chili peppers, mushrooms, spinach, figs, olives, and certain nonacidic tomatoes. Unlike the spores, the toxin itself is heat labile and can be destroyed by heating to 176°F (80°C) for 30 minutes or to 212°F (100°C) for 10 minutes. At high altitudes, where the boiling point of water may be as low as 202.5°F (94.7°C), a minimum of 30 minutes of boiling may be required to destroy the toxin. Under high-altitude conditions, pressure cooking at 13–14 lb of pressure often is necessary to achieve appropriate temperatures to destroy the toxin.

Food contaminated with *C. botulinum* toxin types A and B may look or smell putrefied because of the action of proteolytic enzymes.[64] In contrast, because toxin type E organisms are saccharolytic and not proteolytic, food contaminated with toxin type E may look and taste normal.[18]

PHARMACOKINETICS AND TOXICOKINETICS

BoNT is the most poisonous substance known. The LD_{50} for mice is 3 million molecules injected intraperitoneally. The human oral lethal dose is 1 μg/kg.[117]

Foodborne botulism results from ingestion of preformed BoNT from food contaminated with *Clostridium* spores. The toxin is complexed to associated proteins (hemagglutinins and a nontoxic nonhemagglutin)[129] which protect it from the acidic and proteolytic environment in the stomach. In the intestine, the alkaline pH dissociates the toxin from the associated proteins, allowing for subsequent absorption into the bloodstream.[92] Because the toxin is often demonstrated only in the stool, determining what percentage of the toxin actually is absorbed is difficult.[52,54] The median incubation period for all patients is 1 day, but ranges from 0–7 days for toxin type A, 0–5 days for toxin type B, and 0–2 days for toxin type E.[155]

Infant botulism results not from ingestion of preformed BoNT but from ingestion of *C. botulinum* spores, which germinate in the gastrointestinal tract and produce toxin. The immaturity of the bacterial flora in the infant GI tract facilitates colonization by the *Clostridia.* Adults with altered GI flora can also develop botulism in the same way; onset of symptoms typically follows ingestion by a month or two. A single case of foodborne botulism associated with home-canned baby food has been reported in a 6-month-old infant.[6]

In wound botulism, spores proliferate in a wound or abscess and locally elaborate toxin. The incubation period is typically less than 2 weeks but may be as long as 51 days.[70]

The duration of action of the BoNT types may vary, depending on the components of the neurotransmitter release apparatus that are disrupted (see Pathophysiology). The persistence of clinical effect may result from the individual cleavage target, the intraneuronal biological half-life of the toxin, or both. Current evidence indicating intraneuronal toxin metabolism or elimination is inadequate.[128]

PATHOPHYSIOLOGY

BoNT is produced as a protein consisting of a single polypeptide chain with a molecular weight of 900 kDa, which includes a 750-kDa nontoxic protein and a 150-kDa neurotoxic component. To become fully active, the single-chain polypeptide 150-kDa neurotoxin must undergo proteolytic cleavage to generate a dichain structure consisting of a heavy chain (100 kDa) linked by a disulfide bond to a light chain (50 kDa). The dichain form of the molecule is responsible for all clinical manifestations.[67,28] It appears that both the single polypeptide chain toxin and the dichain form both are resistant to gastrointestinal degradation.[82]

The ingested toxin binds to serotype-specific receptors on the mucosal surfaces of gastric and small intestinal epithelial cells, where endocytosis followed by transcytosis permits release of the toxin on the serosal (basolateral) cell surface.[75,83] The dichain form travels intravascularly to peripheral cholinergic nerve terminals, where it binds rapidly and irreversibly to the cell membrane and is taken up by endocytosis. The heavy chain is responsible for cell-specific membrane binding to acetylcholine-containing neurons.[104]

Once inside the cell, the light chain acts as a zinc-dependent endopeptidase to cleave presynaptic membrane polypeptides that are essential components of the soluble *N*-ethylmaleimide-sensitive factor attachment receptor (SNARE) apparatus which subserves acetylcholine exocytosis, thereby inhibiting release.[117] BoNT types specifically cleave different proteins belonging to the SNARE family, and these differences may be responsible for their variable toxicity.[126] SNARE proteins targeted by proteolysis include vesicle-associated membrane protein (VAMP, also known as synaptobrevin) localized on synaptic vesicles, syntaxin found on the presynaptic membrane, and synaptosomal-associated protein (SNAP)-25 which is attached to syntaxin and to the presynaptic membrane. Toxin types A and E cleave SNAP-25; types B, D, F, and G act on VAMP/synaptobrevin; and type C cleaves both syntaxin and SNAP-25 (Fig. 46–1).[75] All BoNT types impair transmission at acetylcholine-dependent synapses in the peripheral nervous system, but cholinergic synapses in the central nervous system are not thought to be affected. Very high concentrations of BoNT can also impair release of other neurotransmitters including norepinephrine and serotonin.[63]
FIGURE 46–1. Botulinum toxin consists of two peptides linked by disulfide bonds. The heavy chain is responsible for specific binding to acetylcholine (ACh)-containing neurons. Following binding to the cell surface, the entire complex undergoes endocytosis and subsequent translocation of the light chain into the nerve cell cytoplasm. The light chain contains a zinc-requiring endopeptidase that cleaves proteins required by the docking/fusion complex critical to neuroexocytosis. Botulinum toxin types B , D, F, and G target the vesicle-associated soluble NSF (N-ethylmaleimide sensitive factor) attachment protein receptor (v-SNARE) protein synaptobrevin, a docking protein located on the acetylcholine-containing synaptic vesicles (synaptosome). Botulinum toxins types A , C and and E proteolyse the target associated soluble NSF attachment protein receptors (t-SNAREs) synaptosomal associated protein (SNAP)-25 and syntaxin, a component of the presynaptic cell-membrane docking complex (associated with syntaxin). After these components of the docking complex are cleaved by the endopeptidase, acetylcholine will not be released, resulting in impaired neuromuscular transmission.

CLINICAL MANIFESTATIONS

■ FOODBORNE BOTULISM

Although botulism is the most dreaded of all food poisonings, the initial phase of the disease (which typically occurs the day following ingestion) often is so subtle that it goes unnoticed. Botulism often is misdiagnosed on the first visit to a physician.[30,156] When gastrointestinal symptoms are striking and food poisoning is suspected, the differential diagnosis should include other acute poisonings, such as metals, plants, mushrooms, and the common bacterial, viral, and parasitic agents discussed in Chap. 45.

Early gastrointestinal signs and symptoms of botulism include nausea, vomiting, abdominal distension, and pain. A time lag (from 12 hours to several days, but typically not more than 24 hours) may be observed before neurologic signs and symptoms appear. Common findings include diplopia (often with lateral rectus palsy), blurred vision with impaired accommodation, and bilaterally symmetric flaccid paralysis which typically begins in cranial muscles and descends to the limbs. Constipation due to smooth muscle involvement is frequent, and urinary retention and ileus may also occur. Dry mouth, dysphagia, and dysarthria/dysphonia (manifested by a nasal quality to the voice) may be severe, and many patients exhibit fixed mydriatic pupils and ptosis. Deep tendon reflexes are usually reduced or absent. Hypotension and bradycardia sometimes develop, but temperature regulation is normal.

Weakness of respiratory muscles may necessitate intubation and mechanical ventilation. Approximately 67% of patients with toxin type A require intubation, compared to 52% of patients with toxin type B, and 39% with toxin type E botulism.[155]

Importantly, mental status and sensation remain normal. These negatives, along with the absence of tachycardia, distinguish botulism from the anticholinergic syndrome, which shares many features with botulism.

The differential diagnosis of botulism includes a variety of toxicologic and nontoxicologic conditions (Tables 46–1A and 46–1B).

The most difficult and frequently encountered diagnostic challenge is differentiating between botulism and the Miller Fisher variant of the Guillain-Barré syndrome (Table 46–2). Because physicians so rarely encounter botulism (especially compared to other much more common diseases in the differential diagnosis), initiation of appropriate management often is seriously delayed. The index case of an epidemic or an isolated case often is misdiagnosed at a stage when the risk of morbidity and mortality still could be substantially diminished. This is particularly true of toxin type E botulism, which typically initially causes much more prominent gastrointestinal signs than neurologic signs.[18] The differences in the initial clinical symptoms associated with the various serotypes may be related to the presence of proteolytic enzymes in toxin types A and B and saccharolytic enzymes in toxin types E and C botulism.

■ INFANT BOTULISM

First described in California[10,68,71] in 1976, several thousand cases of infant botulism have now been confirmed across the world. Interestingly, 95% of these cases are reported in the United States.[49,101] Although infant botulism is reported from approximately half of the states in the United States and all inhabited continents except Africa,[49] 50% of reported cases originate from California, Utah, Pennsylvania, and New Mexico.[154] In California, aggressive surveillance and educational efforts have been practiced since 1976, which may help to explain the disproportionate distribution of reported cases.[7]

Infant botulism is the most common form of botulism in the United States, and 99% of cases are due to BoNT type A or B.[42] Affected children are younger than 1 year (median of 15 weeks) and characteristically have normal gestation and birth. The first signs of infant botulism are constipation; difficulty with feeding, sucking, and swallowing; feeble cry; and diffusely decreased muscle tone ("floppy baby").[40] The hypotonia is particularly apparent in the limbs and neck. Ophthalmoplegia, loss of facial grimacing, dysphagia, diminished gag reflex, poor anal sphincter tone, and respiratory failure are often

TABLE 46–1A. Differential Diagnosis of Botulism: Toxicologic Conditions

Condition	Associated Findings
Aminoglycoside poisoning	Postanesthetic paralysis, exposure to aminoglycoside antibiotics
Anticholinergic poisoning	Mydriasis, vasodilation, fever, tachycardia, ileus, dry mucosa, altered mental status
Buckthorn (*Karwinskia humboldtiana*) poisoning	Rapidly progressive ascending paralytic neuropathy with quadriplegia
Carbon monoxide poisoning	Headache, nausea, altered sensorium, tachypnea, elevated carboxyhemoglobin concentration
Diphtheria (demyelinating neuropathy)	Exudative pharyngitis, cranial polyneuropathy (late), cardiac manifestations, hypotension
Elapid (coral snake) envenomation	Euphoria, light-headedness, fasciculations, tremor, weakness, salivation, nausea, vomiting followed by bulbar palsy and paralysis including slurred speech, diplopia, ptosis, dysphagia, dyspnea, respiratory compromise
Organic phosphorus compound poisoning	Salivation, lacrimation, urination, defecation, fasciculations, bronchorrhea, delayed neuropathy
Paralytic shellfish poisoning	Incubation <1 h, dysesthesias, paresthesias, impaired mentation, respiratory paralysis
Thallium poisoning	Constipation, cranial neuropathy, ascending sensory neuropathy, Mees' lines, alopecia

present, but fever does not occur. Mydriasis is typical, and hypotension may occur. The differential diagnosis of infant botulism initially includes dehydration, failure to thrive, sepsis, and a viral syndrome. Because the toxin in infant botulism is absorbed gradually as it is produced, the onset of clinical manifestations may be less abrupt than in severe cases of foodborne botulism which are caused by large amounts of preformed toxin absorbed over a brief period of time.

Infant botulism may result from ingestion of *C. botulinum* organisms in food or following the inhalation or ingestion of organism-laden aerosolized dust. A number of factors determine a child's susceptibility to development of botulism. While bile acids and gastric acid in the gastrointestinal tract may inhibit clostridial growth in older children and adults, gastric acidity is reduced in the infant during the first few months of life.[84] Also, some infants may be deficient in immunologic mechanisms for spore control, resulting in a permissive environment for spore germination and toxin development within their gastrointestinal tracts and subsequent gut absorption. Approximately 70% of infant botulism cases occur in breastfed infants, even though only 45%–50% of all infants are breastfed. Formula-fed infants are rapidly colonized by *Coliforme* spp, *Enterococcus* spp, and *Bacteroides* spp,

TABLE 46–1B. Differential Diagnosis of Botulism: Nontoxicologic Conditions

Condition	Associated Findings
Lambert-Eaton myasthenic syndrome	Neoplasm (especially small cell lung cancer), limb weakness exceeding ocular/bulbar weakness , increased strength following sustained contractions, postexercise facilitation on repetitive nerve stimulation, antibodies to voltage-gated calcium channels
Encephalitis	Fever, mental status abnormalities, seizures CSF: elevated protein and pleocytosis
Food "poisoning" (other bacterial)	Rapid onset of disease, absence of cranial nerve findings
Guillain-Barré syndrome/ acute inflammatory demyelinating polyneuropathy (and Miller Fisher variant)	Areflexia, paresthesias, ataxia CSF: elevated protein without pleocytosis, slowed nerve conduction velocity
Hypermagnesemia	Respiratory compromise, diffuse flushing, weakness, thirst
Inflammatory myelopathies	Complete (transverse) or incomplete spinal syndrome with paraparesis and/or sensory level, back pain, may be preceded by viral illness, CSF pleocytosis
Myasthenia gravis	Aggravation of fatigue with exercise, fluctuating weakness, positive edrophonium (Tensilon) test, acetylcholine receptor antibodies, decremental response on rapid repetitive nerve stimulation
Poliomyelitis	Fever, GI symptoms, asymmetric neurologic findings CSF: elevated protein and pleocytosis
Polymyositis	Insidious onset, proximal limb weakness, dysphagia, muscle tenderness sometimes present, elevated CK, aldolase, c-reactive protein and ESR, fibrillations and sharp waves on electromyography
Stroke	Asymmetric paralysis, abnormal brain imaging
Tetanus	Rigidity, cranial nerve defects (rare)
Tick paralysis (*Dermacentor* species)	Rapidly evolving paralysis, ptosis, absence of paresthesias, normal CSF analysis, presence of an embedded tick with resolution upon removal

CK = creatine kinase; CSF = cerebrospinal fluid; ESR = erythrocyte sedimentation rate; GI = gastrointestinal.

TABLE 46–2. Differentiating Botulism from Guillain-Barré Syndrome

	Botulism	Guillain-Barré Syndrome	Miller Fisher Variant of Guillain-Barré Syndrome
Fever	Absent (except in wound botulism)	Occasionally present	Occasionally present
Pupils	Dilated or unreactive (50%)	Normal	Normal
Ophthalmoplegia	Present (early)	May be present (late)	Present (early)
Paralysis	Descending	Ascending (classically, but not necessarily)	Descending
Deep tendon reflexes	Diminished	Absent	Absent
Ataxia	Absent	Often present	Present
Paresthesias	Absent	Present	Present
CSF protein	Normal	Elevated (late)	Elevated (late)

CSF = cerebrospinal fluid.

which may inhibit *C. botulinum* proliferation; conversely, the absence of these typical organisms in breastfed infants may facilitate *C. botulinum* multiplication.[68]

Epidemiologic studies in Europe have found that ingestion of honey was associated with 59% of cases of infant botulism.[15] When *C. botulinum* spores were isolated from honey implicated in cases of infant botulism, the same toxin type was isolated from the infant and, as expected, no preformed toxin was isolated from the honey.[10] Honey is the only food generally considered likely to be a risk factor for infant botulism,[10] although a recent report from the United Kingdom implicated a milk formula in the development of infant botulism.[97] It is possible that spoiled pollen and nectar carried by worker bees results in contamination of honey with spores of *Clostridia* found in soil.[95] In addition, the oxidative metabolism of *Bacillus alvei*, another common contaminant of honey, may promote spore germination by creating a anaerobic microenvironment.[92]

Previous studies suggested a correlation between the presence of both *C. botulinum* organisms and toxin and sudden infant death syndrome (SIDS).[9,134] However, in a prospective study of 248 infants with SIDS, *C. botulinum* was not found on stool culture of any of the children.[31]

Cases of infant botulism must be managed in the hospital, preferably in a pediatric intensive care unit for at least the first week, when the risk of respiratory arrest is greatest. In one study, approximately 80% of children with botulism required intubation for reduced vital capacity, and 25% of these children had frank respiratory compromise.[119] In a group of 57 affected infants 18 days to 7 months of age managed during the decade ending in the mid-1980s, 77% were intubated and 68% required mechanical ventilation. In the subsequent decade,

investigators from the same institution found that 61.7% of 60 infants required endotracheal intubation (for a mean duration of 21 days).[4] The apparent decrease in intubations and complications was ascribed to better understanding of disease progression and closer observation of patients. However, a similar study at another institution revealed that 54% of 24 infants admitted between 1985 and 1994 required ventilatory support, compared to 75% of 20 infants admitted in the subsequent decade.[144] All but one patient in this study required nasogastric feeding. Airway complications of intubation such as stridor, granuloma formation, and subglottic stenosis are common, yet tracheotomy is infrequently performed.[3] The survival rate in infant botulism is approximately 98%.[120]

■ WOUND BOTULISM

Wound contamination previously was considered an uncommon cause of botulism. The first case of wound botulism was not reported until 1943. The classic presentation of wound botulism is that of a patient injured in a motor vehicle who sustains a deep muscle laceration, crush injury, or compound fracture treated with open reduction. The wound typically is dirty and associated with inadequate débridement, subsequent purulent drainage, and local tenderness, although in some cases the wound appears unremarkable. Four to 18 days later, cranial nerve palsies and other neurologic findings typical of botulism may appear.[90] Other manifestations characteristic of food-related botulism, such as gastrointestinal symptoms, usually are absent.

In wound botulism, fever may be prominent and associated with abscess, sinusitis, or other tissue infection presumed to harbor the clostridial organisms. Although some patients may require management for wound-related problems, in other cases the wounds appear clean and uninfected. Recognition of botulism as a potential complication of wound infections is essential for appropriate early and aggressive therapy.

The prevalence of wound botulism has risen in recent years, predominantly in association with injection of illicit drugs, although the number of cases identified by the CDC decreased from 45 in 2006 to 22 in 2007.[42] In 2007, BoNT type A accounted for 91% of cases, while 9% were type B.[42] Use of heroin, particularly subcutaneous injection ("skin-popping") of black tar heroin, is associated with an increasing number of wound botulism cases.[43,103,115,152] This increased frequency associated appears to be related, at least in part, to the physical characteristics of black tar heroin such as its viscosity, its potential to facilitate anaerobic growth and spore germination, and its ability to devitalize tissue or inhibit wound resolution.[21] Wound botulism also has been reported in association with subcutaneous,[107] intravenous,[137] and intranasal[74,110] cocaine use. The first case of wound botulism with BoNT type E was reported recently, affecting a drug user in Sweden.[13]

In a small series of parenteral drug-using patients with botulism in New York City, the most prominent symptoms were dysphagia, dysarthria, and dry mouth. BoNT type A toxin was detected in the serum of one patient, and in another patint *C. botulinum* was isolated from an abscess. In four other drug abusers with clinically comparable presentations, CDC investigators were not able to find any organism or toxin in serum, stool, or skin lesions.[80]

■ ADULT INTESTINAL COLONIZATION BOTULISM

While gastrointestinal colonization is the typical pathogenetic mechanism responsible for infant botulism, it is rare in adults. Prior to 1997 only 15 cases had been reported.[62,88] Patients invariably have anatomic or functional gastrointestinal abnormalities. Risk factors favoring organism persistence and *C. botulinum* colonization include achlorhydria (surgically or pharmacologically induced), previous intestinal surgery,

and probably recent antibiotic therapy. Cases of adult infectious botulism have occurred in patients after ileal bypass surgery and Crohn disease,[22] jejunoileal bypass for obesity,[58,87] gastroduodenostomy,[87] vagotomy and pyloroplasty,[87] and necrotic volvulus.[79]

There is a well-documented case of botulism resulting from the ingestion of a food source contaminated with *C. botulinum* type A organisms and no preformed toxin.[47] In this case, the long incubation period with toxin present in the serum and stool for 3 weeks after exposure in combination with the absence of disease in the patient's spouse who shared the food suggested *in vivo* intraluminal elaboration of toxin. This patient was a very unusual host in that she had a history of peptic ulcer disease treated with truncal vagotomy, antrectomy, and a Billroth I anastomosis. She had received perioperative antibiotics 5 weeks prior to the development of botulism. All of these factors may have compromised the gastric and bile acid barrier, gut flora, and motility, thus allowing spore germination, altered bacterial growth, and toxin development.

In another case report,[62] a 67-year-old man with long-standing Crohn disease who had undergone terminal ileum and right colonic resection presented with abdominal pain. Prior to admission, the patient had experienced several episodes of diplopia. After admission, systemic paralysis developed. The patient had a prolonged recovery after receiving two courses of equine trivalent (ABE) botulinum antitoxin and 81 days of antibiotic treatment. Of note, a high concentration of endogenously produced antibody to toxin type A was identified. This finding highlights a distinct characteristic of adult intestinal colonization botulism, as endogenous antitoxin immunity does not develop in patients with foodborne botulism.[117]

◼ IATROGENIC BOTULISM

Two preparations of BoNT are available in the United States: botulinum toxin type A (Botox [also available in Europe as Dysport]) and botulinum toxin type B (Myobloc). The therapeutic use of BoNT injections in humans was first investigated in the 1970s, and the FDA approved BoNT type A for the treatment of strabismus and blepharospasm in 1989. Subsequently, both types A and B were approved for treatment of cervical dystonia. A 1990 consensus statement by the National Institutes of Health recommended treatment with BoNT for patients with blepharospasm, adductor spasmodic dysphonia, jaw-closing oromandibular dystonia, and cervical dystonia.[96] BoNT type A is approved by the FDA for treatment of cervical dystonia, facial nerve disorders, strabismus, axillary hyperhidrosis, and for cosmetic use to minimize wrinkles; BoNT type B is FDA-approved for cervical dystonia. BoNTs are also used off-label for treatment of a variety of conditions such as spasticity, migraine, achalasia, and anal fissure.

These xenobiotics are thought to exert their therapeutic effect in most cases by causing temporary weakness in muscles whose overactivity results in the clinical condition. Doses range widely depending on the size of the muscle to be treated, the degree of weakness required, and the commercial preparation of the toxin. The injected toxin blocks the local neuromuscular junction by inhibiting release of acetylcholine. The "chemodenervated" muscles recover within 2–4 months as nerve transmission is restored through sprouting of new nerve endings and formation of functional connections at motor endplates,[2,117] necessitating repeated injections of BoNT for prolonged clinical efficacy.

Doses of BoNT are measured in functional units corresponding to the median intraperitoneal lethal dose (LD_{50}) in female Swiss-Webster mice weighing 18–20 grams.[102] The units of each marketed xenobiotic are distinctly different and may confuse the clinician, leading to inadvertent overdosing.[33] The potential for confusion may be substantial when switching between type A and type B BoNT, because their relative potencies are quite different. [98,113,122] As an approximation,

1 Unit of Botox (onabotulinumtoxinA) is roughly equivalent to 50 Units of Myobloc (rimabotulinumtoxinB) or 3–5 Units of Dysport (abobotulinumtoxinA).[29,141] Estimated quantities of type A BoNT lethal to humans by different routes of administration are given in Table 46–3.

Although one early marketing assumption was that the neurotoxin does not diffuse from the injection site, BoNT does diffuse into adjacent tissues and produce local adverse effects.[111] Systemic manifestations are of concern when an inadvertent, excessive, or misdirected dose of toxin is administered, or in the setting of a neuromuscular disorder which may be previously undiagnosed, as in one case in which injection of BoNT type A unmasked Lambert-Eaton myasthenic syndrome[53]. In addition, a number of studies demonstrate that even appropriately injected doses result in neuromuscular junction abnormalities throughout the body, occasionally producing autonomic dysfunction without muscle weakness.[59,76,99] Several cases of iatrogenic botulism-like symptoms, including diplopia and severe generalized muscle weakness with widespread electromyographic abnormalities, have resulted from therapeutic doses of intramuscular BoNT injections.[19,24,145] A very recent report raised the possibility that BoNT type A may undergo retrograde axonal transport and transcytosis to afferent neurons,[5] suggesting a potential mechanism for such generalized effects. However, the reproducibility and clinical significance of these findings have yet to be established.

In a large series of 139 patients with cervical dystonia randomized to treatment with BoNT type A or BoNT type B, no difference in efficacy was found between serotypes; the groups were also equivalent in frequency of adverse effects such as neck pain and neck weakness, but dry mouth and dysphagia were more common in the group treated with BoNT type B.[50]

Following repeated injections of therapeutic doses of BoNT, patients may develop neutralizing antibodies that subsequently may limit the toxin's efficacy; this situation should prompt a clinician to switch to use of a different toxin type.[28] In Japan and the United Kingdom, a preparation of BoNT type F is available for use when antibodies to type A develop.[125] Some studies suggest that animals receiving BoNT type F have more transient and reversible weakness than that associated with types A and B.[26] In 1998, the formulation of Botox was changed to reduce the amount of potentially antigenic protein, and studies in rabbits demonstrate a much lower rate of development of anti-BoNT antibodies with the new batch compared with the previous preparation.[23]

In a well-publicized case in late 2004, four patients in Florida developed paralysis after being injected with BoNT type A. An FDA investigation revealed that these patients were injected by an unlicensed physician who obtained raw toxin (not approved for medical purposes) and administered it at a dose 2000 to 100,000 times greater than that used in clinical practice.[3] These events were not felt to be relevant to the approved uses of medicinal BoNT. In February 2008, the FDA

issued an Early Communication stating that it is reviewing safety data on Botox (onabotulinumtoxinA) and Myobloc (rimabotulinumtoxinB) after receiving reports of hospitalization or death in patients injected with these agents, mostly in children treated for cerebral palsy–associated spasticity;[147] this review is ongoing as of the time of this writing.

■ INHALATIONAL BOTULISM

Inhaled BoNT is estimated to be 100 times more potent than orally ingested BoNT; a single gram of toxin, if disseminated evenly, could kill more than 1 million people.[11] A 1962 report from West Germany described three veterinary workers who inhaled BoNT type A from the fur of animals they were handling; on the third day after exposure they developed mucus in the throat, dysphagia, and dizziness, while on the next day they developed ophthalmoparesis, mydriasis, dysarthria, gait dysfunction, and weakness.[11] Use of aerosolized BoNT as a bioweapon has been attempted by terrorists in Japan, and Iraq has developed BoNT (along with anthrax and aflatoxin) as part of a biological warfare program.[11,157] (see Chap. 132)

■ DIAGNOSTIC TESTING

The CDC case definition for foodborne botulism is established in a patient with a neurologic disorder manifested by diplopia, blurred vision, bulbar weakness, and symmetric paralysis in whom[36]

- BoNT is detected in serum, stool, or implicated food samples; or
- *C. botulinum* is isolated from stool; or
- A clinically compatible case is epidemiologically linked to a laboratory-confirmed case of botulism.

Routine laboratory studies, including CSF analysis, are normal in patients with botulism. Specific tests that can be helpful in diagnosing botulism are discussed below.

■ TENSILON TESTING

Edrophonium (Tensilon) is a rapidly acting and short-acting cholinesterase inhibitor that can be useful in the diagnosis of myasthenia gravis. It is occasionally used to differentiate myasthenia gravis from botulism. This drug inhibits the metabolism of acetylcholine located in synapses, permitting continued binding with the reduced number of postsynaptic acetylcholine receptors in myasthenia gravis.

A syringe containing 10 mg of edrophonium is prepared, and then a test dose of 1–2 mg is administered intravenously. A positive result (ie, consistent with myasthenia gravis) consists of dramatic improvement in the strength of weak muscles within 30–60 seconds, lasting 3–5 minutes. If there is no effect, the remainder of the edrophonium is given and the same effect sought. Ideally, a second syringe is filled with saline and the test performed under double-blind conditions.

Because release of acetylcholine is impaired in botulism, preventing its metabolism has little clinical effect. In rare cases, early in the course of botulism injection of edrophonium results in limited improvement in strength that is far less dramatic than occurs in patients with myasthenia gravis.[105] Anticholinesterase drugs such as edrophonium have no effect on the action of BoNT but may affect patients clinically if some cells can still release acetylcholine.

■ ELECTROPHYSIOLOGIC TESTING

In all forms of botulism, sensory nerve action potentials are normal. Motor potentials are typically reduced in amplitude (although this reduction may not be appreciated unless severely affected muscles are

studied), but conduction velocity is not affected. Repetitive nerve stimulation at high frequencies would be expected to result in an increment of the amplitude of the motor potential, given the presynaptic localization of the defect, but this finding is neither sensitive nor specific; it may be more common in disease due to BoNT type B than with type A.[46,85] A marked incremental response is more likely to suggest Lambert-Eaton myasthenic syndrome (LEMS) than botulism. Likewise, a decremental response to low-frequency repetitive nerve stimulation is characteristic of LEMS but is not consistently present in botulism.[85]

The needle electromyography (EMG) examination in botulism is characterized by low-amplitude, short-duration motor unit action potentials (MUAPs), due to blockade of neuromuscular transmission in many muscle fibers (Fig. 46–2). Polyphasic MUAPs are also common. Recruitment is usually normal but may be reduced in severely affected muscles if all muscle fibers of a motor unit are blocked. Spontaneous activity, including positive sharp waves and fibrillation potentials, is often seen.

Although these electrodiagnostic abnormalities can support the diagnosis of botulism, they can be subtle. Nerve conduction studies and EMG are most useful in their ability to exclude differential diagnostic considerations, including Guillain-Barré syndrome and other neuropathies (both demyelinating and axonal), poliomyelitis, and myasthenia gravis. Moreover, there are no pathognomonic electrophysiologic findings in botulism; in particular, the findings can closely resemble those of a myopathic process, and muscle biopsy may be necessary to exclude such a condition.[85]

■ LABORATORY TESTING

Samples of serum, stool, vomitus, gastric contents, and suspected foods should be subjected to anaerobic culture (for *C. botulinum*) and mouse bioassay (for BoNT) (Table 46–4). A list of the patient's medications should accompany each sample to exclude other xenobiotics that might interfere with the assay (eg, pyridostigmine) or be toxic to the mice. The serum samples must be collected prior to initiation of antitoxin therapy. If wound botulism is suspected, serum, stool, exudate, débrided tissue, and swab samples should be collected. For infant botulism, feces and serum samples also should be obtained. Infants who are constipated may require an enema with nonbacteriostatic sterile
FIGURE 46–2. Electromyographic findings. Schematic representations of repetitive nerve stimulation at low (5/sec) and high (50/sec) frequencies. In botulism (**A**), repetitive stimulation produces a small-muscle action potential that facilitates (increases in amplitude) at higher frequencies. This effect (which, although classic, is not found in all cases of botulism) results from increased acetylcholine release with high-frequency stimulation because of intracellular calcium accumulation. In contrast, myasthenia gravis (**B**) is associated with a normal muscle action potential amplitude and a decremental response at low-frequency stimulation with a normal response at high-frequency stimulation. Myasthenia gravis, a disorder of the muscle end plate, produces this decremental response at low frequencies because the natural reduction in acetylcholine response with subsequent stimulation falls below threshold.[105,148]

TABLE 46–4. Epidemiologic and Laboratory Assessment of Botulism

Classification	Foodborne	Infant	Wound	Adult Intestinal Colonization
Toxin type	A, B, E, F, G in humans; C, D in animals	A, B, C, F	A, B	A
Route	Ingestion of toxin	Ingestion of bacteria and spores	Wound, abscess (sinusitis)	Ingestion of bacteria and spores
Specimens	Stool: positive for bacteria/spores and toxin	Stool: positive for bacteria/spores and toxin for up to 8 weeks after recovery	Wound site: Gram stain, aerobic and anaerobic cultures; positive for bacteria/spores	Stool: positive for bacteria/spores and toxin
Botulinum toxin in serum	Yes	Yes	Yes	Yes
Bacteria/spores in food	Yes	Yes	No	Yes
Botulinum toxin in food	Yes	No	No	No

"Toxin" refers to botulinum toxin. "Bacteria/spores" refers to *C. botulinum*.

water to facilitate collection. All enema fluid and stool should be sent for analysis. The specimens should be refrigerated (not frozen) and examined as soon as possible after collection. Detailed information on specimen collection and examination is available online from the CDC (http://www.cdc.gov/ncidod/dbmd/diseaseinfo/files/botulism.pdf).[38]

In the mouse lethality assay, the standard test for detecting BoNT, the sample (serum, stool, or food) is injected intraperitoneally into mice which are then observed for development of signs of botulism. Control mice are injected with the sample as well as antitoxin. This test is very sensitive, with a detection limit of 0.01 ng/mL of sample eluate. However, it is laborious, expensive, and a positive result may not appear for several days, reducing its usefulness in early diagnosis of botulism.[78] Alternative methods for detecting BoNT, including immunological methods (eg, enzyme-linked immunosorbent assay [ELISA]) and endopeptidase assays, are being explored.[78]

C. botulinum can be cultured under strict anaerobic conditions. Stool specimens are incubated anaerobically and then subcultured on egg yolk agar to assess for lipase production, although this test is not specific as other clostridia also produce lipase. Numerous protocols using polymerase chain reaction and probe hybridization to detect and identify *C. botulinum* are described but these have not yet been applied widely in clinical practice.[78]

MANAGEMENT

■ SUPPORTIVE CARE

Respiratory compromise is the usual cause of death from botulism. To prevent or treat this complication, hospital admission of the patient and of all individuals with suspected exposure is mandatory. Careful continuous monitoring of respiratory status using parameters such as vital capacity, peak expiratory flow rate, negative inspiratory force (NIF), pulse oximetry, and the presence or absence of a gag reflex is essential to determine the need for intubation or tracheostomy, as the patient begins to manifest signs of bulbar paralysis.[119] The most reliable, readily obtainable test is the NIF, which can be used in most institutions to determine the need for intubation. When suspicion of disease is high, and the vital capacity is less than 30% of predicted or the NIF is less than −30 cm H_2O, intubation should be strongly considered.[89,139]

Reverse Trendelenburg positioning at 20°–25° with cervical support has been suggested to be beneficial by enhancing diaphragmatic function, but the clinical application to seriously ill patients has not been validated.[11] This approach may reduce the risk of aspiration while decreasing the pressure of abdominal viscera on the diaphragm, with resultant improvement in ventilatory effort.

In addition to attention to respiratory issues, patients require nutrition (enteral or parenteral) and prompt recognition and treatment of secondary infections.

■ GASTRIC DECONTAMINATION

An attempt should be made to remove the spores and toxin from the gut. Although most patients present after a substantial time delay, the etiologic agent may still be present hours or even days later. Activated charcoal should be a routine part of supportive care, because in vitro it adsorbs BoNT type A and probably also the other BoNT types.[60] Gastric lavage or emesis should be initiated only for an asymptomatic person who has very recently ingested a known contaminated food. If a cathartic is chosen, sorbitol is the preferable agent because others such as magnesium salts may exacerbate neuromuscular blockade. Theoretically, whole-bowel irrigation may have a role in decontamination, particularly if there is concern about initiating emesis, but interventions other than activated charcoal have not been evaluated under these circumstances.

■ WOUND CARE

Thorough wound débridement is the most critical aspect in the management of wound botulism and should be performed promptly.[70,79] Antibiotic therapy alone is inadequate, as evidenced by several case reports of disease despite antibiotic therapy. Aminoglycoside antibiotics[116] and clindamycin[121] should not be used because they may interfere with neuromuscular transmission.

Penicillin G is one of many drugs with excellent in vitro antimicrobial efficacy against *C. botulinum* and is useful for wound management.[138] However, penicillin has no role in the management of botulism caused by preformed toxin, nor does it prevent gut spores from germinating. For these reasons, penicillin is not considered useful in infant and adult infectious botulism, and it is not by itself considered adequate for wound botulism.

GUANIDINE, 4-AMINOPYRIDINE, AND 3,4-DIAMINOPYRIDINE

Guanidine is no longer recommended for treatment of botulism, because its merits were not substantiated.[55,72] (See previous editions of this text for a more extensive discussion.) Several studies[114] and case reports[51] have proposed that 4-aminopyridine and 3,4-diaminopyridine are effective in improving neuromuscular transmission by enhancing acetylcholine release from the motor nerve terminal.[114] In a rat BoNT type A model, 3,4-diaminopyridine restored neuromuscular function and enhanced animal survival.[127] The therapeutic efforts for those with LEMS and the successful animal results all suggest that further investigative efforts are necessary. The potential of 4-aminopyridine to induce seizures at therapeutic doses limits its clinical usefulness. The fact that 3,4-diaminopyridine does not substantially cross the blood–brain barrier, resulting in limited CNS manifestations, makes this xenobiotic appropriate for further investigation.

BOTULINUM ANTITOXIN

Since the 1960s, passive immunization with antitoxin has been used to neutralize unbound BoNT. In the United States, the CDC supplies equine-derived antitoxin through state and (except in California and Alaska) local health departments. It is indicated for patients with foodborne or wound botulism. Currently, the CDC formulary includes a bivalent antitoxin effective against BoNT types A and B, and an antitoxin against type E is available as an investigational product.[39] A trivalent (ABE) antitoxin that was used in the past is not currently available. A heptavalent (ABCDEFG) antitoxin has been developed by the US Army on an investigational basis; its efficacy has yet to be elucidated.[11,69] Although the antitoxins are highly serotype specific, type E antitoxin may have partial neutralizing potential against BoNT type F; in disease due to type F, use of type E antitoxin may be warranted.[65,88,108]

In a review of 132 cases of type A foodborne botulism, a lower fatality rate and a shorter course of illness were demonstrated for patients who received trivalent antitoxin, even after controlling for age and incubation period.[139] The earlier a patient received antitoxin, the shorter was the clinical course. In addition, no respiratory arrests occurred more than 5 hours after antitoxin was administered. Two studies on the use of antitoxin in the presence of wound botulism demonstrated that the longer the delay to antitoxin administration, the more prolonged the requirement for ventilatory support and the poorer the outcome.[45] Consequently, antitoxin should be requested from the CDC at the time the diagnosis of botulism is first suspected.

Unless the BoNT serotype is known, permitting type-specific therapy, combined therapy with both bivalent AB antitoxin (7500 U type A, 5500 U type B) and E antitoxin (5000 U type E) should be used for foodborne botulism. Bivalent antitoxin AB should be used for presumptive wound botulism. The entire 10-mL vial of antitoxin should be given intravenously as a 1:10 vol/vol dilution in 0.9% sodium chloride over several minutes. Because antitoxin is an equine globulin preparation, hypersensitivity skin testing for horse serum should be performed prior to treatment, with desensitization of patients who exhibit a wheal-and-flare response (as described in the antitoxin package insert[16,17]). Epinephrine and diphenhydramine should always be readily available to treat anaphylaxis or hypersensitivity reactions. The overall rate of adverse reactions, including hypersensitivity and serum sickness,[27] is reported as 9%–17%, with an incidence of anaphylaxis as high as 1.9%.[18,91] In recent years, the frequency of serious reactions in patient treated with a single vial of antitoxin is less than 1%.[132] Because the amount of antibody in each vial far exceeds the quantity needed to neutralize all BoNT in the serum, and because the antitoxin has a circulating half-life of 5 to 8 days, repeat treatment is usually not needed.[38]

BoNT antitoxin neutralizes only unbound toxin, and consequently can prevent paralysis but does not affect already paralyzed muscles.[57] Due to the high mortality rate associated with foodborne botulism, the antitoxin should be given to patients in whom the diagnosis is suspected; treatment should not be delayed while awaiting laboratory confirmation of the diagnosis. In the event of a potential outbreak of foodborne botulism, asymptomatic individuals should be closely monitored for early signs of illness so that antitoxin can be administered promptly.[124] (see A8 Botulinum Antitoxin)

TREATMENT OF INFANT BOTULISM

Like adults, infants with botulism require intensive care, with meticulous monitoring for respiratory compromise. Autonomic dysfunction may also occur. Constipation may be severe.

Equine-derived antitoxin is not recommended in infant botulism because of doubtful efficacy as well as safety concerns.[38,71,77,118] In October 2003 the FDA licensed human-derived botulism immune globulin (BIG) as BabyBIG for treatment of infant botulism.[8] A randomized trial of 122 cases of infant botulism showed that treatment with intravenous BIG significantly reduced the length of hospital stay and intensive care, duration of mechanical ventilation and tube or intravenous feeding, and cost of hospitalization relative to placebo, without causing serious adverse effects.[12,56] Similar results were seen in a recent retrospective chart review.[146] BabyBIG is available from the California Department of Health Services Infant Botulism Treatment and Prevention Program.[32]

PREVENTION

Measures used to prevent infant botulism include limiting exposure to spores by thoroughly washing foods and objects that might be placed in a child's mouth. In addition, honey should not be given to infants younger than 6 months.

A pentavalent (ABCDE) botulinum toxoid is available as an investigational new drug; the CDC recommends immunization for laboratory personnel working with *C. botulinum* or BoNTs, as well as military personnel at risk of exposure.[39] Numerous vaccination strategies are under investigation, including several recombinant vaccines that have shown promise in protecting against botulism in animal and human trials.[20,131]

PROGNOSIS

The prolonged and variable period of recovery that occurs after exposure to BoNT is directly related to the extent of neuromuscular blockade and neurogenic atrophy as well as the regeneration rates of nerve endings and presynaptic membranes.[86] If the patient has excellent respiratory support during the acute phase and receives adequate parenteral nutrition, residual neurologic disability may not occur. Although the initial course may be protracted, near-total functional recovery can follow within several months to 1 year. Common long-term sequelae include dysgeusia, dry mouth, constipation, dyspepsia, arthralgia, exertional dyspnea, tachycardia, and easy fatigability.

The status of 13 patients who survived a toxin type B botulinum outbreak was characterized 2 years later by persistent dyspnea and fatigue, although surprisingly, pulmonary function tests had returned to normal in all patients.[152] Inspiratory muscle weakness persisted in 4 of 13 patients. Maximal oxygen consumption and maximal workload during exercise were diminished in all patients, and all had more rapid shallow breathing and a higher dyspnea score than controls. The reasons for premature exercise termination may be multifactorial. Although persistent respiratory muscle weakness may be an explanation, most dyspnea and

fatigue appeared to be related to reduced cardiovascular fitness, leg fatigue, and diminished nutrition.[153]

A recent case-control series reported long-term outcomes in 217 adults with foodborne botulism in the Republic of Georgia. Six patients died; the remaining 211 were interviewed a median of 4.3 years after onset of disease. They were significantly more likely than control subjects to report ongoing fatigue, dizziness, weakness, dry mouth, difficulty lifting things, and difficulty breathing with moderate exertion.[61]

PREGNANCY

At least three cases of botulism occurring during pregnancy have been reported. One case occurred during the second trimester,[109] and two cases occurred during the third trimester.[135] Although in two cases BoNT or *C. botulinum* was isolated from the mother prior to administration of antitoxin therapy, no detectable toxin was isolated from the neonates in either of the third-trimester cases. The large molecular weight of the neurotoxin (150 kDa) makes passive diffusion through the placenta unlikely,[67] and, although theoretically possible, no active transport system has been identified.[135] None of the three neonates had neurologic evidence of botulism. Appropriate care of the mother and preparation for maternal complications of delivery appear to assure the best potential outcome for the infant.

A recent survey of physicians identified 16 women who were treated with BoNT type A during 19 pregnancies. (One patient was injected while carrying twins, and another was treated during three separate singleton pregnancies.) One patient who received a single session of 300 U of BoNT for cervical dystonia miscarried; she had a history of previous miscarriages. Another patient underwent a therapeutic abortion. No other complications occurred. Nevertheless, the authors "do not recommend injection of pregnant women … until more data are available."[93] Botox (onabotulinumtoxinA) and Myobloc (rimabotulinumtoxinB) are both FDA pregnancy category C. Additionally, it is unknown whether BoNT is excreted in breast milk.

EPIDEMIOLOGIC AND THERAPEUTIC ASSISTANCE

Whenever botulism is suspected or proven, the local health department should be contacted. The health department should report to the CDC Emergency Operations Center at 770-488-7100. The CDC can provide or facilitate diagnostic, consultative, and laboratory testing services, access to botulinum antitoxin, and assistance in epidemiologic investigations. All foods that are potentially responsible for the illness should be refrigerated and preserved for epidemiologic investigation. The merits of this surveillance and antitoxin release system were demonstrated in Argentina,[149] where the CDC assisted in establishing nation-specific principles, including local stocking of antitoxin and establishing mechanisms for distribution, emergency identification, response, and laboratory confirmation of suspected cases. Expansion of this system to other nations will enhance worldwide botulism surveillance for foodborne botulism and for potential terrorist dissemination of BoNT.[123]

SUMMARY

Botulism remains one of the rarest poisonings, yet its etiologies have become increasingly diverse. The incidence of wound botulism has increased dramatically. Previously unrecognized complications of therapeutic BoNT use now permit a better understanding of the effects of the toxin and an appreciation of its risks. The international experience with botulism epidemics has allowed the CDC to enhance epidemiologic surveillance and to prepare for the possible use of BoNT as a biologic weapon. Promising treatment strategies currently being developed include recombinant vaccines and other creative advances.

ANTIDOTES IN DEPTH (A8)

BOTULINUM ANTITOXIN

Lewis R. Goldfrank and Howard L. Geyer

Type-specific botulinum antitoxins are available as immunoglobins derived from equine and human sources. Various forms of monovalent to pentavalent botulinum antitoxins are available for the various serotypes of clostridium botulinum. Antitoxins may be beneficial for most clinical forms of botulism, but evidence has demonstrated preventive benefits rather than the reversal of clinical manifestations.

EQUINE IMMUNOGLOBULINS

The production of antitoxin is complex, requiring almost 2 years to immunize healthy horses against botulinum toxin. The resultant immunoglobulin product, which is then defibrinated, digested, dialyzed, and purified as a 20% protein antitoxin,[10] can be lyophilized and preserved.[27] Bivalent (serotypes A and B) and serotype E botulinum antitoxin are the equine immunoglobulin preparations available in the United States, the latter as an investigational new drug.[9] Whereas the bivalent (AB) preparation is used for patients with presumed wound botulism, both AB and E antitoxins should be administered to patients with foodborne botulism. The trivalent (serotypes A, B, and E) product is no longer available.

Botulinum antitoxin is distributed from the nine regional centers of the Centers for Disease Control and Prevention (CDC) on a named-patient basis after a probable diagnosis of botulism has been established. Each vial of the bivalent botulinum antitoxin contains 7500 IUnits (2381 US units) of type A botulinum antitoxin and 5500 IUnits (1839 US units) of type B antitoxin.[2] The type E product contains 5000 IUnits of antitoxin.[3] If both are given, each should be administered separately.[3]

Evidence substantiating the efficacy of types A and E antitoxin is available,[17,31] but the efficacy of type B antitoxin has not been established in clinical trials.

Currently, only limited data are available on the relationship of dose and route of administration, the amount of circulating antitoxin found in treated patients, the toxin-neutralizing capacity of this material, and the half-life of the antitoxin. Peak serum concentrations of antitoxin are 10 to 1000 times higher than the concentrations of antitoxin calculated to be necessary to achieve toxin neutralization.[14] Ninety percent of the activity of the equine antitoxin administered was detected when all the circulating toxin was neutralized.[10,19] The half-lives for antitoxin persistence in a single patient treated with trivalent antitoxin were calculated at 6.5, 7.6, and 5.3 days for antitoxin types A, B, and E, respectively.[14] The prolonged half-life of the antitoxin and the exceedingly small quantities of toxin measured explain the limited decrease in antitoxin titers after toxin–antitoxin binding.

In the presence of disease, 1 vial of the antitoxin is administered slowly intravenously (IV) over several minutes as a 1:10 vol/vol dilution in 0.9% sodium chloride solution. Subsequent doses can be given IV every 2 to 4 hours if there is progression of clinical findings.[2,3,10,13]

For prevention, 20% of a vial of the type A/type B bivalent botulinum antitoxin and 20% of a vial of the type E botulinum antitoxin can be given intramuscularly (IM) followed by a full dose (IV) if signs and symptoms occur.[2,3]

As is the case with many other heterologous proteins, administration of this horse serum-derived preparation results in significant adverse effects.[18] Each patient who was treated with antitoxin during the first decade during which it was available (1967–1977) was studied to determine both hypersensitivity reaction rates and the efficacy of the treatment of botulism. The overall rate of adverse reactions, including hypersensitivity and serum sickness, was 9% to 17%, with an incidence of anaphylaxis as high as 1.9%.[4,5,21] However, the doses of antitoxin used in that era were substantially larger than those currently used. Because of the lethality of botulinum toxin, the risk of adverse drug reaction for the antitoxin is considered acceptable for anyone with presumed illness and for anyone potentially exposed to the toxin. Pregnancy is not a contraindication to antitoxin administration, and antitoxin has been used successfully in these circumstances.[26,30]

Anaphylaxis should be anticipated, and the clinician should be prepared to treat this complication immediately with epinephrine. However, the smaller quantities of botulinum antitoxin used for botulism present a far smaller risk for serum sickness[4] than do the larger amounts of antivenom used to treat snake envenomation. The risk of serum sickness from the refined serum proteins in botulinum antitoxin is approximately 4% to 10%.[5,13]

Patients who received antitoxin within the first 24 hours after exposure had a shorter clinical course of botulism without regression of symptoms but a comparable mortality rate to those who received antitoxin later.[31] Reduced mortality can only be demonstrated in animal models.[23] Morbidity and mortality studies are difficult to perform for a disorder that is so rare and often recognized at a delayed stage, when the toxin already is tightly bound to the neuromuscular junction. Also, most of the reported case series involve patients who received varying degrees of supportive care, further making evaluation or comparison unreliable.

INVESTIGATIONAL ANTITOXINS

$F(ab')_2$ "despeciated" heptavalent (against toxin types A, B, C_1, D, E, F, and G) botulism immune globulin (dBIG) was previously available from the CDC.[25] This equine immune globulin[11] is extensively purified to eliminate fibrinogen, plasminogen, and other proteins. Pepsin is used to remove the Fc fragment of the immunoglobulin to reduce the potential for allergic manifestations if reexposure to equine protein occurs.[16] It contains 4000 IU of types A, B, C, E, and F and 500 IU of types D and G.[16,25] Although 10 of 45 patients given dBIG in the Egyptian type E botulism outbreak manifested adverse reactions, nine were considered mild and one episode was classified as serum sickness.[16] In this botulism epidemic, the incidence of adverse effects of dBIG was comparable to those of numerous other internationally available botulinal antitoxins. Although follow-up of individuals was limited, the antitoxin appeared to be as safe as other commercially available antitoxins.

HUMAN IMMUNOGLOBULINS

Human-derived preparations of type E antitoxin were developed as 5000 IUnits per 2-mL vials for IM use. This human-derived type E botulinum antitoxin was dosed between 1000 and 5000 IU based on the estimated quantity of botulinum toxin ingested by the 100 Egyptians who presumably had eaten (or consumed) toxin-contaminated, uneviscerated, salted mullet fish.[12,34] The safety of the human-derived preparation allowed for repetitive dosing in any individual who developed clinical findings.[11] This regimen was based on the premise that effective treatment could be achieved by delivering small antitoxin doses before tissue binding of circulating toxin.

Human-derived botulism immune globulin (BIG) was developed for use in the treatment of botulism in infants. This pentavalent (types A, B, C, D, and E) immune globulin is harvested by plasmapheresis from human donors who received multiple immunizations with pentavalent botulinum toxoid.[24,32] Use of a human immune globulin obviously avoids the risk of hypersensitivity that is associated with equine proteins. It is indicated in treatment of patients younger than 1 year of age with infant botulism caused by toxin type A or B. The half-life is approximately 28 days. Treatment with IV BIG significantly reduces the length of both overall hospital stay and intensive care, the duration of mechanical ventilation and tube or IV feeding, and the cost of hospitalization.[1]

A single-dose vial contains 100 mg ± 20 mg of lyophilized powder, which should be reconstituted with 2 mL of sterile water, which results in a 50- to 60-mg/mL solution. The reconstituted product contains antibody titers against botulinum toxin type A of at least 15 IUnits/mL and titers of antibodies against botulinum toxin type B of at least 2.7 IUnits/mL. BIG should be infused at 0.5 mL/kg/hr IV. If there are no untoward reactions within 15 minutes, the rate can be decreased to 1 mL/kg/hr. The principal adverse effect is erythematous rash on the face or trunk that is mild and transient.[8]

OTHER INVESTIGATIONAL TREATMENTS

A pentavalent toxoid vaccine (types A, B, C, D, and E) was developed at the US Army Medical Research Institute of Infectious Diseases (USAMRID) at Fort Detrick, Maryland, and has been under study for more than 40 years.[6,19] Its use remains investigational and is suggested only for laboratory personnel who work with *Clostridium botulinum* or who might be first responders in cases of terrorism.[9,28] It is available for these laboratory personnel in 5-mL multidose vials. Each dose is 0.5 mL and contains 5 μg of inactivated toxin (toxoid).[9] An additional monovalent toxoid type F vaccine was manufactured for the US Army and remains under study by USAMRID.[15,20]

Recombinant vaccines,[6,29] recombinant monoclonal antibodies, recombinant oligoclonal antibodies,[22] and drugs that act as metalloproteinase inhibitors (thereby preventing toxin uptake) are all currently under investigation by the Department of Defense.[11] Humanized monoclonal antibodies, small peptides and peptide mimetics, receptor mimics, and small molecules targeting the endopeptidase activity are all promising avenues being explored for treatment of botulism.[7]

SUMMARY

Consultation with a regional poison center and local health department and ultimately between the health department and the CDC at 770-488-7100, 24 hours per day, 7 days per week (or other comparable agencies in other parts of the world) provides improved access to rapid diagnostic tests for botulism and effective therapeutic modalities. Earlier disease recognition and the currently organized public health approach appear to be responsible for decreasing morbidity and increasing survival after typical foodborne botulism.[27,33] Since 2003, IV BIG has been licensed by the FDA for treatment of infant botulism and is an effective therapy for this form of the disease.

PHARMACEUTICALS

CHAPTER 47
ANTICONVULSANTS

Suzanne Doyon

Therapeutic serum concentrations		
Xenobiotic	mg/L	μmol/L
Carbamazepine	4–12	17–51
Ethosuximide	40–100	283–708
Gabapentin	12–20	12–88
Lamotrigine	3–14	≤19.5
Phenobarbital	15–40	65–172
Phenytoin	10–20	40–79
Valproic acid	50–120	347–833

A seizure is defined as the clinical manifestation of excessive neuronal activity within the central nervous system (CNS). It is accompanied by varying degrees of motor, sensory, and cognitive dysfunction. Seizures result from one of four possible cellular mechanisms: sustained repeated firing of the sodium channels, excessive calcium conductance, increased excitatory neurotransmission (eg, glutamate), or loss inhibitory neurotransmitter control (eg, γ-aminobutyric acid [GABA]).

HISTORY AND EPIDEMIOLOGY

Historically, seizures were treated by a variety of methods, including ketogenic diets, fluid restriction, and surgical excision of scars or irritable cortical foci. The first effective anticonvulsant therapy was introduced in 1857, when administration of bromides was noted to sedate patients and significantly reduce their seizures. Phenobarbital, another sedative-hypnotic, was first used to treat seizures in 1912. Most of the subsequently introduced anticonvulsants, such as primidone, had chemical structures similar to that of phenobarbital, and sedation was erroneously believed to be an essential component of anticonvulsant therapy.

The search for nonsedating anticonvulsants led to the introduction of phenytoin in 1938.[114] After 1965, benzodiazepines, carbamazepine, and valproic acid (VPA) were introduced and gained wide use as anticonvulsants. These were the only anticonvulsants available until the 1990s, when new anticonvulsants became available for clinical use: gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiramate, felbamate, vigabatrin, lacosamide and zonisamide.

Anticonvulsants are also currently used for treating mood disorders, refractory pain syndromes such as trigeminal neuralgia, bruxism, migraine headaches, drug withdrawal syndromes, and social phobias.

In a review of more than 5000 patient suicides, anticonvulsants were implicated in 8.2% of cases, suggesting a fairly high rate of suicidal ideation among people with access to these medications.[71,73] In the last decade, as reported in the American Association of Poison Control Centers (AAPCC) National Poison Data System (NPDS), a shift occurred from predominantly carbamazepine and phenytoin exposures to VPA and newer anticonvulsants (Chap. 135).

This chapter reviews the toxicity and management of overdoses with anticonvulsants other than the benzodiazepines and barbiturates, which are discussed in Chap. 74.

PHARMACOLOGY

The mechanisms of action of anticonvulsants correspond to one of four categories: sodium channel inhibition, calcium channel inhibition, inhibition of excitatory amines, and GABA agonism. Frequently, more than one mechanism accounts for the anticonvulsive action of a drug.

Electrophysiologic analyses demonstrate that a high-frequency pattern of neuronal firing occurs during seizure activity. This pattern is not observed during normal neuronal activity. Voltage-activated sodium and calcium channels are primarily responsible for this high-frequency firing. Sodium-channel blocking anticonvulsants preferentially bind to inactivated conformations of the voltage-activated sodium channels hindering recovery and preventing them from firing at high frequencies. Phenytoin, carbamazepine, VPA, lamotrigine, topiramate, oxcarbazepine, zonisamide, and felbamate all bind to the batrachotoxin site (or adjacent area) on the sodium channel and reduce its ability to recover from inactivation.[187,189] At therapeutic concentrations, effects on sodium channels are selective and no effect on spontaneous activity is noted. At toxic concentrations, selectivity is lost and both high-frequency firing and spontaneous sodium channel activity are inhibited.[113] Voltage-activated calcium channels are multisubunit complexes that are broadly classified into low-voltage and high-voltage groups. The low-voltage group encompasses the T-type calcium channels. Zonisamide, VPA, and ethosuximide inhibit flow of calcium through these channels, thus reducing the T current, also known as the *pacemaker current*.[59,131,142] The high-voltage group consists of the L, R, P/Q, and N subtypes. These channels regulate calcium entry. Levetiracetam inhibits the N-type calcium channels.[106,142]

The *N*-methyl-D-aspartate (NMDA) receptor is the glutamate receptor of greatest clinical importance with respect to development of seizures. When stimulated by glutamate, the NMDA receptor activates a ligand-gated ion channel that permits entry of Na^+ and Ca^{2+} into the neuronal cells. Suppression of the glutamate–NMDA interaction protects against seizures.[113] Felbamate and possibly VPA are competitive glutamate antagonists at the NMDA receptors.[65] More specifically, felbamate acts at the strychnine-insensitive glycine recognition site on the NMDA receptor (Chap. 13). Lamotrigine and possibly high-dose

phenytoin inhibit glutamate release by binding to presynaptic Na$^+$ channels.[60] Topiramate binds to kainate, another excitatory amino acid receptor subtype, and blocks Na$^+$ entry into the neuronal cell.[135]

GABA acts through fast chloride-permeable ionotropic GABA$_A$ receptors and slower G protein–coupled GABA$_B$ receptors. Vigabatrin irreversibly inhibits GABA transaminase, the enzyme primarily responsible for GABA metabolism.[73,113] VPA may have similar effects.[113] Tiagabine inhibits the GABA transporter GAT-1 and thereby prevents reuptake of GABA into presynaptic neurons following its release.[73,113] Despite its structural similarities to GABA, the mechanism of action of gabapentin is poorly understood.[73,113] Figure 47–1 summarizes these mechanisms.

Broad spectrum antiepileptics treat all seizure types. This group includes lamotrigine, leveritacetam, topiramate, and valproic acid. Narrow spectrum antiepileptics treat specific seizure types or syndromes such as localization-related (focal) epilepsy with partial and secondarily generalized seizures. Narrow spectrum antiepileptics are less effective than broad spectrum antiepileptics in treating the idiopathic generalized epilepsy syndromes and may exacerbate certain seizure types.[53] The terms *anticonvulsant* and *antiepileptic* are used interchangeably in this chapter. The anticonvulsants will be discussed in alphabetical order.

CARBAMAZEPINE

Carbamazepine is structurally related to the cyclic antidepressants. It is a narrow spectrum anticonvulsant. Carbamazepine is a first-line anticonvulsant for seizures and may be especially useful for the management of epilepsy in pregnancy.[53]

■ PHARMACOKINETICS AND TOXICOKINETICS

Carbamazepine is lipophilic, with slow and unpredictable absorption following oral administration, and rapid distribution to all tissues. Peak concentrations are reached as late as 12–24 hours postingestion, especially after large ingestion of sustained-release preparations.[44,190] Carbamazepine also possesses weak anticholinergic properties and can decrease gastrointestinal motility, delaying its own absorption. Hence, no simple relationship exists between the dose and the serum concentration of carbamazepine.

Carbamazepine is metabolized primarily by CYP3A4 to carbamazepine 10,11-epoxide, which is pharmacologically active. This quantifiable metabolite is further degraded by epoxide hydrolase to carbamazepine-diol, a largely inactive compound.[85] Elimination of carbamazepine increases over the first few weeks of therapy because of autoinduction,
FIGURE 47–1. The mechanisms of action of anticonvulsants can generally be placed into one of four categories: sodium channel inhibition, calcium channel inhibition, inhibition of excitatory amines, and GABA agonism. SSA = succinic acid semialdehyde; GABA-T = GABA transaminase; NMDA = N-Methyl-D-Aspartate; GABA = γ-Aminobutyric acid.

TABLE 47–1. Pharmacokinetics of Anticonvulsants.[12,73,53,113,123]

	Time to Max Serum Concentration (h)	Therapeutic Serum Concentration (mg/L)	Vd (L/kg)	Protein Binding (%)	Urinary Elimination Unchanged (%)	Active Metabolite	Elimination Half-life (h)
Carbamazepine	3–24 in overdose	4–12	0.8–1.8	75	1–2	CBZ 10, 11-epoxide	6–20 acute 5–12 chronic
Gabapentin	3	12–20	0.8–1.3	0	100	None	5–7

and the half-life on chronic therapy shortens substantially. Therefore, the dose must be increased gradually over a 2- to 4-week period to a final daily dose of 10–20 mg/kg for adults and 20–70 mg/kg for children. Children require a higher dose because they eliminate the drug more rapidly. During chronic therapy, the elimination half-life ranges from 10–20 hours.[100] Furthermore, at very high serum concentrations, zero order kinetics of elimination are observed[190] (Tables 47–1 and 47–2).

CLINICAL MANIFESTATIONS

Neurologic signs and symptoms and possibly some cardiovascular effects characterize acute carbamazepine toxicity. The initial neurologic disturbances include nystagmus, ataxia, and dysarthria. In patients with large overdoses, fluctuations in level of consciousness and coma

occur.[38,44,69,151,155,188] Carbamazepine toxicity may cause seizures in both in epileptic and nonepileptic patients.[22,107] The mechanism underlying carbamazepine-induced seizures is poorly understood.[69,131] In some cases, an increase in seizure frequency, without neurologic symptoms, is the presenting symptom of carbamazepine toxicity. Status epilepticus may complicate acute carbamazepine toxicity.[157,164,182] In a case series, 55% of adult patients with carbamazepine concentrations greater than 40 mg/L developed seizures.[69] Children may experience seizures at even lower concentrations.[163]

Cardiovascular effects include sinus tachycardia, which occurs in 35% of overdoses as a result of an anticholinergic mechanism, hypotension with myocardial depression, and cardiac conduction abnormalities.[58,69,98] High concentrations of carbamazepine may cause depression of phases 0, 2, and 4 of the action potential in cardiac tissue.[32,167] In a large case series of carbamazepine overdoses, a 15% incidence of QRS complex prolongation (>100 msec), 50% incidence of QT interval prolongation (>420 msec), and no cases of terminal 40-msec axis deviation of the QRS complex in limb leads were observed.[7] These abnormalities can be delayed for as long as 20 hours and may occur with chronic therapy but are not associated with life-threatening dysrhythmias or permanent sequelae.[7,32,43,79,171] The toxicity of carbamazepine in children differs slightly from that in adults. Children experience a higher incidence of dystonic reactions, choreoathetosis, and seizures and have a lower incidence of electrocardiographic abnormalities.[16,163,170] Chronic carbamazepine overdose can result in headaches, diplopia, or ataxia. Idiosyncratic adverse events are common.[146]

The incidence of carbamazepine-induced hyponatremia ranges from 1.8% to 40%. Increased antidiuretic hormone secretion or increased sensitivity of peripheral osmoreceptors to antidiuretic hormone are suggested mechanisms.[56,93,113] (Chap. 16).

DIAGNOSTIC TESTING

Serum carbamazepine concentrations should be obtained in all cases of moderate-to-severe carbamazepine overdose. Because of erratic absorption,

the concentrations should be repeated every 4–6 hours and closely monitored until a downward trend is observed. In one case report, peak concentrations were reached 106 hours postingestion in a patient who ingested a sustained release preparation.[22] Serum concentrations greater than 40 mg/L are associated with coma, seizures, respiratory depression, and prolongation of the QRS and QT intervals.[69] Carbamazepine may cross-react with toxicology screening for cyclic antidepressants (Chap. 73).[51]

Patients receiving multiple anticonvulsants, especially combination therapy with VPA and lamotrigine, may develop carbamazepine toxicity at serum concentrations within the therapeutic reference range due to elevated concentrations of the circulating carbamazepine-10,11-epoxide metabolite (Table 47–3). This finding is attributed to the additive inhibitory effects of VPA and lamotrigine on the enzyme epoxide hydrolase. Carbamazepine-10,11-epoxide concentrations in the 1–4 mg/L range are detected at therapeutic doses of carbamazepine and in the 1–10 mg/L range in overdoses.[134,190]

■ MANAGEMENT

Cardiac monitoring for occurrence of QRS or QT abnormalities is recommended. Although not formally studied, sodium bicarbonate should be administered if the QRS duration exceeds 100 msec. Carbamazepine-induced seizures are treated with benzodiazepines. Multiple-dose activated charcoal (MDAC) reduces enterohepatic and enteroenteric circulation of carbamazepine.[14,76,107,125,182] In a randomized trial, MDAC was associated with a reduction in the elimination half life of carbamazepine from 28 to 13 hours, a decrease in need for mechanical ventilation, a shorter coma, and a shorter length of stay in the intensive care unit.[14] Hemodialysis and charcoal hemoperfusion both effectively lower serum carbamazepine concentrations.[22,58,133] Clearance rates with high flux hemodialysis rival those obtained by charcoal hemoperfusion.[154] Continuous venovenous hemofiltration and hemodialfiltration were used successfully in 2 children.[8,192]

TABLE 47–3. Anticonvulsant Drug Interactions[53,73]

	Toxicity Increased by	Anticonvulsant Effect Decreased by	Increases Concentrations of	Decreases Concentrations of
Carbamazepine	Allopurinol, cimetidine, danazol, diltiazem, fluoxetine, fluvoxamine, gemfibrozil, INH, ketoconazole, lamotrigine, macrolides, nefazodone, nicotine, propoxyphene, protease inhibitors, verapamil	Benzodiazepines, felbamate, isotretinoin, phenobarbital, phenytoin, primidone, succinimides, valproic acid	None	Doxycycline, felbamate, haloperidol, lamotrigine, ?methadone, OCP, phenytoin, primidone, tiagabine, VPA, warfarin

Zonisamide	None	CBZ, phenobarbital, phenytoin	?CBZ	?CBZ

CBZ = carbamazepine, VPA = valproic acid, INH = isoniazid, OCP = oral contraceptives.

Extracorporeal drug removal techniques should be reserved for severe life-threatening overdoses. MDAC is safer, easier, and produces similar outcomes to hemodialysis and hemoperfusion.

FELBAMATE

Felbamate is structurally similar to meprobamate, a sedative hypnotic rarely used today (see Chap. 74). Because of potential adverse effects, including hepatic failure and aplastic anemia, it is reserved as a therapy of last resort for management of seizures. It is absorbed quickly, and 50% of an ingested dose is excreted unchanged in the urine.[65] Mild lethargy and gastrointestinal symptoms are reported following acute overdose.[122] Crystalluria and reversible renal failure following an acute overdose are reported.[140] Treatment of felbamate overdose is largely supportive.

GABAPENTIN

Gabapentin, a derivative of GABA, is approved as adjunctive therapy for the management of seizures in adults and children and postherpetic neuralgia. It is also currently used as a treatment for posttraumatic stress disorder, behavioral disorders, mood disorders, bruxism, migraine prophylaxis, idiopathic trigeminal neuralgia, neuropathic pain, and a number of other neurologic disturbances. Pregabalin is a gabapentin prodrug. Both gabapentin and pregabalin are narrow spectrum antiepileptics.[53]

■ PHARMACOKINETICS AND TOXICOKINETICS

The bioavailability of gabapentin is approximately 60% with therapeutic dosing. Absorption kinetics may be dose dependent with decreasing bioavailability at increased dose, possibly due to a saturable transport system. It is highly lipophilic and easily crosses the blood–brain barrier. Dosage adjustments are necessary in patients with decreased renal function (creatinine clearance <60 mL/min). It is not metabolized by, and does not affect, the CYP450 system[113] (Table 47–1).

■ CLINICAL MANIFESTATIONS

Sedation, ataxia, movement disorders,[136] and gastrointestinal symptoms are observed following acute overdose.[67,91,137,183] Similar symptoms occur in patients with renal failure after initial dosing.[41,70,183] In a case series of 20 patients with overdose, lethargy, ataxia, and gastrointestinal symptoms resolved within 4–24 hours.[91]

Catatonia following abrupt withdrawal of gabapentin is described.[145] Pregabalin-induced psychosis is reported.[128]

■ DIAGNOSTIC TESTING

Consensus regarding a precise therapeutic range is not available. Because gabapentin is not appreciably protein bound, serum concentrations essentially represent free gabapentin.

■ MANAGEMENT

Treatment is largely supportive. Although activated charcoal (AC) may limit absorption, the lack of severe toxicity and rapidity of CNS depression generally makes the administration of AC both unnecessary and unwise. No specific antidote exists. Patients with persistent neurologic symptoms should be admitted to the hospital. Hemodialysis and hemoperfusion are not generally required, except in patients with significant renal impairment, because supportive care is sufficient in most instances.[21,41,70,137]

LAMOTRIGINE

Lamotrigine, a broad spectrum anticonvulsant, is approved as an adjunctive medication for treatment of seizures in adults and children. It also is approved for maintenance treatment of bipolar mood disorder.[108]

■ PHARMACOKINETICS AND TOXICOKINETICS

The bioavailability of lamotrigine is 98%. It is predominantly glucuronidated to lamotrigine 2-N-glucuronide. The elimination half-life is approximately 25 hours but can be halved in the presence of phenytoin and carbamazepine and doubled in the presence of VPA. Phenytoin and carbamazepine induce glucuronidation. VPA competes with lamotrigine for the same step in the glucuronidation process. Significantly reduced clearance of lamotrigine occurs in patients with Gilbert syndrome (a syndrome of defective glucuronidation). Lamotrigine does not affect the CYP450 system or the metabolism of other drugs except when it is administered concomitantly with carbamazepine, where it is associated with accumulation of the carbamazepine epoxide metabolite.[60]

■ CLINICAL MANIFESTATIONS

Neurologic manifestations such as lethargy, ataxia, nystagmus, and gastrointestinal symptoms are described following overdose. Coma, seizures, and QRS prolongation may occur.[15,20,102,126,130,139,153]

A chronic overdose presented with a rash, rhabdomyolysis, and elevation of hepatic aminotransferases and serum creatinine phosphokinase concentrations, suggesting a hypersensitivity reaction.[150] All abnormalities resolved upon withdrawal of the drug.[121]

■ DIAGNOSTIC TESTING

Lamotrigine concentrations greater than 14 mg/L are potentially toxic.

■ MANAGEMENT

Activated charcoal should be administered. Supportive care and ECG monitoring are recommended. Lamotrigine-induced seizures should be treated with benzodiazepines.[20,178] Data on hemodialysis and hemoperfusion are not available, but based on its size, relatively low protein binding, and volume of distribution (1.4 L/kg), lamotrigine should be removed by hemodialysis. However, hemodialysis should be reserved for severe life-threatening overdoses.

LEVETIRACETAM

Levetiracetam was approved in 1999 as an "add-on" medication for the management of intractable epilepsy. Its mechanism of action remains incompletely understood, although it is known to inhibit N-type calcium channels. Research has illustrated both a neuroprotective and an antiinflammatory effect.[66,109] Levetiracetam is a broad spectrum antiepileptic medication with a wide margin of safety in administration and very favorable pharmacokinetics.[66]

■ PHARMACOKINETICS AND TOXICOKINETICS

The bioavailability of levetiracetam approaches 100%. The major metabolic pathway involves enzymatic hydrolysis of the acetamide group. This reaction is not dependent on hepatic CYP450 activity. There are no active metabolites. Dosage adjustments are necessary in patients with decreased renal function (creatinine clearance <60 mL/min).[73]

■ CLINICAL MANIFESTATIONS

In one report of overdose, lethargy, coma, and respiratory depression were noted. Symptoms persisted for 24 hours.[11] Two children receiving supratherapeutic doses developed only mild effects such as decrease in muscle tone, which reversed immediately after the doses were adjusted.[9]

■ DIAGNOSTIC TESTING

Therapeutic concentrations are 10–40 mg/L. Because of its large therapeutic window, routine monitoring of serum levetiracetam concentrations may not be necessary.[73]

■ MANAGEMENT

Activated charcoal should be considered. Supportive care is recommended.

OXCARBAZEPINE

Oxcarbazepine is an analog of carbamazepine that functions as a prodrug. Presystemic 10-ketoreduction metabolizes oxcarbazepine to monohydroxycarbazepine (MHD), which is pharmacologically active.[113] MHD is subsequently conjugated and renally eliminated. It is a less potent inducer of CYP3A4 than carbamazepine, and has minimal effects on its own metabolism.[113] Somnolence, tinnitus, bradycardia and hypotension occur following acute single overdose.[75,181] In these cases, serum oxcarbazepine concentrations reached 12–31.6 mg/L (approximately 10-fold therapeutic concentrations), yet concentrations of MHD were only 59–65 mg/L, less than 2-fold the therapeutic concentrations (10–35 mg/L). These findings suggest that the formation of MHD is rate limited.[55,181]

Activated charcoal should be administered and supportive care should be provided. The rate-limited enzymatic conversion from inactive prodrug to active metabolite may limit its toxicity. Hemodialysis does not increase the clearance of oxcarbazepine or its metabolite and is not useful. [55]

PHENYTOIN/FOSPHENYTOIN

Phenytoin is still widely considered a first-line anticonvulsant for treatment of most seizure disorders, except absence seizures. It is a narrow spectrum antiepileptic agent that is nonsedating in therapeutic doses and therefore often used successfully for long-term management of epilepsy.[53]

Introduced in 1997, fosphenytoin is a water soluble phosphate ester prodrug of phenytoin. Advantages include availability for intramuscular administration and low potential for tissue injury at injection sites.[17,113]

■ PHARMACOKINETICS AND TOXICOKINETICS

Phenytoin is rapidly distributed to all tissues. Oral loading doses of 20 mg/kg phenytoin are well tolerated and yield therapeutic (>10 mg/L) serum concentrations at 5.6 ± 0.2 hours.[173] In very large oral overdoses, gastrointestinal absorption can be delayed even more for up to several days.[25,34] Some authors suggest that phenytoin absorption may continue in the colon because of its lipophilic properties.[168] Additionally, phenytoin occasionally forms concretions in the gastrointestinal tract.[25,34]

Phenytoin is extensively bound to serum proteins, mainly albumin. Only the unbound free fraction can traverse biologic membranes and become pharmacologically active. A significant fraction of phenytoin remains unbound in neonates, uremic patients, and other patients with hypoalbuminemia, such as patients in the intensive care unit.[37,62]

Less than 5% of a given dose of phenytoin is excreted unchanged in the urine. The remainder is metabolized in the liver. The major phenytoin metabolite, a parahydroxylphenyl derivative, is inactive but is the putative metabolite responsible for the hypersensitivity reaction associated with phenytoin administration.[92] The Michaelis-Menten model of saturable enzyme kinetics explains the relationship between phenytoin doses and serum concentrations at steady state. At phenytoin concentrations below 10 mg/L, elimination usually is first order, and elimination half-life ranges between 6 and 24 hours. At higher concentrations, zero-order elimination occurs as a result of saturation of the hydroxylation reaction, and the apparent elimination half-life increases to 20–60 hours.[28,113] Therefore, the apparent half-life of elimination of phenytoin is progressively prolonged as plasma concentration increases (Chap. 8).

Fosphenytoin is metabolized by tissue and blood phosphatases to phenytoin, phosphate, and formaldehyde. The bioavailability of the derived phentyoin is 100% when compared to intravenously administered phenytoin regardless of the route of administration (intravenous or intramuscular). The half-life of conversion of fosphenytoin to phenytoin is 7–15 minutes. After administration of an intravenous loading dose, time to therapeutic serum concentration of phenytoin (>10 mg/L) is approximately 0.2 hours whether fosphenytoin 150 mg/min or phenytoin 50 mg/min is administered.[173] Faster rates of intravenous infusion and displacement of phenytoin from protein binding sites by fosphenytoin compensate for the conversion-related delay in appearance of phenytoin in serum.[50] The dose of fosphenytoin is expressed in phenytoin equivalents (PE).

■ CLINICAL MANIFESTATIONS

Acute toxicity produces predominantly neurologic dysfunction that typically affects the cerebellar and vestibular systems. Phenytoin concentrations greater than 15 mg/L are associated with nystagmus, concentrations greater than 30 mg/L are associated with ataxia and poor coordination, and concentrations exceeding 50 mg/L are associated with lethargy, slurred speech, and pyramidal and extrapyramidal manifestations.[34,95,115,117] Toxic concentrations rarely cause de novo seizures.[169] Young children and the elderly may present with atypical manifestations of toxicity. Decreased appetite, poor feeding, diminished activity, abdominal distension, chorea, and opisthotonic posturing are reported following oral overdoses in children.[104,115]

Cardiotoxicity resulting from oral overdoses of phenytoin is not reported.[45,191] However, IV phenytoin impairs myocardial contractility, decreases peripheral vascular resistance, and depresses myocardial conduction. In a large case series, IV phenytoin was associated with a 3.5% incidence of hemodynamic complications.[45] Deaths following IV administration of phenytoin are reported.[61,147,186,193] Hypotension, dysrhythmias and cardiac arrest correlate with rate of administration and total dose infused. All can be at least partially attributed to propylene glycol (40%) and ethanol (10%), the diluents used in the IV preparation of phenytoin.[118] Propylene glycol in particular depresses myocardial tissue and decreases peripheral vascular resistance (Chap. 55). Fosphenytoin, available only as a parenteral preparation, does not contain propylene glycol, but the metabolism of this prodrug releases phosphate and formaldehyde. Two reports describe bradycardia, hypotension, and asystole following 5- to 10-fold dosing errors in young infants suffering from status epilepticus.[97,144] One infant had a serum phenytoin concentration of 77.2 mg/L and marked hyperphosphatemia (serum phosphate of 25.9 mg/L), although the serum calcium, magnesium, and blood urea nitrogen were normal.[144] Another report describes hyperphosphatemia without hemodynamic instability or electrocardiographic abnormality 9 hours after the administration of fosphenytoin 667 mg PE intravenously to a patient with end stage renal failure; the serum phosphate was 12.1 mg/dL and serum calcium was

8.2 mg/dL. A third report describes hypocalcemia and prolongation of the QT interval following the administration of fosphenytoin 1500 mg PE intravenously to an adult patient with normal renal function, however, no phosphate measurements were obtained.[84]

Intravenous phenytoin is commonly associated with local irritation. Extravasation may lead to local skin necrosis, possibly necessitating surgical intervention.[30,45,89] The risk of fosphenytoin-induced skin necrosis is lower because of its high water solubility.

Chronically elevated phenytoin concentrations occasionally results in gingival hyperplasia, frontal bossing, cerebellar effects, behavioral changes, and encephalopathy. Hyperactivity, confusion, lethargy, and hallucinations characterize the behavioral changes. Chronic use of phenytoin is also associated with agranulocytosis. Phenytoin may produce hepatotoxicity. The drug rash with eosinophilia and systemic symptoms (DRESS) syndrome is discussed later in this chapter.

■ DIAGNOSTIC TESTING

Serum phenytoin concentrations should be obtained in all cases of moderate-to-severe phenytoin overdose. Because of unpredictable absorption, phenytoin concentrations should be repeatedly monitored. Therapeutic concentrations are 10–20 mg/L. Because of zero-order elimination, high serum phenytoin concentrations may take days or weeks to return to the therapeutic range.[34,104,117]

Patients with impaired or decreased protein-binding capacity can develop symptoms at total phenytoin concentrations within the therapeutic range. Patients at greatest risk include neonates, the elderly, hypoalbuminemic, hyperbilirubinemic, and uremic patients, and patients undergoing combination therapy with VPA, salicylates, and sulfonamides because these xenobiotics displace phenytoin from its albumin binding sites. In such patients, determination of the free phenytoin concentration is helpful because it compares more reliably with the CSF concentrations than does the total phenytoin concentration.[37] Therapeutic free phenytoin concentrations are 1.0–2.1 mg/L.[13]

Equation 47–1 approximates the total phenytoin concentration that would be experience based on a given measured serum phenytoin concentration and measured albumin concentration.[35]

$$[\text{Phenytoin}] = \frac{[\text{Measured phenytoin}]}{(0.25 \times [\text{Measured albumin}]) + 0.1} \quad (47–1)$$

■ MANAGEMENT

The treatment of patients with acute or chronic phenytoin overdoses remains largely supportive. Phenytoin-related deaths are rare, even after massive overdoses. MDAC reduces the elimination half-life of intravenously administered phenytoin from 44.5 to 22.3 hours. It is recommended in patients in whom serial serum concentrations are increasing or persistently elevated irrespective of route of exposure.[110] Hemodialysis, charcoal hemoperfusion, and other techniques including molecular adsorbents recirculating systems (MARS) are of little benefit in the management of phenytoin overdose and do not improve outcomes.[37,81,95,117,152] Otherwise healthy patients admitted to the hospital after isolated oral phenytoin overdoses require neurologic assessments but do not require routine cardiac monitoring because they do not experience dysrhythmias or cardiovascular complications.[46,191] Phenytoin-induced agranulocytosis can be treated successfully with administration of granulocyte colony-stimulating factor.[172]

Hypotension, cardiac dysrhythmias, and dyskinesias during IV administration of phenytoin are generally transient and usually resolve in 30–60 minutes unless complications occur. Stopping the phenytoin infusion for a few minutes and administering a bolus of 250–500 mL 0.9% sodium chloride solution generally is sufficient to treat the hypotension. Restarting the infusion at half the initial rate is recommended.

Electocardiographic abnormalities, especially a prolonged QT interval temporally related to fosphenytoin infusions, may be due to hyperphosphatemia and hypocalcemia and those electrolyte abnormalities should be rapidly corrected. In one case hemodialysis was required to correct the hyperphosphatemia.[112] Life-threatening dysrhythmias may require prolonged periods of cardiopulmonary resuscitation.[97,144]

The management of extravasation is discussed in Special Considerations: Extravasation.

TIAGABINE

Tiagabine inhibits GABA reuptake and is approved as an adjunctive treatment of seizures. It is also prescribed for a variety of psychiatric disorders. Tiagabine is a narrow spectrum antiepileptic medication.[53]

■ PHARMACOKINETICS AND TOXICOKINETICS

Tiagabine is quickly and completely absorbed within 2–3 hours of ingestion. It is widely distributed and easily crosses the blood–brain barrier.[90] It is metabolized by the CYP3A4 system to inactive metabolites. The elimination half-life is reduced by 50% in patients taking enzyme-inducing anticonvulsive agents.[105] It has no effect on the CYP450 system.[96,105]

■ CLINICAL MANIFESTATIONS

Lethargy, facial myoclonus (grimacing), nystagmus, and posturing are described following overdose.[24,165] Seizures and status epilepticus are reported at therapeutic doses as well as in overdose.[54,72,83,129] A previously healthy toddler developed three seizures after an unintentional overdose of tiagabine; serum concentrations were 0.53 mg/L.[83] A patient presented in status epilepticus and was believed to be noncompliant with therapy until a tiagabine concentration of 1.87 mg/L was obtained and an acute overdose determined.[72,129] Stimulation of the presynaptic $GABA_B$ receptors in the thalamus is suggested as the underlying mechanism for tiagabine-induced seizures.[141] Symptoms generally persist for 12–24 hours, and permanent neurologic sequelae usually are not found.[24,83,129,165]

■ DIAGNOSTIC TESTING

Therapeutic tiagabine concentrations are 5–70 ng/mL.

■ MANAGEMENT

Activated charcoal and supportive care are recommended. Seizures respond to administration of benzodiazepines even though the beneficial effects of the GABA agonists like benzodiazepines seem paradoxical when treating seizures from tiagabine.[54,72,83,129] Status epilepticus should be treated with barbiturates or propofol. Posturing and grimacing are treated with benzodiazepines as well.[24] Data on the use of hemodialysis and hemoperfusion are not available, but because of high protein binding, hemodialysis will likely not be effective.

TOPIRAMATE

Topiramate is approved as adjunctive therapy for seizures in adults, as well as for migraine prophylaxis, infantile spasms, and other refractory seizure disorders in infants and children. Topiramate is a broad spectrum antiepileptic. Its sulfamate moiety weakly inhibits carbonic anhydrase, specifically the carbonic anhydrase II and IV isoforms present in the kidney and CNS.[40,156]

■ PHARMACOKINETICS AND TOXICOKINETICS

Topiramate is readily bioavailable. Only 20% of the dose is hepatically metabolized via hydroxylation, hydrolysis, and glucuronidation;

the remaining 80% of the drug is eliminated unchanged in the urine (Table 47–1).

■ CLINICAL MANIFESTATIONS

Lethargy, ataxia, nystagmus, myoclonus, coma, seizures, and status epilepticus are all reported following topiramate overdose.[29,49,103,162] Lethargy may be accompanied by abnormal speech patterns, such as echolalia, and word-finding difficulties following acute overdose.[29,179] Nonanion gap metabolic acidosis resulting from inhibition of renal cortical carbonic anhydrase may be present (lowest reported bicarbonate concentration 12 mEq/L) along with hyperchloremia (range 110–120 mEq/L). The nonanion gap metabolic acidosis typically appears within hours of ingestion and can persist for days.[29,49,132,179]

■ DIAGNOSTIC TESTING

A death with a postmortem concentration of 170 mg/L is reported.[94] Serum chemistry and/or arterial blood gas analysis should be adequate to evaluate for hyperchloremia, hypokalemia, and metabolic acidosis.

■ MANAGEMENT

Activated charcoal and supportive care are recommended. Severe hyperchloremic metabolic acidosis should be treated with sodium bicarbonate 1–2 mEq/kg intravenously. However, systemic administration of sodium bicarbonate may impair the anticonvulsive effect of topiramate.[29,49] Hemodialysis can increase topiramate clearance 4- to 6-fold.[57] Hemodialysis is generally recommended in patients with life-threatening topiramate overdoses presenting with significant neurologic impairment, intractable electrolyte abnormalities, or renal insufficiency.

VALPROIC ACID

Valproic acid (di-*n*-propylacetic acid [VPA]) is a simple branched chain carboxylic acid that is used for treatment of seizure disorders, mania associated with bipolar disorder, and in migraine prophylaxis. It is a broad spectrum antiepileptic agent.

■ PHARMACOKINETICS, TOXICOKINETICS, AND PATHOPHYSIOLOGY

Valproic acid is almost 100% absorbed from the gastrointestinal tract. Peak concentrations usually are reached in 6 hours, except for enteric-coated and extended-release preparations, where peak concentrations are delayed for up to 24 hours.[18,47,64,87,116] VPA is 90% protein bound at therapeutic concentrations, but the percentage decreases to 35% as the VPA concentration exceeds 300 mg/L[174] (Table 47–1).

VPA metabolism is complex and involves conjugation by glucuronic acid or oxidation. Glucuronidation accounts for 80% of VPA metabolism.[174] Oxidation can occur in mitochondria or in cytosolic microsomes. Mitochondrial β-oxidation accounts for 14% of VPA metabolism and cytosolic ω-oxidation the remaining 6%.

β-oxidation occurs in the mitochondrial matrix and begins with the transport of VPA across the double-layered mitochondrial membrane using acetyl CoA and L-carnitine[101,174] (Fig. 47-2 and Table 47–4). β-oxidation of VPA depletes both carnitine and acetyl CoA stores through a number of different mechanisms. VPA increases carnitine excretion via formation of valproylcarnitine, which can be renally excreted. Second, valproylcarnitine inhibits the ATP-dependent carnitine transporter located on the plasma membrane. Third, VPA metabolites trap mitochondrial CoA. Mitochondrial CoA trapping (or depletion) decreases ATP production, which in turn negatively affects the carnitine transporter.[101,138] Depletion of carnitine will halt
FIGURE 47–2. Valproic acid metabolism by the hepatocyte. Valproic acid is linked to coenzyme A (CoA) by acyltransferase I and subsequently transferred to carnitine. Valproylcarnitine (VPA-carnitine) is shuttled into the mitochondrion where, after transfer back to CoA by acyltransferase II, it undergoes β-oxidation yielding several metabolites. These metabolites sequester CoA, preventing its use in the β-oxidation of other fatty acids. This process may lead to a Reyelike syndrome of hepatic steatosis. Alternatively, valproylcarnitine may diffuse from the cell and be renally eliminated, or it may inhibit cellular uptake of carnitine. In either case, the cellular depletion of carnitine shifts valproate metabolism toward microsomal ω-oxidation, which occurs in the endoplasmic reticulum. This pathway forms 4-en-valproate, a putative hepatotoxin. ω-Oxidation products also interfere with carbamoylphosphate synthase I (CPS I), the initial step in the urea cycle, resulting in hyperammonemia.

β-oxidation. Subsequent fatty acid accumulation in the cytoplasm may cause steatosis.[86]

Depletion of acetyl CoA also halts the formation of *N*-acetylglutamate, a required cofactor for carbamoylphosphate synthetase I (CPS I). CPS I is the primary enzyme responsible for incorporation of ammonia into the urea cycle. The result of CoA depletion is impaired ureogenesis and hyperammonemia.[2,101] Ammonia can damage muscle and brain.[10]

■ CLINICAL MANIFESTATIONS

Overdoses of VPA result in symptoms varying from lethargy to coma and can be associated with cerebral edema. In one large case series, 100% of patients with serum VPA concentrations greater than 850 mg/L manifested coma, 63% manifested respiratory depression requiring intubation and mechanical ventilation, and 25% developed hypotension.[160,166]

Metabolic complications following acute VPA overdoses include hypernatremia, hypocalcemia, anion gap metabolic acidosis and hyperammonemia.[6,47,161,166] Anion gap metabolic acidosis following overdose is a poor prognostic sign.[48,120] It results from accumulation of ketoacids, lactic, carboxylic, and proprionic acids.[6,31,63,119,143]

Bone marrow suppression occurs 3–5 days following acute massive overdoses of VPA and is characterized by pancytopenia.[6,166] These hematopoietic disturbances usually resolve spontaneously within a few days.

Pancreatitis, hepatotoxicity, and renal insufficiency are rare manifestations of acute toxicity.[5,31,88] Chronic VPA therapy may lead to

TABLE 47–4. Adverse Events Associated with Anticonvulsants

	Common	Serious
Carbamazepine	Dizziness, sedation, blurred vision, ataxia, weight gain, nausea, leukopenia	Agranulocytosis (1/200000), aplastic anemia (1/500000), rash (10%), SJS (rare), hyponatremia (1.8%–40%)
Gabapentin	Sedation, dizziness, mild weight gain, ataxia, behavioral effect (children)	None
Lamotrigine	Dizziness, blurred vision, insomnia, headache	Rash, SJS (1–3/1000), hypersensisivity (rare), hepatotoxicity (rare)
Levetiracetam	Fatigue, irritability, anxiety, asthenia	Psychosis (rare)
Oxcarbazepine	Fatigue, dizziness, ataxia, diploplia, nausea, headache	Rash, SJS or TEN (0.5–6/million), hyponatremia (2.5%), anaphylaxis (rare)
Phenytoin	Fatigue, dizziness, ataxia, nausea, headache, gingival hypertrophy, hirsutism, osteopenia	Blood dyscrasia (rare), rash, SJS or TEN (2–4/10000), hepatotoxicity (rare), lupus-like syndrome
Tiagabine	Fatigue, dizziness, ataxia, somnolence, anxiety	Seizures
Topiramate	Sedation, ataxia, word-finding difficulty, slowed speech, difficulty concentrating, anorexia, weight loss, paresthesias, oligohydrosis (children)	Metabolic acidosis (3%), nephrolithiasis (1.5%), acute glaucoma (rare), heat stroke
Valproic acid	Sedation, ataxia, weight gain, nausea, tremor, hair loss	Hepatotoxicity (1/20000), thrombocytopenia, hyperammonemia, aplastic anemia (rare), pancreatitis (1/3000)
Vigabatrin	Fatigue, headache, dizziness, weight gain	Vision loss, psychosis
Zonisamide	Sedation, ataxia, difficulty concentrating, irritability, nausea, headache	Aplastic anemia, nephrolithiasis (0.2%–4%), rash (1%–2%), SJS or TEN (rare), heat stroke (rare)

SJS = Stevens-Johnson syndrome TEN = toxic epidermolysis.

Data from Ref: 53.

hepatotoxicity and microvesicular steatosis secondary to the afore-mentioned metabolic aberration in fatty acid metabolism rather than, as with other anticonvulsants, a hypersensitivity reaction.[19,42,86] Clinical findings may vary from asymptomatic elevation of aminotransferase concentrations to fatal hepatitis.

Valproate-induced hyperammonemic encephalopathy is character-ized by impaired consciousness with confusion or lethargy, focal or bilateral neurologic signs, and increased seizure frequency. It is not always accompanied by elevated VPA concentrations. The etiology is uncertain, but elevated ammonia concentrations coupled with elevated concentrations of some of the more neurotoxic VPA metabolites may be responsible.[23,47]

■ DIAGNOSTIC TESTING

Serum VPA concentrations should be obtained in all cases of moderate-to-severe VPA overdose, and repeated every 4–6 hours until a down-ward trend is observed. Therapeutic concentrations are 50–100 mg/L, although some clinicians use higher concentrations.

All nine VPA metabolites can be measured in the urine. In large over-doses the 4-en-VPA concentration may be elevated, indicating a shift toward ω-oxidation. The β-oxidation metabolite 2-en-VPA may be low or absent, indicating inhibition of β-oxidation and/or carnitine deple-tion. Concentrations of the 2-en-VPA metabolite increased 1–3 days following acute ingestion, signaling the return to normal β-oxidation.[120]

Electrolytes, blood gases, liver function tests, platelets and serum lactate, and serum ammonia concentrations should be monitored in all patients with severe VPA overdose with evidence of neurologic impairment. Hyperammonemia (>80 μg/dL or >35 μmol/L) occurs in 16%–52% of patients receiving chronic VPA therapy.[33,127,184]

■ MANAGEMENT

Supportive management is sufficient to ensure complete recovery in most patients with VPA overdoses. Discontinuation of all medications that likely affect VPA metabolism is also recommended (Table 47-2).

MDAC is useful in preventing absorption of VPA, especially in overdoses of enteric-coated or extended-release preparations.[3,49] As expected, naloxone is not effective in VPA-induced CNS or respiratory depression.[26,77,180]

L-Carnitine should be administered if evidence indicates the pres-ence of hyperammonemia or hepatotoxicity.[36,80] Intravenous carnitine is preferred in symptomatic patients whereas oral L-carnitine is sufficient in asymptomatic patients. The intravenous loading dose is 100 mg/kg over 30 minutes (maximum 6 g) followed by 15 mg/kg IV over 10–30 minutes every 4 hours until clinical improvement occurs (Antidotes in Depth A9: L-Carnitine).

Published data on extracorporeal removal of VPA are limited. Hemodialysis alone reduced the elimination half-life of VPA to 2.2–2.9 hours.[18,39,68,74,78,159] Charcoal hemoperfusion alone and in combination with hemodialysis were not superior to hemodialysis alone.[52,63,161,176] Continuous venovenous hemodialfiltration did not significantly improve elimination in one patient with a serum valproic acid concentration of 1402 mg/L.[82] Since hemodialysis will additionally remove ammonia it is also recommended for hemodynamically or neurologically unstable patients or patients who have severe metabolic disturbances such as life-threatening hyperammonemia following VPA overdose.[4]

■ VIGABATRIN

Vigabatrin, or vinyl GABA, is a stereospecific irreversible inhibitor of GABA-transaminase. Although vigabatrin has a short elimination half-life, its duration of action is 24 hours. Dosage adjustments are neces-sary in patients with impaired renal function.[113] Agitation, coma, and long-term psychosis are reported after acute ingestion.[35,99]

Chronic toxicity may result in psychosis, dizziness, vision loss and tremor, which usually is mild and transient, as well as depression and psychosis.[99] Treatment of vigabatrin toxicity is largely supportive. Severe agitation is best treated with IV benzodiazepines. Some cases of mild vigabatrin-induced psychosis resolve simply by withdrawal of the medication.[99]

ZONISAMIDE

Zonisamide is a sulfonamide derivative that inhibits sodium channels, low-voltage T-type calcium channels, and possibly also inhibits carbonic anhydrase similarly to topiramate.[113] Somnolence is a commonly reported adverse effect. Overdose experience with zonisamide is limited. In one case report, status epilepticus, coma, and death were attributed to zonisamide overdose despite a minimally elevated concentration of 44 mg/L (therapeutic 10–40 mg/L).[175] Activated charcoal should be considered. Supportive care is recommended.

DRESS SYNDROME OR ANTICONVULSANT HYPERSENSITIVITY SYNDROME

Drug rash with eosinophilia and systemic symptoms (DRESS) syndrome, previously named "drug hypersensitivity syndrome," is a severe adverse drug event that was first described in 1950.[177] DRESS syndrome is a distinct severe adverse drug reaction triad characterized by fever, rash, and internal organ involvement. DRESS occurs in approximately 1 of every 1000–10,000 uses of anticonvulsants, usually aromatic anticonvulsants such as phenytoin, carbamazepine, phenobarbital, primidone, and lamotrigine. Literature also supports the inclusion of oxcarbazepine as a causative agent. The incidence remains the same regardless of the patient's gender and ethnic origin. Data suggest a genetic defect in drug metabolism as the causative lesion. First-degree relatives of patients with DRESS have a 25% risk of developing this syndrome.[92,185]

DRESS occurs most frequently within the first 2 months of therapy and is not related to dose or serum concentration. The pathophysiology is related to the accumulation of reactive arene oxide metabolites resulting from decreased epoxide hydrolase enzyme activity. These metabolites bind to macromolecules and cause cellular apoptosis and necrosis. They also form neoantigens that may trigger immunologic responses. Interestingly, the same metabolite is believed to cause other serious dermatologic reactions, such as Stevens-Johnson syndrome and toxic epidermal necrolysis (see Chap. 29 and Figure 29–4).

Initial symptoms also include malaise and pharyngitis (including tonsillitis). A skin eruption characterized by macular erythema evolves into a pruritic and confluent papular rash primarily involving the face, trunk, and later the extremities. A tender lymphadenopathy usually follows. The rash usually spares the mucous membranes but severely affected cases develop toxic epidermal necrolysis. Multiorgan involvement usually occurs 1–2 weeks into the syndrome. The liver is the most frequently affected organ, although involvement of the CNS (encephalitis), cardiac muscle (myocarditis), lungs (pneumonitis), renal system (nephritis), and thyroid (hyperthyroid thyroiditis followed by hypothyroidism) are possible. Eosinophilia and mononucleosis-type atypical lymphocytosis are common. Liver disturbances range from mildly elevated aminotransferase concentrations to fulminant hepatic failure.[92,185] Fatality rates are reportedly as high as 10%.[177]

Skin biopsies reveal nonspecific perivascular lymphocytic infiltration, spongiotic or lichenoid dermatitis, and variable degrees of edema.[185] Lymph node histology reveals benign hyperplasia, atypical lymphoid cells, or lymphoma. Other laboratory abnormalities include a positive rheumatoid factor, antinuclear antibodies, anti–double-stranded DNA smooth muscle antibodies, cold agglutinins, and hypogammaglobulinemia or hypergammaglobulinemia. A novel, easy, fast, objective lymphocyte toxicity assay is being studied.[124]

Prompt discontinuation of the offending agent is essential to prevent symptom progression. Patients should be admitted to the hospital and receive methylprednisolone 0.5–1 mg/kg/d divided in four doses.[27,185] Other promising therapies include use of IV immunoglobulin.[111,149,185]

In one case series, 90% of patients with DRESS showed in vitro cross-reactivity to other aromatic antiepileptics.[1] Based on this evidence, avoidance of phenytoin, carbamazepine, phenobarbital, primidone, lamotrigine, and oxcarbazepine is recommended whereas benzodiazepines, levetiracetam, VPA, gabapentin, topiramate, and tiagabine are safe alternatives.[158]

SUMMARY

All anticonvulsant drugs produce CNS symptoms when taken in overdose and therefore differentiation based on clinical findings is difficult. Lethargy, sedation, ataxia, and nystagmus occur following overdoses of almost all the anticonvulsants. Coma occurs following substantial overdose of all anticonvulsants with the exception of gabapentin. Seizures, including status epilepticus, may occur with carbamazepine, lamotrigine, tiagabine, topiramate and zonisamide overdoses.

Hemodynamic instability and abnormal electrocardiograms are rare findings. Carbamazepine, lamotrigine, and possibly topiramate can cause QRS prolongation. Electrolyte abnormalities occur following overdoses with carbamazepine, oxcarbezipine, VPA and topiramate. Topiramate is uniquely associated with hyperchloremic metabolic acidosis.

Except for VPA overdoses there are no specific antidotes or overdoses of anticonvulsants. Supportive care alone usually yields beneficial outcomes. Administration of activated charcoal is generally recommended because of its safety and efficacy. Anticonvulsant-induced seizures are treated with benzodiazepines, barbiturates, or propofol. Patients with severe VPA overdoses or VPA-induced hyperammonemia should be treated with carnitine. Extracorporeal drug removal is rarely necessary and should be reserved for severe carbamazepine, VPA, or topiramate overdose patients with concurrent electrolyte abnormalities, hemodynamic instability, and/or clinical deterioration. Data on overdoses with the newer anticonvulsants are limited.

ANTIDOTES IN DEPTH (A9)

L-CARNITINE

Mary Ann Howland

$$H_3C-\overset{\overset{\displaystyle CH_3}{|}}{\underset{\underset{\displaystyle CH_3}{|}}{N^+}}-CH_2\text{-}\overset{\overset{\displaystyle OH}{|}}{CH}-CH_2\text{-}\overset{\displaystyle O}{\underset{\displaystyle O^-}{C}}$$

L-Carnitine

L-Carnitine (levocarnitine) is an amino acid that is vital to mitochondrial utilization of fatty acids. It is an orphan drug approved by the Food and Drug Administration for treatment of L-carnitine deficiency that results from inborn errors of metabolism, is associated with hemodialysis, occurs secondary to valproic acid toxicity, and for zidovudine (AZT)-induced mitochondrial myopathy[10,11,20] and pediatric cardiomyopathy.[17]

L-Carnitine decreases valproic acid–induced hyperammonemia and limits valproic acid–induced hepatic toxicity. L-Carnitine should be administered intravenously (IV) to symptomatic patients because of the limited bioavailability after oral (PO) administration.

HISTORY

L-Carnitine is found in mammals, in many bacteria, and in very small amounts in most plants.[37] Carnitine was first discovered in 1905 in extracts of muscle, and its name is derived from *carnis*, the Latin word for flesh.[21] Over the next 25 years, its chemical formula and structure were identified, and in 1997, its enantiomeric properties were confirmed.[37] Carnitine was formerly known as vitamin BT.

CHEMISTRY

Carnitine is a water-soluble amino acid that can exist as either the D or L form; however, the L isomer, which is found endogenously, is active and should be used therapeutically. L-Carnitine ($C_7H_{15}NO_3$) has a molecular weight of 161 daltons. At physiologic pH, L-carnitine contains both a positively charged quaternary nitrogen ion and a negatively charged carboxylic acid group.[15]

Fatty acids provide 9 kcal/g and are an important source of energy for the body, especially for the liver, heart, and skeletal muscle. The utilization of fatty acids as an energy source requires L-carnitine–mediated passage through both the outer and inner mitochondrial membranes to reach the mitochondrial matrix where β-oxidation occurs (see Figs. 47-2 and 12-8). Enzymes in the outer and inner mitochondrial membranes (carnitine palmitoyltransferase and carnitine acylcarnitine translocase) catalyze the synthesis, translocation, and regeneration of L-carnitine.[33] Binding of L-carnitine to fatty acids occurs through esterification at the hydroxyl group on the chiral carbon.[15] The L-carnitine regenerated in the mitochondrial matrix can also translocate in the opposite direction, from the matrix and through the inner membrane back to the space between the outer and inner membrane. Acyl-coenzyme A (CoA) is transported by carnitine from the cytosol to the mitochondria and undergoes β-oxidation in the mitochondrial matrix, generating acetyl-CoA, which then enters the citric acid cycle for the generation of adenosine triphosphate (ATP).

L-CARNITINE HOMEOSTASIS

Approximately 54% to 87% of the body stores of L-carnitine is derived primarily from meat and dairy products in the diet; the remainder is synthesized.[37] Although most plants supply very little L-carnitine, avocado and fermented soy products are exceptionally rich in this amino acid. The remainder of the carnitine needed by the body is synthesized from trimethyllysine. This amino acid, found largely in skeletal muscle, is converted to trimethylammoniobutanoate (γ-butyrobetaine) and then carried to the liver and kidney for hydroxylation to L-carnitine.[21] Synthesis of L-carnitine in the liver and kidney occurs at a rate of approximately 2 μmol/kg/d and is regulated by the amount of diet-derived trimethyllysine.[21,37] L-Carnitine is filtered by the kidneys, and tubular reabsorption maintains serum L-carnitine concentrations in the normal range.

PHARMACOKINETICS OF EXOGENOUS L-CARNITINE

Our current understanding of L-carnitine pharmacokinetics is largely derived from three major studies.[9,19,43] L-Carnitine is not bound to plasma proteins. Its volume of distribution of the central compartment (Vc) is 0.15 L/kg, approximating extracellular fluid volume. Its volume of distribution (Vd) is 0.7 L/kg. Both vary depending on the compartment model analyzed. The α half life is 0.6 to 0.7 hours with a terminal elimination half-life of 10 to 23 hours but may be 25% to 50% shorter. Baseline serum concentrations for L-carnitine are 40 μmol/L but increase to 1600 μmol/L after administration of 40 mg/kg IV over 10 minutes. Whereas 2 g of L-carnitine administered IV produces a peak plasma concentration of 1000 μmol/L, PO administration of 2 g produces peaks of only 15 to 70 μmol/L. The time to peak concentrations after PO administration occurs at 2.5 to 7.0 hours, indicating slow uptake by intestinal mucosal cells. After a 2-g carnitine dose, PO absorption is rapidly saturated, and no further absorption occurs after administration of 6 g PO. After a radiolabeled dose, most L-carnitine is metabolized to trimethylamine *N*-oxide and butyrobetaine, with only approximately 4% to 8% remaining unchanged. The metabolites trimethylamine and trimethylamine *N*-oxide may accumulate after chronic high-dose PO therapy in patients with severely compromised renal function.[9] Fecal excretion of L-carnitine is less than 1% of the total dose.

Carnitor (levocarnitine) tablets are bioequivalent to the Carnitor PO solution, with an absolute bioavailability of approximately 15%. After 4 days of dosing at 1980 mg (6 × 330-mg tablets) twice daily or 2 g twice daily of the PO solution, the maximum serum concentration was 80 μmol/L.

VALPROIC ACID AND HYPERAMMONEMIA

Valproic acid may cause hyperammonemia (defined as serum ammonia concentration >80 μg/dL or >35 μmol/L) regardless of symptoms or liver function. Hyperammonemia and hepatic toxicity may be associated either with therapeutic dosing or an acute overdose. Approximately 35% of patients receiving valproic acid demonstrate hyperammonemia, often with corresponding reduced serum L-carnitine concentrations.[7] In the absence of hepatic dysfunction, the postulated mechanisms for hyperammonemia are unclear but may result from interference with hepatic synthesis of urea or a small increase in ammonia production by the kidney.[27,45] Valproic acid induces both carnitine and acetyl-CoA deficiencies by combining with L-carnitine as valproylcarnitine and with acetyl CoA as valproyl-CoA. Ultimately, β-oxidation of all fatty acids is reduced, resulting in decreased energy production. Valproylcarnitine formation may inhibit the renal reabsorption of L-carnitine.[32]

Valproic acid stimulates glutaminase, favoring glutamate uptake and ammonia release from the kidney. Reduced glutamate concentrations lead to impaired production of *N*-acetylglutamate (NAGA), a cofactor for carbamoyl phosphate synthetase I (CPS I), which is used in the liver to synthesize urea from ammonia.

In humans taking valproic acid, L-carnitine supplementation reduces ammonia concentrations.[1,3,5,7,18,25,31,34,35,39,46] The exact time frame for normalization of ammonia concentrations is unknown, but a preliminary report suggests hastening of ammonia elimination with L-carnitine (3–15 h) compared with published controls (11–90 h), although the difference was not statistically significant.[41,42]

VALPROIC ACID AND HEPATOTOXICITY

Valproic acid therapy is commonly associated with a transient dose-related asymptomatic increase in liver enzyme concentrations and a rare symptomatic, life-threatening, idiosyncratic hepatotoxicity similar to Reye syndrome.[4] Liver histology of the latter demonstrates microvesicular steatosis, similar to that described in both hypoglycin-induced Jamaican vomiting sickness (see Chap. 118) and Reye syndrome. This occurrence presumably results from L-carnitine and acetyl-CoA deficiency, which inhibits mitochondrial β-oxidation of valproic acid and other fatty acids, causing them to accumulate in the hepatocyte. One study compared valproic acid administration in mice bred to have decreased carnitine stores with normal mice and found that the mice with decreased carnitine stores developed microvesicular steatosis of the liver. In addition, evaluation of their isolated liver mitochondria demonstrated decreased oxidative capacity.[23]

Evidence for the benefit of L-carnitine treatment in improving survival from valproic acid–induced hepatotoxicity comes from the retrospective analysis of patients identified by the International Registry for Adverse Reactions to valproic acid.[6] When 50 patients with acute, symptomatic hepatic dysfunction who were not treated with L-carnitine were compared with 42 similar patients treated with L-carnitine, only 10% of the untreated patients survived but 48% of the L-carnitine–treated patients survived.[6] Early diagnosis of patients, prompt discontinuance of valproic acid, and administration of IV rather than PO L-carnitine resulted in the greatest survival.[6] Most patients received 50 to 100 mg/kg/d of L-carnitine regardless of the route of administration.[6] Additionally, case reports and animal studies[40] offer both support[38,44] and lack of support for the beneficial effects of L-carnitine in the presence of valproic acid–induced hepatotoxicity.[24,25,30,41]

L-CARNITINE CONCENTRATIONS

In the serum, 80% of L-carnitine is free, and the rest is acylated.[14] In adults who eat all food groups and children older than 1 year of age, the normal serum concentrations of free L-carnitine are 22 to 66 μmol/L and of total L-carnitine concentrations are 28 to 84 μmol/L. Vegetarians have L-carnitine concentrations 12% to 30% lower than omnivores.[36]

Studies in patients taking valproic acid demonstrate decreases in both free and total serum L-carnitine concentrations[35] and decreases in both total and free muscle carnitine concentrations.[2]

Case studies demonstrate reduced serum free L-carnitine concentrations and abnormal valproic acid metabolite profiles that normalize with L-carnitine supplementation.[22,28,29] All of these data support the use of L-carnitine and provide a potential mechanism for its beneficial effects in valproic acid–induced hepatotoxicity.

ADVERSE EFFECTS AND CONTRAINDICATIONS TO L-CARNITINE

L-Carnitine administration is well tolerated.[26] Transient nausea and vomiting are the most common side effects reported, with diarrhea and a fishy body odor noted at higher doses.[9] After chronic high doses of L-carnitine in patients with severely compromised renal function, the potentially toxic L-carnitine metabolites trimethylamine and methylamine *N*-oxide accumulate. The importance of this accumulation is unknown. Trimethylamine and its metabolite dimethylamine may contribute to cognitive abnormalities and the fishy odor.[13] In a pharmacokinetic study after IV administration of 6 g of L-carnitine over 10 minutes, two of six subjects complained of transient visual blurring; one subject also complained of headache and lightheadedness. The manufacturer of L-carnitine has received case reports of convulsive episodes after L-carnitine use by patients with or without a preexisting seizure disorder. These reports are currently noted in the package insert. No reports of seizures related to L-carnitine use can be found in the human literature. The only data suggesting carnitine-related seizures are found in a rat model.[16]

There are no known contraindications to the use of L-carnitine. However, only the L isomer and not the racemic mixture should be used because the DL mixture may interfere with mitochondrial utilization of L-carnitine. L-carnitine is considered FDA pregnancy Category B.

OVERDOSE OF L-CARNITINE

No cases of toxicity from overdose have been reported, although large PO doses may cause diarrhea.[9] The LD_{50} in rats is 5.4 g/kg IV and 19.2 g/kg PO.[9]

DOSAGE AND ADMINISTRATION

The optimal dosing of L-carnitine for valproic acid–induced hyperammonemia or hepatotoxicity has not been established. Recommendations for IV L-carnitine administration to patients with acute metabolic disorders resulting from L-carnitine deficiency range from 50 to 500 mg/kg/d.[9,12] A loading dose equal to the daily dose may be given initially, followed by the daily dose divided into every 4 hourly doses. The 500-mg/kg/d dose was intended for children[8] and did not list a maximum dose After the loading dose, we suggest a maximal daily dose of 6 g . The PO dosing of L-carnitine usually is 50 to 100 mg/kg/d up to 3 g/d and should be reserved for patients who are not acutely ill.

For patients with end-stage renal disease undergoing hemodialysis, the package insert recommends an IV starting dose of 10 to 20 mg/kg dry body weight as a slow IV bolus over 2 to 3 minutes after completion of dialysis followed by a dose adjustment according to L-carnitine trough (predialysis) serum concentrations (normal, 40–50 μmol/L).

For patients with an acute overdose of valproic acid and without hepatic enzyme abnormalities or symptomatic hyperammonemia, L-carnitine administration can be considered prophylactic, and enteral doses of 100 mg/kg/d divided every 6 hours up to 3 g/d are appropriate. For patients with valproic acid–induced symptomatic hepatotoxicity or symptomatic hyperammonemia, IV L-carnitine should be administered. We suggest a dose of 100 mg/kg IV up to 6 g administered over 30 minutes as a loading dose followed by 15 mg/kg every 4 hours administered over 10 to 30 minutes.

AVAILABILITY

L-Carnitine (Carnitor) is available as a sterile injection for IV use in 1 g/5 mL single-dose vials.[9] L-Carnitine is supplied without a preservative. After the vial is opened, the unused portion should be discarded. Carnitor injection is compatible with and stable when mixed with normal saline or lactated Ringer solution in concentrations as high as 8 mg/mL for as long as 24 hours.[9] L-Carnitine (Carnitor) is also available as a 330-mg tablet; as an PO solution with artificial cherry flavoring, malic acid, sucrose syrup, and methylparaben and propylparaben as preservatives; and as a sugar-free PO solution (Carnitor SF) at a concentration of 100 mg/mL.[8] The PO solution may be consumed without diluting, or it may be dissolved in other drinks to mask the taste. Slow consumption reduces gastrointestinal side effects.[9]

CHAPTER 48

ANTIDIABETICS AND HYPOGLYCEMICS

George M. Bosse

Glucose

MW	=	180 daltons
Normal fasting range (blood)	=	60–100 mg/dL
	=	3.3–5.6 mmol/L

Although various xenobiotics and medical conditions may cause hypoglycemia, this chapter focuses on the medications used for treatment of diabetes mellitus. These medications include insulin, incretin mimetics, and oral agents: the sulfonylureas, biguanides, α-glucosidase inhibitors, thiazolidinediones, meglitinides, and gliptins. Some of the medications in these chemically heterogeneous groups of xenobiotics can cause unique toxic effects in addition to hypoglycemia.

In general, neurohormonal control of glucose production in healthy individuals maintains a fasting serum glucose concentration in the range of 60–100 mg/dL. In diabetes mellitus, the body fails to maintain normal blood glucose concentrations. The two glycemic complications of diabetes mellitus and its therapy are hyperglycemia and hypoglycemia.

Most patients with diabetes mellitus are classified as having either insulin-dependent diabetes mellitus (IDDM), also known as type I diabetes, or non–insulin-dependent diabetes mellitus (NIDDM), also known as type II diabetes. This classification scheme for diabetes mellitus is not perfect. For example, some patients with type II diabetes may require insulin in addition to oral hypoglycemics. Early in the course of type I diabetes, patients may enter a remission period during which exogenous insulin is not required.

HISTORY AND EPIDEMIOLOGY

Insulin first became available for use in 1922 after Banting and colleagues successfully treated diabetic patients with pancreatic extracts.[10] In an attempt to more closely simulate physiologic conditions, additional "designer" insulins with unique kinetic properties have been developed, including an ultrashort-acting preparation known as *lispro*.[62,130] Several oral delivery systems for insulin have been studied.[87] Development of an oral delivery system for use in humans has not been successful because of poor intestinal absorption and degradation of the oral form of insulin by digestive enzymes. Using zonula occludens toxin, modulation of intestinal tight junctions in animal models has resulted in significant increases in enteral absorption of insulin.[38] An inhaled form of insulin had recently become available, but has been withdrawn from the market due to poor sales.[83]

The hypoglycemic activity of a sulfonamide derivative used for typhoid fever was noted during World War II.[70] This discovery was verified later in animals. The sulfonylureas in use today are chemical modifications of that original sulfonamide compound. In the mid-1960s, the first-generation sulfonylureas were widely used. Newer second-generation drugs differ primarily in their potency.

Although insulin is widely used for treating diabetes mellitus, sulfonylurea exposures are much more commonly reported to poison centers than are insulin exposures, based on 15 years of data from 1993 to 2007 (Chap. 135). These data likely reflect a significant percentage of intentional overdose cases. In a review of 1418 medication-related cases of hypoglycemia, sulfonylureas (especially the long-acting chlorpropamide and glyburide) alone or with a second hypoglycemic accounted for the largest percentage of cases (63%).[120] Only 18 of the sulfonylurea cases in this series involved overdose with suicidal intent. However, hypoglycemia is reported in as many as 20% of patients using sulfonylureas.[55] Despite the lack of evidence reported in the literature, we speculate that insulin-induced hypoglycemia occurs frequently in settings other than volitional overdose. Besides sulfonylurea use, advanced age and fasting are identified as major risk factors for hypoglycemia. Other causes of hypoglycemia are listed in Table 48–1.

The biguanides metformin and phenformin were developed as derivatives of *Galega officinalis,* the French lilac, recognized in medieval Europe as a treatment for diabetes mellitus.[8] Phenformin was used in the United States until 1977, when it was removed from the market because of its association with life-threatening metabolic acidosis with hyperlactatemia (64 cases/100,000 patient-years). However, phenformin still is available outside the United States.[101]

Development of the α-glucosidase inhibitors began in the 1960s when an α-amylase inhibitor was isolated from wheat flour.[116] Acarbose was discovered more than 10 years later and approved for use in the United States in 1995. Troglitazone and repaglinide were approved for use in the United States in 1997. The FDA subsequently directed the manufacturer of troglitazone to withdraw the product from the US market in 2000 because of associated liver toxicity. Exenatide, a synthetic form of a compound found in the saliva of the Gila monster, is an incretin mimetic. Incretins are endogenous compounds in humans which stimulate insulin secretion in response to an oral glucose load. Most recently, the gliptins, which inhibit the enzyme responsible for the inactivation of incretins, have been introduced.

PHARMACOLOGY

Insulin is synthesized as a precursor polypeptide in the β-islet cells of the pancreas. Proteolytic processing results in the formation of proinsulin, which is cleaved, giving rise to C-peptide and insulin itself, a double-chain molecule containing 51 amino acid residues. Glucose concentration plays a major role in the regulation of insulin release.[107] Glucose is phosphorylated after transport into the β-islet cell of the pancreas. Further metabolism of glucose-6-phosphate results in the formation of ATP. ATP inhibition of the K^+ channel results in cell depolarization, inward calcium flux, and insulin release. After release, insulin binds to specific receptors on cell surfaces in insulin-sensitive tissues, particularly the hepatocyte, myocyte, and fat cells. The action of insulin on these cells involves various phosphorylation and dephosphorylation reactions.

Figure 48–1 depicts the chemical structures of oral agents representing the major classes of antidiabetic and hypoglycemic agents. The sulfonylureas stimulate the β cells of the pancreas to release insulin; therefore, they are ineffective in type I diabetes mellitus resulting from islet cell destruction (Fig. 48–2). This stimulatory effect diminishes with chronic therapy. All the sulfonylureas bind to high-affinity receptors on the pancreatic β-cell membrane, resulting in closure of K^+ channels.[36,43,44] Inhibition of potassium ion efflux mimics the effect of naturally elevated intracellular ATP and results in insulin release. High-affinity sulfonylurea receptors also present within pancreatic β cells are postulated to be either located on granular membranes or part of a regulatory exocytosis kinase. Binding to these receptors promotes exocytosis by direct interaction with secretory machinery not involving closure of the plasma membrane K^+ channels.[36,43,44]

TABLE 48–1. Causes of Hypoglycemia

Artifactual	**Miscellaneous**	**Neoplasms**	Disopyramide
Chronic myelogenous leukemia	Acquired immunodeficiency syndrome (AIDS)	Carcinomas (diverse extrapancreatic)	Ethanol
Polycythemia vera	Anorexia nervosa	Hematologic	Hypoglycin (Ackee)
Endocrine disorders	Autoimmune disorders	Insulinoma	Pentamidine
Addison disease	Burns	Mesenchymal	Propoxyphene
Glucagon deficiency	Diarrhea (childhood)	Multiple endocrine adenopathy type 1 (Werner syndrome)	Quinidine
Panhypopituitarism (Sheehan syndrome)	Graves disease		Quinine
	Leucine sensitivity	**Reactive hypoglycemia**	Ritodrine
Hepatic disease	Muscular activity (excessive)	**Renal disease**	Salicylates
Acute hepatic atrophy	Postgastric surgery (including gastric bypass)	Chronic hemodialysis	Streptozocin
Alcoholism	Pregnancy	Chronic renal insufficiency	Sulfonamides
Cirrhosis	Protein calorie malnutrition	**Xenobiotics**	Vacor
Galactose or fructose intolerance	Rheumatoid arthritis	β-Adrenergic antagonists	Valproic acid
Glycogen storage disease	Septicemia	Alloxan	
Neoplasia	Shock	Antidiabetics (insulin, sulfonylureas, miglitinides)	
	SLE		
FIGURE 48–1. Chemical structures of representative oral antidiabetics.
FIGURE 48–2. Under normal conditions, cells release insulin in response to elevation of intracellular ATP concentrations. Sulfonylureas potentiate the effects of ATP at its "sensor" on the ligand-gated K$^+$ channels and prevent efflux of K$^+$. The subsequent rise in intracellular potential opens voltage-gated Ca^{2+} channels, which increases intracellular calcium concentration through a series of phosphorylation reactions. The increase in intracellular calcium results in the release of insulin. Release of insulin is also caused by binding of sulfonylureas to postulated receptor sites on regulatory exocytosis kinase and insulin granular membranes.

Repaglinide and nateglinide are oral agents of the meglitinide class and differ structurally from the sulfonylureas.[111] However, they also bind to K$^+$ channels on pancreatic cells, resulting in increased insulin secretion. Compared to the sulfonylureas, the hypoglycemic effects of the meglitinides are shorter in duration.

The linkage of two guanidine molecules forms the biguanides. Metformin is an oral compound approved for treatment of type II diabetes mellitus. Its glucose-stabilizing effect is caused by several mechanisms, the most important of which appears to involve inhibition of gluconeogenesis and subsequent decreased hepatic glucose output. Enhanced peripheral glucose uptake also plays a significant role in maintaining euglycemia. Metformin's ability to lower blood glucose concentrations also occurs as a result of decreased fatty acid oxidation and increased intestinal use of glucose.[9,132] In skeletal muscle and adipose cells, metformin causes enhanced activity and translocation of glucose transporters. Although the details are unclear, the mechanism by which this process occurs involves an interaction between metformin and tyrosine kinase on the intracellular portion of the insulin receptor. Figure 48–3 depicts the mechanism of action of metformin.

Insulin resistance in patients with type II diabetes mellitus may occur because of secretion of biologically defective insulin molecules, circulating insulin antagonists, or target tissue defects in insulin action.[96] The thiazolidinedione derivatives decrease insulin resistance by potentiating insulin sensitivity in the liver, adipose tissue, and skeletal muscle. Uptake of glucose into adipose tissue and skeletal muscle is enhanced, while hepatic glucose production is reduced.[17,54]

Acarbose and miglitol are oligosaccharides that inhibit α-glucosidase enzymes such as glucoamylase, sucrase, and maltase in the brush border of the small intestine. As a result, postprandial elevations in blood glucose concentrations after carbohydrate ingestion are blunted.[139] Delayed gastric emptying may be another mechanism for the antihyperglycemic effect of these oligosaccharides.[110]

Exenatide is structurally similar to glucagon-like peptide-1 (GLP-1), a human gut hormone that is released in response to an oral glucose
FIGURE 48–3. Under normal conditions, insulin binding to its receptor on myocytes and adipocytes activates tyrosine kinase, resulting in phosphorylation and activation of the membrane-bound glucose transporter GLUT. Non–insulin-dependent diabetes mellitus is causally associated with an increased activity of PC-1, a glycoprotein that inhibits tyrosine kinase activity and thus reduces myocyte and adipocyte glucose uptake. Metformin reduces PC-1 activity in these cells, enhancing peripheral glucose utilization. In addition, gluconeogenesis in hepatic cells is reduced through interference with pyruvate carboxylase, the enzyme responsible for conversion of pyruvate to oxaloacetate.

load. GLP-1 enhances the release of insulin, delays gastric emptying, and reduces food intake. GLP-1 is metabolized very rapidly, rendering it ineffective as a therapeutically administered agent. Exenatide has a much longer half-life, rendering it useful in the treatment of type II diabetes mellitus.[136] Sitagliptin and saxagliptin inhibit dipeptidyl peptidase-4 (DPP-4), the enzyme responsible for the inactivation of GLP-1.[1]

PHARMACOKINETICS AND TOXICOKINETICS

Pharmacokinetic parameters of the hypoglycemics are given in Tables 48–2 and 48–3. Insulin is a peptide that is poorly absorbed and degraded in the gut and therefore is not active by the oral route. The onset and duration of action in therapeutic doses varies considerably among preparations. Insulin overdose usually occurs after administration by the subcutaneous or intramuscular route. As might be predicted based on slow onset and prolonged duration of action of some of the preparations, insulin overdose may result in delayed and prolonged hypoglycemia. However, hypoglycemia may also occur with short-acting forms because of some unusual toxicokinetic features. Some of these unpredicted responses may be caused by a depot effect following intramuscular or subcutaneous administration, and poor absorption may be further potentiated by the poor perfusion that can occur during periods of hypoglycemia.[88,129] Further complicating the prediction of the clinical course is the delayed release of insulin from adipose tissue at the injection site(s). In diabetics, the presence of insulin antibodies may explain a patient's recovery in spite of massive overdoses.[117] Because there are a finite number of insulin receptors, insulin overdoses of varying amounts probably are equivalent in terms of the degree of resultant hypoglycemia once receptor saturation occurs, but not in terms of its duration. A comparison can be made with the current treatment of diabetic ketoacidosis, in which lower doses of insulin are as effective as the higher doses used in the past.[61]

Many of the sulfonylureas have a long duration of action, which may explain the unusually long period of hypoglycemia that can occur in both therapeutic use and overdose. The first-generation sulfonylureas (acetohexamide, chlorpropamide, tolazamide, tolbutamide) reduce hepatic clearance of insulin and produce active metabolites via hepatic metabolism. These drugs are dependent on their effective urinary excretion to maintain euglycemia and prevent hypoglycemia.

Second-generation sulfonylureas (glimepiride, glipizide, glyburide) have half-lives that approach 24 hours and are characterized by substantial fecal excretion of the parent drug. These drugs frequently cause hypoglycemia (Table 48–2). Like insulin, the sulfonylureas may cause delayed onset of hypoglycemia following overdose.[98,108] The reason for the potential delayed onset of effects with sulfonylureas cannot be simply explained by known kinetic principles, but may be related to effective counter regulatory mechanisms that fail over time.

Metformin metabolism is negligible, and the majority of an absorbed dose is actively secreted in the urine unchanged. Plasma protein binding also is negligible.[9] The kinetics of acarbose are notable for minimal systemic absorption and metabolism that occurs in the gastrointestinal tract. As a result, serious systemic toxicity is not expected.[118] Despite extensive gastrointestinal absorption of miglitol, serious toxicity is unlikely. Adverse clinical effects due to α-glucosidase inhibitors are usually gastrointestinal. Repaglinide and nateglinide are prandial glucose regulators characterized by short onset and short duration of action. Overdose experience and toxicokinetic data for repaglinide are lacking. Whether after-overdose hypoglycemia would be prolonged or delayed in onset is not clear. In one case of nateglinide overdose, hypoglycemia occurred early and was short lived.[89] Exenatide is available only for parenteral (subcutaneous) injection.

Both sitagliptin and saxagliptin have long half-lifes and cause pronounced inhibition of DPP-4, resulting in a long duration of action (approximately 24 hours) after therapeutic doses.[68]

PATHOPHYSIOLOGY OF HYPOGLYCEMIA

To varying degrees, the antidiabetics may all produce a nearly identical clinical condition of hypoglycemia. The etiologies of hypoglycemia are divided into three general categories:[40] physiologic or pathophysiologic conditions (Table 48–1), direct effects of various hypoglycemics (Tables 48–2 and 48–3), and potentiation of hypoglycemics by interactions with other xenobiotics (Table 48–4).

Central nervous system (CNS) symptoms predominate in hypoglycemia because the brain relies almost entirely on glucose as an energy source. However, during prolonged starvation, the brain can utilize ketones derived from free fatty acids. In contrast to the brain, other major organs such as the heart, liver, and skeletal muscle often function during hypoglycemia because they can use various fuel sources, particularly free fatty acids.[122]

Emphasis on tighter diabetic control as a means of preventing microvascular effects carries with it an increased risk for hypoglycemia.[30,31] Regulation of glucose control to near-normal glucose concentrations, the characteristics of each individual's awareness of hypoglycemia, and the individual counterregulatory mechanisms define the frequency and intensity of hypoglycemia.[121] The Diabetic Control and Complications Trial (DCCT) research group reported 62 episodes of blood glucose concentration less than 50 mg/dL with CNS manifestations requiring assistance for every 100 patient-years in patients undergoing an intensive insulin therapy regimen. This was in comparison to a conventional therapy group, which had 19 such episodes per 100 patient-years.[30,31] The intensive therapy group received three or more insulin injections per day or used a pump in an effort to achieve a glucose concentration as close to normal as possible, whereas the conventional therapy group received 1 or 2 daily insulin injections.

There has also been a recent emphasis in tighter control of glucose in critically ill patients, even when they are not known to have diabetes mellitus. Hyperglycemia occurs in critically ill patients due to several mechanisms, and is associated with increased mortality in patients with a variety of medical and surgical diagnoses.[63] In a study of critically ill surgical patients tight control of glucose was associated with decreased morbidity and mortality.[141] However, such benefits in other studies are not always clearly replicated, and significant hypoglycemia has been reported.[37,140] Further large studies are ongoing and will hopefully clarify the risks and benefits of tight control.

The autonomic nervous system regulates glucagon and insulin secretion, glycogenolysis, lipolysis, and gluconeogenesis. β-Adrenergic antagonists affect all of these mechanisms and can result in hypoglycemia. In the presence of chronic renal failure, β-adrenergic antagonist–induced hypoglycemia is a particular risk[47] secondary to increased insulin half-life and reduced renal gluconeogenesis.[99] In addition, the clinical presentation of hypoglycemia may be muted when β-adrenergic antagonists are present because the expected autonomic responses of tachycardia, diaphoresis, and anxiety may not occur. Although this is assumed to be true, an adverse effect on hypoglycemic awareness could not be demonstrated in healthy volunteers given metoprolol, atenolol, and propranolol.[60]

The concept of hypoglycemia-associated autonomic failure in diabetes mellitus is well described.[28] Recent episodes of hypoglycemia result in autonomic failure by causing defective glucose counterregulation and hypoglycemic awareness. As glucose concentrations fall, normal sensing mechanisms result in decreased insulin secretion and increased

TABLE 48–2. Characteristics of Noninsulin Hypoglycemics and Antidiabetics

Xenobiotic	Duration of Action (h)	Active Hepatic Metabolite	Active Urinary Excretory Product (% of Dose)	Fecal Excretion (% of Dose)	Frequency of Severe Hypoglycemia (Other Complications)
I. Sulfonylureas					
First generation					
Acetohexamide (Dymelor)	12–18	Hydroxyhexamide (+++)	Hydroxyhexamide (65%) Acetohexamide (2%)	Negligible	~1%
Chlorpropamide (Diabinese)	24–72	2-Hydroxychlorpropamide (+) 3-Hydroxychlorpropamide (+)	Chlorpropamide (20%) 2-Hydroxychlorpropamide (55%) 3-Hydroxychlorpropamide (2%)	Negligible	4%–6%
Tolazamide (Tolinase)	16–24	Hydroxytolazamide (++)	Hydroxytolazamide (35%) Tolazamide (7%)	Negligible	~1%
Tolbutamide (Orinase)	6–12	Hydroxytolbutamide (+)	Hydroxytolbutamide (30%) Tolbutamide (2%)	Negligible	<1%
Second generation					
Glimepiride (Amaryl)	24	Cyclohexylhydroxy ethyl derivative (++)	Cyclohexylhydroxy methyl derivative (63%)	15%	1%–2%
Glipizide (Glucotrol, Glucotrol XL)	16–24	None	Glipizide (3%)	12%	2%–4%
Glyburide (Micronase, Glynase, DiaBeta)	18–24	4-Hydroxyglyburide (++)	4-Hydroxyglyburide (36%) Glyburide (3%)	50%	4%–6%
II. Biguanides					
Metformin (Glucophage, Glucophage XR) Metformin/Glyburide (Glucovance) Metformin/Rosiglitazone (Avandamet) Metformin/Glipizide (Metaglip)	1.3–4.5	None	Metformin (90%)	Negligible	Rare (lactic acidosis 0.03 cases/1000 patient-years)
Phenformin	6–8	None	Phenformin (66%)	Negligible	Uncommon (lactic acidosis 0.64 cases/ 1000 patient-years)
III. α-Glucosidase Inhibitors					
Acarbose (Precose)	2	None	4-Methyl pyrogallol derivative (<2%)	None	None
Miglitol (Glyset)	2	None	100%	None	None
IV. Thiazolidinedione Derivatives					
Pioglitazone (Actos)	16–24	Hydroxy derivative Keto derivative	?<15–30%	70%	None
Rosiglitazone (Avandia)	12–24	None	None	23%	None
V. Meglitinides					
Nateglinide (Starlix)	2–4	Isoprene derivative (++) Hydroxylation metabolites (+)	~16% as parent	10%	<1%
Repaglinide (Prandin)	1–3	None	None	90%	4%–6%
VI. Gliptins					
Sitagliptin (Januvia)	24	None	Sitagliptin (70%–80%)	16%–20%	None
Saxagliptin (Onglyza)	24	5-hydroxy	Saxagliptin (24%) 5-hydroxy (36%)	22%	4–6% mono; 13–15% poly
VII. GLP-1 Analogues					
Exenatide (Byetta)	6-8	None	None	Negligible	Rare

+ = Weakly active; ++ = moderately active; +++ = more active than parent xenobiotic. The durations of action for the oral xenobiotics are cited for therapeutic doses. These values increase for overdoses.

TABLE 48–3. Characteristics of Routinely Used Forms of Insulin

Insulin	Onset of Action (h)	Duration of Action (h)	Peak Glycemic Response (h)
Rapid and Ultrashort-acting			
Aspart	0.25	3–5	0.75–1.5
Glulusine	0.5	<5	1.5–2
Lispro	0.25–0.5	<5	0.5–2.5
Short-acting			
Regular	0.5–1	5–8	2.5–5
Intermediate-acting			
Lente	1–3	18–24	6–14
NPH	1–2	18–24	6–14
Long-acting			
Detemir	1.5	24	No true peak
Glargine	1.1	24	No true peak
Ultralente	4–6	20–36	8–20

glucagon and epinephrine secretion. These counterregulatory defenses against hypoglycemia are defective in most people with type I diabetes mellitus and in many with type II diabetes mellitus.

Although various xenobiotics can cause hypoglycemia (Table 48–1), salicylates and ethanol are particularly notable for their unintended hypoglycemic effects. The mechanism of ethanol-induced hypoglycemia is discussed in Chap. 77. Salicylate inhibition of prostaglandin synthesis in the β cell of the pancreas is postulated to result in enhanced insulin secretion.[11] Salicylates may also cause hypoglycemia by poorly defined mechanisms that do not involve enhanced insulin secretion.

Besides decreasing glucose concentrations, the hypoglycemics can produce a number of adverse effects, both in overdose and in therapeutic doses. The sulfonylureas, predominantly chlorpropamide, can cause a syndrome of inappropriate antidiuretic hormone secretion.[57] Concomitant use of sulfonylureas, predominantly chlorpropamide

TABLE 48–4. Xenobiotics Known to React with Hypoglycemics Resulting in Hypoglycemia

Angiotensin-converting enzyme (ACE) inhibitors	Methotrexate
Allopurinol	Monamine oxidase inhibitors
Anabolic steroids	Pentamidine
β-Adrenergic antagonists	Phenylbutazone
Chloramphenicol	Probenecid
Clofibrate	Quinine
Disopyramide	Salicylates
Ethanol	Sulfonamide
Fluoroquinolones	Trimethoprim sulfamethoxazole
Haloperidol	Warfarin

See Table 48–1 for list of xenobiotics that cause hypoglycemia independently.

and ethanol can cause a disulfiram–ethanol reaction, as sulfonylureas inhibit aldehyde dehydrogenase.[104]

CLINICAL MANIFESTATIONS

Hypoglycemia and its secondary effects on the CNS (neuroglycopenia) are the most common adverse effects related to insulin and the sulfonylureas. It is essential to remember that hypoglycemia is primarily a clinical and not a numerical disorder. Clinical hypoglycemia is the failure to maintain a serum glucose concentration that prevents signs or symptoms of glucose deficiency. The clinical presentations of patients with hypoglycemia are extremely variable. Hypoglycemia must be considered to be the etiology of any neuropsychiatric abnormality, whether persistent or transient, focal or generalized. The cerebral cortex usually is most severely affected. Categorization of these findings is as follows:[106]

- Delirium with subdued, confused, or manic behavior.
- Coma with multifocal brainstem abnormalities, including decerebrate spasms and respiratory abnormalities, with preservation of the oculocephalic (doll's eyes), oculovestibular (cold-caloric), and pupillary responses.
- Focal neurologic deficits simulating a cerebrovascular accident (CVA) with or without the presence of coma. During a 12-month study period, 3 (2.4%) of 125 hypoglycemic patients presented with hemiplegia.[76] There are numerous reports[4,125] and series[119,138] of patients with focal neurologic deficits.
- Solitary or multiple seizures.

These neuropsychiatric symptoms are usually reversible if the hypoglycemia is corrected promptly. The morbidity resulting from undiagnosed hypoglycemia is related partly to the etiology and partly to the duration and severity of the hypoglycemia. Because the etiologies of hypoglycemia encompass both severe diseases such as fulminant hepatic failure and benign problems such as a missed meal by an insulin-requiring diabetic, the literature with regard to outcome is confusing. Although a study of 125 emergency department (ED) cases of symptomatic hypoglycemia reported an 11% mortality rate,[76] only 1 death (0.8%) was attributed directly to hypoglycemia. In that same study, nine patients (7.2%) presented with seizures (focal in one case), three patients (2.4%) presented with hemiparesis, and four survivors (3.2%) suffered residual neurologic deficits. In one tertiary care medical center, 1.2% of all admitted patients had hypoglycemia (defined as a glucose concentration less than 50 mg/dL). The overall mortality was 27% for this group of 94 patients.[40] The longer and more profound the hypoglycemic episode, the more likely permanent CNS damage will occur.[7]

No absolute criteria available from the physical examination or history distinguish one form of metabolic coma from another. Moreover, the findings classically associated with hypoglycemia, such as tremor, sweating, tachycardia, confusion, coma, and seizures, frequently may not occur.[52] The glycemic threshold is the glucose concentration below which clinical manifestations develop, a threshold that is host variable. In one study, the mean glycemic threshold for hypoglycemic symptoms was 78 mg/dL in patients with poorly controlled Type 1 diabetes compared to 53 mg/dL in nondiabetics.[15]

Patients with well-controlled Type 1 diabetes may be unaware of hypoglycemia. It appears that even in the presence of numerical hypoglycemia, diabetic individuals with near-normal glycosylated hemoglobin values maintain near-normal glucose uptake by the brain, thereby preserving cerebral metabolism and limiting the response of

counterregulatory hormones. The result of this limited response is unawareness of hypoglycemia.[14,15] A threshold level likely is achieved below which the glucose concentration is inadequate, but this may be a concentration so close to that causing serious neuroglycopenia that patients have limited opportunity for corrective action.[14] Hypoglycemia unawareness is most likely in diabetics with chronic exposure to hypoglycemics because of hypoglycemia-associated autonomic failure.[28] Acute ingestion of hypoglycemic agents in nondiabetic patients likely would cause classic signs and symptoms.

Sinus tachycardia, atrial fibrillation, and ventricular premature contractions are the most common dysrhythmias associated with hypoglycemia.[69,95] An outpouring of catecholamines, hypoglycemia itself, transient electrolyte abnormalities, and underlying heart disease appear to be the most likely etiologies. Based on their mechanisms of action, both insulin and the sulfonylureas are expected to promote the shift of potassium into cells, and hypokalemia after insulin overdose is well documented.[6,129] Other cardiovascular manifestations include angina and ischemia, which rarely may be the sole manifestations of hypoglycemia.[35] Both are directly related to hypoglycemia.[12,103] Increased release of catecholamines during hypoglycemia increases myocardial oxygen demand and may decrease supply by causing coronary vasoconstriction.

Hypothermia may occur in hypoglycemic patients.[41,59,131] If present, hypothermia usually is mild (90°–95°F [32°–35°C]), unless coexisting conditions such as environmental exposure, infection, head injury, or hypothyroidism are present. In a study comparing two groups of patients with depressed mental status, hypothermia was almost exclusively limited to the hypoglycemic patients; of these patients, 53% with demonstrated hypoglycemia showed hypothermia.[131] The central hypothalamic response to hypoglycemia stimulated by the sympathetic nervous system may actually "overshoot" normal temperatures, resulting in hyperthermia following recovery.[25]

Hypoglycemia is reported in two cases of metformin overdose.[134] In both cases, metabolic acidosis with hyperlactatemia was evident on initial presentation. Hypoglycemia was present initially in one of the cases but did not develop until 7 hours later in the second case. Hypoglycemia and metabolic acidosis with hyperlactatemia are reported in a case of overdose with metformin, atenolol, and diclofenac.[48] Hypoglycemia is reported in a case of metformin-associated metabolic acidosis with hyperlactatemia related to therapeutic use.[64] Insufficient evidence supports the concept that metformin-associated hypoglycemia can develop in a patient who is not critically ill without metabolic acidosis. Because many patients receiving metformin also take sulfonylureas, hypoglycemia should be anticipated after overdose. Phenformin is similar to metformin in that ingestion alone rarely causes hypoglycemia, in overdose or following therapeutic use.[120]

The α-glucosidase inhibitors, thiazolidinediones, meglitinides, exenatide, and gliptins, are newer agents for which overdose data are limited. Acarbose and miglitol are not likely to cause hypoglycemia based on their mechanism of action of inhibiting α-glucosidase. The most common adverse effects associated with therapeutic use of these xenobiotics are gastrointestinal, including nausea, bloating, abdominal pain, flatulence, and diarrhea. Elevated aminotransferase concentrations were noted after use of acarbose in clinical trials.[53] Most patients were asymptomatic, and the aminotransferase concentrations returned to normal after the drug was discontinued. The therapeutic use of acarbose in some cases reportedly led to hepatotoxicity that resolved after the drug was discontinued.[5,23]

Although hypoglycemia would not be expected after thiazolidinedione overdose, experience is limited. The most serious adverse effect of troglitazone is the development of liver toxicity with therapeutic doses, which in some cases was severe enough to require liver transplantation.[45,92] Liver toxicity related to therapeutic use of rosiglitazone[3,42] and pioglitazone is also reported.[75,78] Therapeutic use

of pioglitazone and rosiglitazone may precipitate fluid retention in patients with underlying congestive heart failure.[91] A meta-analysis concluded that rosiglitazone therapy is associated with an increased risk of myocardial infarction and death from cardiovascular causes.[94]

Hypoglycemia should be anticipated after repaglinide and nateglinide ingestion. Hypoglycemia has been reported after nateglinide overdose,[89] and a case of intentionally self-induced hypoglycemia secondary to repaglinide is reported.[51] Hypoglycemia did not occur in a recently published case of intentional overdose with a total of 90 μg exenatide.[27] "Severe hypoglycemia" was reported in a phase III clinical trial after inadvertent administration of ten times the normal dose of exenatide. The specific glucose concentration is not noted in the report.[21] Sitagliptin was recently released in the United States and overdose data are lacking.

HYPOGLYCEMIC POTENTIAL OF ANTIDIABETICS

Hypoglycemia may not occur until 18 hours after lente insulin overdose,[88] may persist for up to 53 hours after insulin glargine overdose,[18] and may persist up to 6 days after ultralente insulin overdose.[77] Death after insulin overdose cannot be correlated directly with either the dose or preparation type. Some patients have died with doses estimated in the hundreds of units, whereas others have survived doses in the thousands of units.[117] Mortality and morbidity may correlate better with delay in recognition of the problem, duration of symptoms, onset of therapy, and type of complications, as opposed to the absolute degree of hypoglycemia or persistence of elevated insulin concentrations. A significant correlation exists between the amount of insulin injected and either the total amount of dextrose used for treatment or the duration of dextrose infusion.[129] In a retrospective study of insulin overdose, 7 (41%) of 17 cases developed recurrent hypoglycemia between 5 and 39 hours after overdose despite oral feeding and intravenous dextrose infusion ranging from 5 to 17 g of dextrose per hour.

In a retrospective review of 40 sulfonylurea overdose cases, the time from ingestion to the onset of hypoglycemia, when known, was variable.[98] The longest delay was 21 hours after ingestion of glyburide and 48 hours after ingestion of chlorpropamide. In a retrospective poison center review of 93 cases of sulfonylurea exposures in children, 25 patients (27%) developed hypoglycemia, with a time of onset ranging from 0.5 to 16 hours and a mean of 4.3 hours.[108] In a prospective poison center study of sulfonylurea exposures in children, 56 (30%) of 185 patients developed hypoglycemia, with a time of onset ranging from 1 to 21 hours and a mean of 5.3 hours.[126] Single-tablet ingestions of chlorpropamide 250 mg, glipizide 5 mg, and glyburide 2.5 mg can result in hypoglycemia in young children,[108] and the hypoglycemia may be delayed.[133]

DIAGNOSTIC TESTING

Suspicion of possible hypoglycemia, particularly neuroglycopenia, is important in the patient with an abnormal neurologic examination. The most frequent reasons for failure to diagnose hypoglycemia and mismanaging patients are the erroneous conclusions that the patient is not hypoglycemic but rather is psychotic, epileptic, experiencing a CVA, or intoxicated because of an "odor of alcohol" on the breath (Chap. 77). Compounding the problem of misdiagnosis is the erroneous assumption that a single bolus of 0.5–1 g/kg of dextrose 50% in water ($D_{50}W$) for an adult will always be sufficient.

Serum glucose concentrations are accurate, but treatment cannot be delayed pending the results of laboratory testing. Glucose reagent strip testing can be performed at the bedside. The sensitivity of these tests

for detecting hypoglycemia is excellent, but these tests are not perfect. Bedside glucose testing is discussed in more detail in Antidotes in Depth A10: Dextrose.

Diagnostic studies other than determinations of glucose concentrations may be indicated, depending on the clinical situation. In some instances, determination of serum ethanol concentration may be helpful in confirming alcohol as a contributing or sole etiologic factor. Renal function tests may indicate the presence of renal impairment as a causative factor of hypoglycemia. This commonly occurs in diabetics taking insulin, who often develop renal failure after they have had the disease for several years. Insulin half-life increases as renal function declines. Measures of hepatic function may be a clue to liver disease as a cause of hypoglycemia, although liver disease may also be evident on physical examination. Seizures are commonly associated with hypoglycemia, but other studies, such as electrolytes, calcium, magnesium, and computed tomographic scanning of the brain, may be indicated if doubt about the etiology exists.

In the majority of overdose cases, laboratory testing for specific antidiabetics is not helpful. Exceptions might include malicious, surreptitious, or unintentional overdoses (discussed in the next section). Metformin concentrations in the setting of overdose and metformin-associated metabolic acidosis with hyperlactatemia are variable and do not necessarily correlate with the clinical condition.[2,65,66]

For known diabetics in whom overdose is not suspected, the clinician must search diligently for the cause of hypoglycemia. Sometimes it is as simple as a missed meal in an insulin user or an unusually strenuous exercise routine, but in many cases the cause cannot be clearly defined. Numerous medical conditions, as well as a variety of medications, may be involved (Table 48–1), and diagnostic testing must be individualized for each episode depending on the clinical suspicion. Diagnosing the etiology as "idiopathic" is never acceptable.

EVALUATION OF MALICIOUS, SURREPTITIOUS, OR UNINTENTIONAL INSULIN OVERDOSE

The physical examination may provide helpful clues to the evaluation of a suspected malicious, surreptitious, or unintentional insulin overdose. A meticulous search may reveal a site that is erythematous, hemorrhagic, atypically boggy in nature, or even painful if the subcutaneous (or intramuscular) injection of insulin was particularly large. A simple unexplained needle puncture mark in the appropriate clinical setting may suggest insulin injection.

An understanding of how the β cells of the pancreas secrete insulin in response to glucose concentrations in the blood is essential to understanding the investigation of fasting hypoglycemia.[29] When the plasma glucose concentration is less than 45 mg/dL, insulin secretion should be almost completely suppressed, so plasma insulin concentrations should be minimal or absent.[105] Moreover, insulin is secreted as proinsulin, which is cleaved in vivo to form insulin (a double-stranded peptide) and C-peptide, which are released into the blood in equimolar quantities. Insulin is biologically active, whereas proinsulin has limited activity, and C-peptide has no activity. Although insulin is normally cleared during hepatic transit, C-peptide is not. For this reason, C-peptide can be utilized as a quantitative marker of *endogenous* insulin secretion. Commercially available exogenous human insulin does not contain C-peptide fragments (Table 48–5). When plasma glucose concentration falls to hypoglycemic concentrations (usually less than 60 mg/dL), insulin concentration should fall to less then 6 μUnits /mL. If hypoglycemia is caused by exogenous insulin administration, plasma C-peptide concentrations should be less than 0.2 nmol/L in the presence of insulin concentrations that are substantially higher than insulin concentrations resulting from an insulinoma. With insulinoma, insulin concentrations generally are greater than 6 μUnits /mL in the presence of hypoglycemia. Insulinoma results in elevations of both C-peptide and insulin concentrations. Sulfonylurea overdose is expected to have similar effects, but concentrations in reported cases of sulfonylurea-induced hypoglycemia vary considerably.[33] In the face of uncertainty, sulfonylurea concentrations are readily available from reference laboratories. Animal insulin can be distinguished from human insulin by high-performance liquid chromatography.[46] However, this technique has limited use because of the virtually exclusive use of human insulin at present.

In summary, patients with chronic insulin-induced hypoglycemia will have high insulin concentrations, the presence of insulin-binding antibodies,[39] and low C-peptide concentrations. Those who have taken sulfonylureas will have high insulin concentrations, absent insulin-binding antibodies, high C-peptide concentrations, and presence of urinary sulfonylurea metabolites (Table 48–5). The issues of evidence collection that are appropriate to document malicious or surreptitious use of insulin successfully have been described[73] (Chap. 140).

TABLE 48–5. Laboratory Assessment of Fasting Hypoglycemia

Clinical State	Insulin[a] (Plasma) (μUnit/mL)	C-Peptide (Plasma) (nmol/L)	Proinsulin (pmol/L)	Antiinsulin Antibodies[b]
Normal	<6	<0.2	<5	–
Exogenous insulin	Very high	Low (suppressed)	Absent	Present[c]
Insulinoma	High	High	Present	Absent
Sulfonylurea ingestion[d]	High	High	Present	Absent
Autoimmune	Very high (artifact)	Low (or) high (artifact)	Present	Present
Decreased glucose production	Low	Low	Present	Absent
Neoplasia (non–β-cell)	Low	Low	Present	Absent

[a]Insulin concentrations are determined during fasting hypoglycemia at low concentrations, preferably <60 mg/dL of blood glucose.

[b]The antiinsulin antibodies produced spontaneously differ from those of treated (exposed to exogenous insulin) and those of untreated insulin-dependent diabetics.

[c]The presence of antiinsulin antibodies occurs less frequently in those exposed only to human insulin.

[d]Sulfonylurea ingestion is diagnosed by detection of the drugs or their metabolites in plasma or urine.

MANAGEMENT

Treatment centers on the correction of hypoglycemia and the anticipation that hypoglycemia may recur. Symptomatic patients with hypoglycemia require immediate treatment with 0.5–1 g/kg concentrated intravenous dextrose in the form of $D_{50}W$ in adults, $D_{25}W$ in children, and $D_{10}W$ in neonates. Occasionally, patients require a larger dose to achieve an initial response. If hypoglycemia is suspected but not confirmed, as in the absence of rapid reagent strip availability or when such readings are "borderline," dextrose should be administered. Theoretical risks are associated with use of concentrated dextrose in the setting of cerebral ischemia, but failure to rapidly correct hypoglycemia may lead to deleterious neurologic effects. Appropriate emergency and toxicologic uses of hypertonic dextrose are covered in detail in Antidotes in Depth A10: Dextrose.

Glucagon should not be considered as an antihypoglycemic agent except in the uncommon situation where intravenous access cannot be obtained. Glucagon has a delay to onset of action and may be ineffective in patients with depleted glycogen stores, as in the elderly, cancer patients, or alcoholics. Glucagon also stimulates insulin release from the pancreas, which may lead to prolonged hypoglycemia in settings such as sulfonylurea ingestion and insulinoma.[135]

Numerous studies have evaluated approaches for treating insulin reactions with carbohydrates in tablet, solution, or gel forms in a well-defined diabetic population.[123] None of these forms is appropriate for the undefined, possibly hypoglycemic patient if IV access is available. Patients who have significant clinical symptoms of hypoglycemia are at risk for grave CNS complications unless they are treated quickly and adequately with glucose.

A common occurrence involves symptomatic hypoglycemic patients who receive intravenous dextrose in the prehospital setting and subsequently refuse transport to the hospital. The authors of a retrospective review of 571 paramedic runs involving hypoglycemic patients concluded that out-of-hospital treatment of hypoglycemic diabetic patients is safe and effective even when transport is refused.[124] However, of the 159 patients who agreed to hospital transport, 40% were admitted. The admitted group was older than those released from the Emergency Department (ED). The admission rate for transported patients on oral hypoglycemics was higher than those on insulin. The reasons for admission are not otherwise detailed. The authors of a prospective study involving 132 hypoglycemic diabetic patients who refused transport after therapy concluded that most such patients have good short-term outcome, but they still encouraged transport because of the risk of recurrent hypoglycemia.[84] One patient died in each of these two studies. A prospective study in 35 patients with 38 hypoglycemic events related to insulin use concluded that most patients were successfully treated in the prehospital setting without transport.[71] However, two patients developed recurrent hypoglycemia that they treated themselves, and one of these patients required placement in a long-term care facility for posthypoglycemic encephalopathy. We *emphatically* encourage the further education of paramedics and restructuring of their protocols, emphasizing the importance of transporting all hypoglycemic patients to EDs if their approach differs from these recommendations.

Emesis, lavage, and catharsis are of limited benefit in the management of patients who overdose on antidiabetics and hypoglycemics. The extensive affinity between chlorpropamide, tolazamide, tolbutamide, glyburide, glipizide, and activated charcoal is demonstrated in vitro.[58] The affinities ranged from 0.45 to 0.52 g/g activated charcoal at pH 7.5 and were higher at pH 4.9. Single-dose activated charcoal should be beneficial in the management of these overdoses. Although affinity studies are lacking for the other antidiabetics and hypoglycemics, their chemical characteristics are such that single-dose activated charcoal is expected to be beneficial for these overdoses as well. Multiple-dose activated charcoal and whole-bowel irrigation may be of benefit and should be considered after overdose of modified-release antidiabetics and hypoglycemics, but outcome studies are not available.

In patients who overdose on insulin, case reports describe the use of surgical excision of the injection site.[22,72,80] However, this technique has not been studied in a systematic fashion, so further data are necessary before this approach can be recommended. Needle aspiration of a depot site is less invasive and should be considered.

Urinary alkalinization to a pH of 7–8 can reduce the half-life of chlorpropamide from 49 hours to approximately 13 hours. Urinary alkalinization is not useful for other oral antidiabetics, because of their limited renal excretion.[93]

MAINTAINING EUGLYCEMIA AFTER INITIAL CONTROL

After the patient is awake and alert, further therapy depends on the xenobiotic involved and pancreatic islet cell function. Some patients, particularly those with prolonged hypoglycemia, may have persistent altered mental status despite euglycemia. Whether the event was unintentional or intentional with suicidal or homicidal intent must be determined. One problem associated with dextrose administration occurs in individuals who can produce insulin via glucose-stimulated insulin release (nondiabetics and those with type II diabetes mellitus), placing them at substantial risk for recurrent hypoglycemia. This complication can occur with insulin overdose but is particularly problematic with overdoses of sulfonylurea or meglitinide because these hypoglycemics stimulate insulin release. Treatment with hypertonic dextrose solutions can be expected to result in dramatic yet only transient increases in glucose concentrations, with a subsequent fall in serum glucose concentration possibly back to hypoglycemic concentrations.

For diabetic patients who unintentionally inject an excessive amount of insulin and are not neuroglycopenic, feeding should be initiated and intravenous access maintained while avoiding routine dextrose infusion. In the event of recurrent hypoglycemia, a concentrated dextrose bolus should be used. Overdose in the setting of suicidal or homicidal intent likely involves significant quantities of insulin. Nondiabetics may be particularly prone to significant hypoglycemia because they lack insulin resistance. Feeding should be initiated and glucose concentrations maintained in the 100–150 mg/dL range using a concentrated dextrose infusion ($D_{10}W$).

Some patients may require even more concentrated dextrose infusions, such as 20% dextrose in water ($D_{20}W$) augmented by repeated doses of $D_{50}W$. Central venous lines should be used when $D_{20}W$ infusion is instituted, because concentrated dextrose solutions are substantial venous irritants. The presence of glycosuria is not an adequate indicator of euglycemia; frequent serial blood or reagent strip glucose concentrations should be obtained. The appropriate timing of glucose monitoring varies depending on the clinical situation. Mental status must be observed. As a rough guide, glucose monitoring every 1–2 hours after initial control is reasonable, with subsequent spacing of the intervals to once every 4–6 hours. Phosphate concentrations should be monitored because glucose loading may lead to hypophosphatemia.[85] Potassium concentrations should be monitored because glucose administration may lead to hypokalemia in nondiabetics and hyperkalemia in patients with impaired insulin secretion.[26] The duration of sampling necessary depends on the stability of the patient, the underlying metabolic disorders, the extent of overdose, and the rate of improvement. When the patient begins to eat an adequate diet and the initial hypoglycemia is controlled, the serum glucose concentration will rise, and the concentration and rate of dextrose infusion can be tapered. Many patients may actually develop significant hyperglycemia.

The therapeutic approach differs for patients who overdose on sulfonylureas or meglitinides. After initial control of hypoglycemia with concentrated dextrose, the patient should be fed. Intravenous access is necessary, but routine dextrose infusion should be avoided. As with insulin overdose, frequent monitoring of glucose concentrations and mental status is critical. We recommend early use of octreotide in this setting because of the significant risk of glucose-stimulated insulin release.

Octreotide, a semisynthetic long-acting analog of somatostatin with an intravenous half-life of 72 minutes, inhibits glucose-stimulated β-cell insulin release via receptors coupled to G proteins on β-islet cells.[13] Somatostatin is present in diverse tissues such as the hypothalamus, pancreas, and GI tract. It alters the secretion of growth hormone and thyroid-stimulating hormone, gastrointestinal secretions, and the endocrine pancreas (glucagon and insulin).[112,113] Octreotide was compared to intravenous hypertonic dextrose and to diazoxide and concomitant dextrose in normal subjects brought to hypoglycemia using glipizide.[13] Fewer episodes of recurrent hypoglycemia occurred after octreotide therapy, and overall dextrose requirements were lower than in the dextrose-alone and dextrose-plus-diazoxide groups. Several successful clinical experiences with octreotide are reported with quinine-induced hypoglycemia resulting from malaria therapy,[102] insulinoma,[50] nesidioblastosis of infancy,[32] hypoglycemia related to therapeutic use of gliclazide,[16] and tolbutamide overdose.[13] In a retrospective study of nine patients with hypoglycemia resulting from either glyburide or glipizide, octreotide effectively reduced the risk of recurrent hypoglycemia.[81]

Octreotide appears to be relatively free of serious side effects. The most likely adverse effects are injection-site discomfort if the agent is administered subcutaneously and gastrointestinal symptoms such as nausea, bloating, diarrhea, and constipation.[74] The suggested adult octreotide dose is 50 μg subcutaneously every 6 hours (Antidotes in Depth A11: Octreotide). The patient should be monitored for 24 hours after the last dose of octreotide to assure that recurrence of hypoglycemia does not occur. Like octreotide, diazoxide may be effective in patients with refractory sulfonylurea-induced hypoglycemia.[56,98] However, because of its potential to cause hypotension, diazoxide should be considered only if octreotide is ineffective or unavailable.

ADMITTING PATIENTS TO THE HOSPITAL

The decision to admit a patient may be complex, but several guidelines can be followed. Admission is required for hypoglycemia related to sulfonylureas, ethanol, starvation, hepatic failure, and renal failure and for hypoglycemia of unknown etiology. The decision to admit a patient often depends on finding an etiology for hypoglycemia, particularly in the setting of insulin use. In most cases, if a diabetic patient on therapeutic doses of insulin develops hypoglycemia after a missed meal, the patient can be discharged after a 4-6-hour observation period during which the individual eats a meal and remains asymptomatic with no evidence of hypoglycemia. Patients receiving therapeutic doses of insulin require inpatient evaluation of recurrent and unexplained hypoglycemic episodes. All patients with hypoglycemia after unintentional overdose with long-acting insulin should be admitted. Hospitalization is recommended after unintentional overdose with ultrashort-acting, short-acting, or intermediate-acting insulin if hypoglycemia is persistent or recurrent during a 4-6-hour observation period in the ED. Many factors may be responsible for unintentional insulin overdose, such as patient error because of impaired vision, syringe structure, and prescription error, and hospital admission may be warranted. Admission is indicated for any patient, regardless of serum glucose concentration or presence or absence of symptoms, who intentionally overdoses on a sulfonylurea or any form of injected insulin, because delayed, profound, and protracted hypoglycemia may

result. Although insulin overdose by the intravenous route is expected to result in more immediate symptoms, experience with this scenario is limited. Admission in this setting is advised unless short-acting insulin is involved. Hypoglycemia related to sulfonylurea use in any setting requires hospitalization.[19]

Patients with possible intentionally self-induced hypoglycemia should be admitted. Intentionally self-induced hypoglycemia is most commonly recognized by members of the medical profession. Administration of insulin to a nondiabetic child is a form of child abuse or an attempt at homicide[34] (see Chap. 31. Children who have been given an inappropriate dose of insulin, as well as any patient who may be a victim of attempted homicide, should be admitted.

A 4 to 6-hour observation period is recommended after metformin overdose. Further observation or hospital admission is not required for patients who remain asymptomatic during this period with no evidence of metabolic acidosis or hypoglycemia. Patients who overdose on α-glucosidase inhibitors are not expected to have delayed or serious systemic toxicity, and routine medical admission is unnecessary. There is limited study of the risk of hypoglycemia and other adverse events after thiazolidinedione ingestion. Based on the mechanism of action and existing clinical experience, hypoglycemia after thiazolidinedione overdose is possible but uncommon. Delayed onset of hypoglycemia or other serious clinical manifestations is unlikely. A 4 to 6-hour observation period after thiazolidinedione overdose is recommended. Significant hypoglycemia is reported with nateglinide overdose,[89] and with repaglinide used in a setting of intentionally self-induced hypoglycemia.[51] Meglitinides are expected to behave pharmacologically like sulfonylureas. For this reason alone, hospital admission after meglitinide overdose is advisable, even when the patient is asymptomatic. Admission after exenatide, sitagliptin, and saxagliptin overdose is advised until more overdose data are obtained. Delays in onset of clinical manifestations, particularly hypoglycemia, are not expected, but there is currently limited clinical experience with regard to overdose.

Children who unintentionally ingest one or more sulfonylurea tablets should be observed for 24 hours. Although this recommendation may be controversial and some authors suggest shorter observation periods[20] or even home monitoring in some cases,[114] we believe that delayed hypoglycemic effects of sulfonylurea ingestion in children are well documented in the literature[108,126,133] and convincing enough to support admission in all cases. Asymptomatic children with single-tablet exposures to sulfonylureas are best managed without prophylactic intravenous dextrose, which could contribute to delayed onset of hypoglycemia.[20] Elevations in glucose concentrations stimulate insulin release by the pancreas. Such patients instead are best managed by early feeding, frequent checks of glucose concentrations, and observation of mental status.

METFORMIN-ASSOCIATED METABOLIC ACIDOSIS WITH HYPERLACTATEMIA

Throughout this chapter, the term *metabolic acidosis with hyperlactatemia* is employed rather than *metformin-associated lactic acidosis*. The biochemical and pathophysiologic processes involving lactate are complex, but a few points are worth summarizing. Hyperlactatemia occurs in various disease states, and can be present in the absence of acidosis. The production of lactic acid does not result in a net increase in hydrogen ion concentration unless there is associated impairment of oxidative metabolism. Impaired oxidative metabolism leads to an increase in hydrogen ion production through the hydrolysis of ATP.[86]

The biguanides are uniquely associated with the occurrence of metabolic acidosis with hyperlactatemia. Phenformin causes lactic acid production by several mechanisms including interference with cellular aerobic metabolism and subsequent enhanced anaerobic metabolism.

Phenformin suppresses hepatic gluconeogenesis from pyruvate and causes a decrease in hepatocellular pH, resulting in decreased lactate consumption and hepatic lactate uptake. Metformin-associated metabolic acidosis with hyperlactatemia occurs 20 times less commonly than that occurring with phenformin. In isolated perfused rat liver, metformin inhibits both hepatic lactate uptake and conversion of lactate to glucose.[109] Metabolic acidosis with hyperlactatemia related to metformin usually occurs in the presence of an underlying condition, particularly renal impairment.[24,64] In this setting, increased tissue burden of metformin, which is renally eliminated, probably occurs. Other risk factors include cardiorespiratory insufficiency, septicemia, liver disease, history of metabolic acidosis with hyperlactatemia, advanced age, alcohol abuse, and use of radiologic contrast media.[9,24] Iodinated contrast material may induce acute renal failure, leading to accumulation of metformin and subsequent risk for development of metabolic acidosis with hyperlactatemia. However, the risk of developing metabolic acidosis with hyperlactatemia after contrast administration is low in patients taking metformin who have normal renal function and no other risk factors.[79,90]

Severe metabolic acidosis with hyperlactatemia occurs after metformin overdose[66,82,97,134] but appears to be uncommon. In one case,[82] metabolic acidosis was not diagnosed until 14 hours after metformin overdose. The patient had early symptoms of repeated vomiting at 1 hour postingestion. In a series of 13 metformin overdose cases reported to a French pharmaceutical company, 7 patients presented with metabolic acidosis with hyperlactatemia.[66] The 13 cases were selected based on the overdose history and for whom arterial pH, arterial lactate, and serum metformin concentrations were obtained. The authors do not document the number of overdose cases not included in the study. In a larger poison center series of 65 adult cases of metformin overdose, 2 patients developed significant metabolic acidosis with hyperlactatemia, 1 of whom died.[127] One patient developed disseminated intravascular coagulation, and hypoglycemia occurred in seven patients with concomitant insulin or sulfonylurea overdose. The remaining cases were described as having minimal toxicity. In a poison center series of 55 children exposed to metformin, metabolic acidosis with hyperlactatemia was not reported, and no significant adverse effects were noted.[128] The doses reportedly ingested ranged from 250 mg to 16.5 g, with a median of 500 mg.

A systematic review from the Cochrane Library concluded that therapeutic use of metformin is not associated with an increased risk of metabolic acidosis with hyperlactatemia compared with other antidiabetic treatments if no contraindications are present.[115] This conclusion was based on a review of prospective comparative trials and observational cohort studies. However, the risk of metformin-associated metabolic acidosis with hyperlactatemia in the setting of overdose setting or renal insufficiency was not assessed. Although metabolic acidosis with hyperlactatemia after overdose is not common, it does occur with sufficient frequency to require vigilance on the part of the treating physician. Case reports were not used in the Cochrane review, and a few cases of metformin-associated metabolic acidosis with hyperlactatemia in the setting of therapeutic use with no underlying risk factors are reported.[24,100,137]

Metformin-associated metabolic acidosis with hyperlactatemia is a potentially lethal condition. Recognition and awareness of this disorder are important. Symptoms may be nonspecific and include abdominal pain, nausea, vomiting, malaise, myalgia, and dizziness. However, gastrointestinal symptoms are common adverse effects associated with therapeutic use of metformin and do not necessarily require discontinuation of the drug. More severe clinical manifestations of metformin-associated metabolic acidosis with hyperlactatemia include confusion, mental status depression, hypothermia, respiratory insufficiency, and hypotension. Serum metformin concentrations can be obtained as a diagnostic aid, but may not correlate with the clinical state in both the acute overdose setting and in the setting of therapeutic metformin use. In a series of 13 cases with metformin overdose, 6 of 7 patients with metabolic acidosis with hyperlactatemia had elevated metformin concentrations.[66] Of the six patients without acidosis, three had markedly elevated metformin concentrations. In a series of cases of metabolic acidosis with hyperlactatemia related to therapeutic use, 10 of 14 patients had elevated serum metformin concentrations.[65]

Aggressive airway management and vasopressor therapy may be required. Indications for use of intravenous sodium bicarbonate in critically ill patients with metabolic acidosis with hyperlactatemia of various etiologies are poorly defined and controversial. Rather than using an arterial pH cutoff, we recommend using sodium bicarbonate given evidence of impaired buffering capacity based on a serum bicarbonate concentration of less than 5 mEq/L. Based on case reports, hemodialysis using a sodium bicarbonate buffer may be effective in improving acid–base status and clinical outcome in patients with significant metabolic acidosis with hyperlactatemia.[49,64,67] In some of these cases, metformin concentrations were measured and remained abnormally high after dialysis. Clinical improvement despite inadequate removal of metformin may be related to correction of acid–base status.

SUMMARY

Numerous xenobiotics and medical conditions may cause hypoglycemia. Hypoglycemia is the predominant adverse effect related to therapeutic use and overdose of the drugs used for treatment of diabetes mellitus. Various clinical manifestations, particularly neurologic, may occur and can be confused with conditions such as ethanol intoxication, psychosis, epilepsy, and cerebrovascular accidents. The potential for delayed and prolonged hypoglycemia must be recognized in overdose situations. Although several treatment options exist, rapid intravenous administration of dextrose is the most important measure. Octreotide is useful for patients with recurrent hypoglycemia following sulfonylurea or meglitinide overdose.

ANTIDOTES IN DEPTH (A10)

DEXTROSE

Larissa I. Velez and Kathleen A. Delaney
Dextrose (D-glucose)

Hypoglycemia is a common cause of altered mental status. Although classically associated with tachycardia, tremor, and diaphoresis, the predictive value of these manifestations is too low to be relied upon. As a result, all patients with altered consciousness require either rapid point-of-care testing of their glucose concentrations or empiric treatment for presumed hypoglycemia. When rapidly diagnosed and treated, hypoglycemic patients typically recover without sequelae. Delayed or incomplete therapy may lead to permanent neurologic dysfunction.

PHYSIOLOGY

Adenosine triphosphate (ATP) provides the metabolic energy that fuels all critical cellular processes in all organs. In the adult brain, the anaerobic and aerobic metabolism of glucose through glycolysis and the citric acid cycle, respectively, are the primary sources of ATP (see Chap. 12). Although the adult brain can use fatty acids, amino acids, and ketones as alternate substrates for ATP synthesis, these are not adequate to sustain normal cerebral function in the setting of glucose deprivation. In the brain of fetuses and neonates, glucose is the only substrate for ATP production.[81,99] Hypoglycemia is defined by organ dysfunction in the setting of inadequate concentrations of glucose; it cannot be safely defined by strict numerical values. The onset of hypoglycemia in both adults and children is followed rapidly by global cerebral dysfunction. In individuals with diabetes, the density of neuronal insulin receptors varies as a function of glycemic control so that diabetics with poor glycemic control have fewer neuronal glucose receptors and may experience hypoglycemic symptoms at much higher concentrations of glucose than those who are normally euglycemic. An important study of diabetics demonstrated that the mean blood glucose concentration for symptomatic hypoglycemia in poorly controlled diabetics was 78 ± 5 mg/dL compared with 53 ± mg/dL in normal control subjects.[11] Hypoglycemia may cause neuropsychiatric sequelae effects that are clinically indistinguishable from those of other toxic-metabolic and structural brain injuries, which may include focal stroke syndromes, movement disorders, seizures, irritability, confusion, delirium, coma, and irreversible encephalopathy.[3,33,59,67,69,70,85,103,108] The heart is partially dependent on glucose for energy production. Hypoglycemia causes myocardial stress that may manifest as angina and or dysrhythmias. This is aggravated by the systemic catecholamine response to hypoglycemia.[34,62,68,71,72]

THE PHYSICAL EXAMINATION IN HYPOGLYCEMIA

The history and physical examination do not reliably detect patients who are hypoglycemic.[47] Tachycardia, diaphoresis, pallor, hypertension, tremors, hunger, and restlessness tend to predominate when the decline in blood glucose concentration is rapid. These signs and symptoms may be blunted or absent from the use of β-adrenergic antagonists. Central nervous system signs of neuroglycopenia are nonspecific. They include visual disturbances, psychiatric disturbances, confusion, stupor, coma, seizures, and focal neurologic findings.[67,86] In children, the only sign of neuroglycopenia may be lethargy or irritability.[110]

TREATMENT

In most cases, the rapid correction of hypoglycemia by the administration of 0.5 to 1.0 g/kg of concentrated intravenous (IV) dextrose (Table A10–1) immediately reverses these neurologic and cardiac effects. However, prolonged or severe hypoglycemia may result in permanent brain injury, myocardial infarction, and death.[15,35,70] Because of the myriad presentations of hypoglycemia, the difficulties inherent in making the clinical diagnosis, and the serious consequences of failure to treat the condition, the empirical administration of hypertonic dextrose to all patients with altered mental status was once a standard prehospital and emergency department practice.[13,47,48]

■ COMPLICATIONS OF DEXTROSE ADMINISTRATION

The most serious complication associated with hypoglycemia is the failure to recognize and treat it. Most complications that are attributed to the administration of concentrated IV dextrose are either clinically insignificant or exceedingly rare. Phlebitis and sclerosis of veins may occur, and tissue necrosis may occur after soft tissue infiltration of $D_{50}W$ and after inadvertent intra-arterial injection.[4,31] Inappropriately large boluses of $D_{50}W$ in children have been associated with seizures, brain hemorrhage, and hyperosmolar coma.[87]

Concerns Regarding Elevated Blood Glucose Concentrations In Patients With Cerebral Ischemia Controlled laboratory investigations of ischemic brain injury in a variety of animal models consistently demonstrate that higher blood glucose concentrations are associated with more extensive cerebral injury. Most of these studies use animal models of global cerebral ischemia that include cardiac arrest, four-vessel ligation, or models of focal ischemia that used one- or two-vessel ligation.[27,77] These studies showed deleterious effects of hyperglycemia on a variety of outcomes, such as death, evidence of cerebral edema, and neurologic recovery.[23,25,26,28,42,49,60,79,89,90] The most severe injuries are evident when ischemia is incomplete or focal so that a small amount of blood flow is present, as when collateral circulation

TABLE A 10-1. Dosing of Dextrose

Age	Concentration	Bolus
Adult	$D_{50}W$ (50% = 0.5 g/mL)	0.5–1.0 g/kg
Child	$D_{25}W$ (25% = 0.25 g/mL)	0.5–1.0 g/kg
Infant	$D_{10}W$ (10% = 0.1 g/mL)	0.5–1.0 g/kg

is present near an area of focal infarction.[24,52,78] Hyperglycemia has not been shown to be detrimental in fetal and neonatal animal models of anoxia.[17,97,98]

The cellular biochemical changes that occur in the setting of ischemia have been extensively investigated. Global ischemia is associated with rapid depletion of brain glucose, ATP, and phosphocreatine, followed by a rapid increase in intracellular lactate, disruption of energy-dependent electrolyte gradients, increased intracellular calcium, activation of phospholipase, activation of inflammatory pathways, and generation of destructive free radicals such as superoxide and peroxynitrite.[10,51,91,102,105,106] Hyperglycemia is associated with increased capillary permeability in ischemic tissue and delays in resolution of intracellular calcium elevation during recovery from ischemia.[5,32] Significant increases in neutrophil deposition are demonstrated in areas of focal brain injury associated with hyperglycemia, suggesting a role in injury production.[64] Hyperglycemia may interfere with membrane repair systems by suppressing the synthesis of "heat shock" proteins in injured cells.[21,106] Administration of insulin to control hyperglycemia decreases the extent of ischemic injury in rat models of cerebral ischemia.[28,29,46,63,104,105] Because insulin promotes the synthesis of "heat shock" protein in ischemic cells, it may have a protective effect that is independent of its effect on blood glucose. Insulin also increases hippocampal γ-aminobutyric acid (GABA) concentrations in animal models, which may be neuroprotective.[88,96,100,101]

The clinical literature demonstrates that the presence of hyperglycemia upon admission is associated with poorer outcomes in patients with acute cerebrovascular accidents.[13,30,37,50,74,80,105] Complications include increased rates of hemorrhagic conversion,[14] larger infarction volumes,[7,20,37] a higher incidence of cerebral edema,[92] and increased mortality.[16,20,111] In several studies, the magnitudes of blood glucose concentration elevation that persisted after an acute stroke were positively correlated with larger infarction volumes, poorer functional outcome, and increased mortality.[7,20,111] The association is stronger in those having acute ischemic strokes but has also been observed in patients with subarachnoid and intracerebral hemorrhages.[43,55,75] A poor prognosis is also demonstrated in animal models of head trauma and hyperglycemia and in head trauma patients with hyperglycemia upon admission.[39,59,112]

The largest study to date is from the second European Cooperative Acute Stroke Study (ECASS-II). In this study, persistent and delayed hyperglycemia were associated with worse outcomes, even in nondiabetic patients.[111] Another study confirms the particularly negative association of hyperglycemia with poor outcome in nondiabetics.[94] An older study of thrombolysis in acute stroke from the National Institute of Neurological Disorders and Stroke (NINDS) showed a strong association of admission hyperglycemia with a worse outcome in thrombotic stroke. Hyperglycemic patients also had an increased risk for subsequent intracranial hemorrhage, whether or not they received thrombolytic therapy.[14] Examination of these data could not prove a cause-and-effect relationship between hyperglycemia and a poorer outcome in stroke.

In clinical studies of global ischemia in patients with cardiac arrest, admission hyperglycemia is a poor prognostic indicator. In 430 pre-hospital patients resuscitated from cardiac arrest, 276 patients who awakened had significantly lower blood glucose concentrations than 154 patients who did not (mean, 262 mg/dL vs. 341 mg/dL, $P = 0.0005$). In 90 awake patients with persistent neurologic deficits, the mean blood glucose concentration was 286 mg/dL compared with 250 mg/dL in patients who recovered fully ($P = 0.02$).[65] In a prospective study of 295 patients with intracerebral hemorrhage, an 18-mg/dL increase in serum glucose was associated with a 33% mortality increase ($P: <0.0001$).[43]

Methods in these studies have not delineated the primary effect of hyperglycemia on the ischemic brain from hyperglycemia that occurs after an intense sympathetic "stress" response to more severe brain injury. Hyperglycemia may also simply be a marker for poor microcirculation in patients with diabetes.[14,20,43,73,109]

The GIST-UK (Glucose Insulin in Stroke Trial—United Kingdom) was designed to answer the question regarding the importance of glycemic control in stroke patients. Unfortunately, it was stopped prematurely because of slow enrollment. Although underpowered, it failed to show any mortality benefit from treatment of hyperglycemia in acute stroke patients.[44,83]

Clinical Implications of Studies of Hyperglycemia and Cerebral Ischemia   The clinical and laboratory studies cited above led to a reassessment of the standard practice of routine inclusion of $D_{50}W$ in the cocktail antidote for patients with altered mental status.[13,47,48] A thoughtful assessment of the literature recognizes the possible detriment of increasing blood glucose concentrations in a patient whose altered mental status or focal neurologic symptoms are caused by a cerebrovascular accident. This must be weighed against the risk of failure to treat hypoglycemia and the potential resultant permanent neurologic injury. This dilemma remains particularly consequential in the prehospital setting, where reliable testing of blood glucose concentration is limited. Without question, the reversal of hypoglycemia is a sound clinical intervention in the patient who is hypoglycemic, and the failure to administer dextrose in a timely fashion to a patient with significant hypoglycemia may result in permanent neurologic injury.

The new guidelines for management of patients with stroke recommend the avoidance of glucose-containing fluids and advocate for aggressive control of hyperglycemia while still avoiding hypoglycemia.[1,12]

BEDSIDE BLOOD GLUCOSE DETERMINATIONS

The bedside diagnosis of hypoglycemia is limited by the sensitivity and specificity of reagent strips, which do not have the reliability and accuracy of the chemistry laboratory.[76] Sensitivities of commonly available reagent strips for detection of hypoglycemia range between 92% and 97% in various studies.[18,19,53,61,66,84] The accuracy of these point-of-care testing methods is affected by the source of blood, whether venous or capillary, and by the poor perfusion associated with shock and cardiac arrest.[6,22,41,54,57,58,95] With reagent strip testing, variations in hematocrit and the presence of isopropyl alcohol in the sample may also alter the accuracy of the test.[9,45] In some specific tests, such as the one using glucose dehydrogenase pyrroloquinolinequinone (GDH-PQQ), accuracy may be affected by a number of interfering substances and xenobiotics, such as serum acetaminophen concentrations above 8 mg/dL, a serum bilirubin concentration above 20 mg/dL, a serum galactose concentration above 10 mg/dL, a maltose concentration above 16 mg/dL, a serum uric acid above 10 to 16 mg/dL, serum triglycerides above 5000 mg/dL, and the presence of D-xylose in the sample. All of these result in falsely elevated glucose measurements.[36] Notably, icodextrin, an ingredient in

peritoneal dialysis, may result in overestimation of glucose measurements because it is metabolized to maltose. In several case reports and at least 18 cases reported in a review, this resulted in excess insulin administration and subsequent hypoglycemia.[36,40,56,82] Maltose is also contained in some immunoglobulin solutions, and the same interference can be expected.[38,93] Glucose measurements by the GDH-PQQ method are also affected by the hematocrit. Whereas hematocrits lower than 20% may result in a falsely elevated glucose measurements, hematocrits above 55% may result in falsely low measured glucose concentrations.[36] In a retrospective review of patients admitted to a hospital over a 12-month period, 1.2% were identified as having interfering substances. Of these, 36% had active orders for insulin products. The most common interferences identified were a low hematocrit (44% of patients) and a high serum uric acid (29% of patients).[36]

A study of 66 critically ill newborns that defined critical hypoglycemia as below 30 mg/dL found a sensitivity of 100% for the detection of critical hypoglycemia for each of two different reagent strips.[66] False-positive capillary determinations of hypoglycemia have been demonstrated in patients in shock and cardiac arrest. Hypoglycemia was identified by capillary samples in eight of 50 patients with cardiac arrest. Three of these were confirmed to be hypoglycemic by the laboratory. Reagent strip testing of venous blood correctly classified these patients. There were no false-negative results.[95] A critical care unit study that evaluated patients in shock showed that 32% were incorrectly diagnosed as euglycemic when capillary blood was used. Results of reagent strip tests of venous blood correlated well with laboratory results, correctly classifying all patients. No cases of hypoglycemia were missed.[6] Therefore, capillary determinations of glucose should be used with caution in the critically ill population, recognizing that false-positive detections of hypoglycemia are common. When feasible, reagent stick testing of venous blood rather than capillary samples is preferable.

Several studies have compared the accuracy of standard reagent strips for the detection of hypoglycemia from capillary and venous blood compared with the gold standard of the laboratory. Two studies, one with 97 subjects[41] and one with 270 subjects,[57] evaluated the agreement between reagent strip determinations of capillary and venous blood glucose in healthy normoglycemic volunteers. In the larger study, 18% of subjects had a more than 15-mg/dL difference between capillary and venous reagent strip tests. In this study, capillary measurements were better correlated with the laboratory values. Whether these results have any clinical significance is not clear because none of the subjects fell out of the euglycemic range. However, the results suggest that the capillary blood glucose test has greater accuracy in the euglycemic range and in healthy individuals.

The "safe" number at which no cases of symptomatic hypoglycemia are missed by reagent strip testing is a subject of debate because of the inherent risk of error from lack of sensitivity. In one study in which hypoglycemia was defined as a blood glucose concentration below 60 mg/dL, two of 33 hypoglycemic patients were not detected at the bedside. A cutoff of 90 mg/dL would have detected 100% of numerically hypoglycemic patients.[61] Based on these studies, it can be argued that a bedside reagent measurement of 90 mg/dL is a conservative cutoff for assurance of clinical euglycemia in all patients.

PHARMACOKINETICS OF DEXTROSE

Accurate prediction of the amount of dextrose required to effectively treat patients with hypoglycemia is difficult. At equilibrium, 25 g of dextrose distributed in total body water in a 70-kg adult is calculated to increase the serum glucose concentration by about 60 mg/dL.[48] In the few clinical studies performed, the magnitude of glucose elevation after oral (PO) or IV dextrose loading was unpredictable. In one study, 25 g (50 mL) of $D_{50}W$ administered to adults (both diabetics and nondiabetics) resulted in a mean blood glucose elevation of 166 mg/dL when measured in the opposite extremity 3 to 5 minutes after the bolus; however, the range of this elevation was 37 to 370 mg/dL above baseline.[2] In a human model of insulin-induced hypoglycemia, PO administration of 20 g of PO dextrose increased the serum blood glucose concentration from 60 to 120 mg/dL over 1 hour, but 10 g also raised the concentration from 60 to 100 mg/dL.[107] Another study used 25 volunteers and administered 25 g of IV dextrose as $D_{50}W$. Glucose concentrations were then measured at 5, 15, 30, and 60 minutes. Volume of distribution formulas could not accurately predict postinfusion glucose concentrations. The serum glucose elevation was statistically significant from baseline at 5 and 15 minutes, with glucose concentrations returning to baseline at 30 minutes postinfusion.[8]

It is important to remember that rapid increases in serum glucose are sufficient to cause insulin release from the pancreas. This may result in reactive hypoglycemia. Therefore, glucose concentrations must be closely followed after a bolus of concentrated glucose solutions.

CONCLUSION: A RATIONAL CLINICAL SOLUTION

An ideal clinical solution to the management of patients with altered mental status or focal neurologic symptoms misses no cases of significant symptomatic hypoglycemia but avoids the administration of dextrose to patients with brain ischemia who are not hypoglycemic. A realistic approach can be fashioned from our understanding of the reliability of reagent test strips and a risk-to-benefit assessment of the presenting problem.

Infants and neonates should receive dextrose when clinically indicated without concern for associated ischemia or anoxia because the detrimental effect of hyperglycemia seems to be absent in this age group. Patients with coma or status epilepticus from hypoglycemia benefit greatly from empiric treatment with dextrose and experience the greatest morbidity if not promptly treated. Furthermore, a patient who is comatose from a major stroke has a very limited chance for recovery, and the acute administration of dextrose likely will not impact heavily on the prognosis compared with the impact of a missed diagnosis of significant hypoglycemia. Administering $D_{50}W$ to patients in coma who have a measured blood glucose less than 90 mg/dL determined by bedside reagent strip testing is rational. Similarly, although confusion and delirium without focal neurologic findings may occur as manifestations of structural brain injury, toxic-metabolic causes are much more common. These patients should receive dextrose if the glucose concentration determined by bedside test is 90 mg/dL or less. When a reliable bedside glucose determination is not readily available, all of these patients should receive $D_{50}W$ empirically.

As previously discussed, rapid reagent glucose samples of capillary blood are especially unreliable in patients with hypotension or cardiac arrest. Bedside reagent strip testing of venous blood appears to be more reliable.[6,84,95] Patients in shock or cardiac arrest should undergo reagent testing using a venous blood sample and should receive dextrose if results indicate they are numerically hypoglycemic (<90 mg/dL). Empiric administration of dextrose to a patient with a cardiac arrest who is euglycemic as determined by reagent strip testing of venous blood should be considered only if the patient is diabetic.

Patients with focal neurological deficits due to ischemia constitute a population that is reasonably expected to derive great benefit from maintenance of euglycemia. Although focal presentations of hypoglycemia are not rare, they are infrequent relative to the numbers of patients with focal presentations who have had strokes. In one study,

3% of patients with hypoglycemia presented with focal symptoms.[67] In patients with a history of diabetes who present with focal symptoms, symptomatic hypoglycemia must be strongly considered when the reagent strip shows a blood glucose concentration below 90 mg/dL.

Patients with a clear history and evidence of significant head injury preceded by normal activity should not be treated unless the bedside test indicates numerical hypoglycemia (<90 mg/dL). Diabetic patients may suffer unintentional injuries predisposed by hypoglycemic episodes. The treating physician must use his or her best judgment of the mechanism and evidence of injury, witness reports, available medical history, and result of bedside glucose determination to decide whether to administer $D_{50}W$ to a traumatized patient with an altered level of consciousness.

SUMMARY

Studies have indicated that the currently available reagent strips reliably demonstrate the absence of significant hypoglycemia at readings above 90 mg/dL. Profound neurologic impairment likely is not the result of hypoglycemia when such concentrations are demonstrated, even in diabetic patients. Dextrose should be administered to all patients with altered levels of consciousness and numerical hypoglycemia (glucose concentration <90 mg/dL measured by reagent strips). Concerns regarding the negative effects of elevated blood glucose concentration on cerebral ischemia should not cause a physician to withhold dextrose in patients with neurologic impairment when symptomatic hypoglycemia cannot be promptly and reliably excluded. Dextrose should be empirically administered to patients with altered mental status when bedside reagent strips are not readily available.

OCTREOTIDE

Mary Ann Howland

Octreotide is a long-acting, synthetic octapeptide analog of somatostatin that inhibits pancreatic insulin secretion. It currently is the essential complement to dextrose for the treatment of refractory hypoglycemia induced by overdoses of oral hypoglycemics (eg, sulfonylureas) and quinine. Octreotide currently is used in toxicology for the treatment of xenobiotic-induced endogenous secretion of insulin.

HISTORY

Somatostatin is a collective term for shorter fragments (SRIF-28, SRIF-25, and SRIF-14) cleaved by tissue-specific enzymes from pre-prosomatostatin (116 amino acids) and prosomatostatin (92 amino acids).[11] Somatostatin was identified in 1973, during the search for growth hormone releasing factor.[6] In addition to its effects on growth hormone and insulin secretion, somatostatin has far-reaching effects as a central nervous system (CNS) neurotransmitter and as a modulator of hormonal release.[32,40] The importance of somatostatin on insulin secretion led to the need to create an analog as a therapeutic tool as somatostatin is limited because of its short duration of action.

Octreotide was synthesized in 1982 in an effort to develop a longer-acting analog of somatostatin.[5] Octreotide is currently FDA approved for the treatment of acromegaly, carcinoid tumors and vasoactive intestinal peptide tumors. It is also used therapeutically for the treatment of pituitary adenomas, pancreatic islet cell tumors, portal hypertension, esophageal varices, and secretory diarrhea.[32] Octreotide is being investigated for its inhibitory effects on tumor cell proliferation through stimulation of apoptosis, antiangiogenesis, immunomodulatory effects, and the suppression of tumor-stimulating growth factors.[31,32,41] Lanreotide and vapreotide are other long-acting somatostatin analogs that are FDA approved.

RECEPTOR AFFINITY

The effects of somatostatin are mediated by high-affinity binding to membrane receptors on target tissues. Five different somatostatin receptor subtypes that belong to a superfamily of G-protein–coupled receptors have been identified and assigned numbers (SSTR1–SSTR5)

according to their order of discovery.[11] Octreotide, lanreotide, and vapreotide have high binding affinity for subtype SSTR2, a lower affinity for SSTR5 and SSTR3, and almost no affinity for SSTR1 and SSTR4.[32] The pancreas contains all 5 subtypes but SSTR5 and SSTR1 are more prevalent in the beta cells and SSTR2 is more prevalent in the alpha cells.[49] SSTR5 is found in many tissues including the brain, pituitary, stomach, intestine, thyroid, and adrenal gland; SSTR2 is found in the brain, pituitary, stomach, liver, kidney, lung, intestine, spleen, thymus, uterus, prostate, and adrenal gland.[32,36,43,49] A variety of pituitary and gastroenteropancreatic tumors contain varying percentages of the SSTR subtypes.

EFFECTS ON INSULIN SECRETION AND OTHER HORMONES

Experiments in both healthy human volunteers and an isolated perfused canine pancreas model demonstrate the ability of somatostatin to inhibit glucose-stimulated insulin release.[1,19] Experiments using a whole-cell patch clamp technique on a hamster β-cell line suggest that somatostatin inhibits insulin secretion by a G-protein–mediated decrease in calcium entry through voltage-dependent Ca^{2+} channels.[25] No evidence indicates that somatostatin inhibits insulin release by promoting K^+ efflux through K^+ channels at physiologic concentrations as do the oral hypoglycemics. (Fig. 48-2).[15,33,42] Instead somatostatin, like epinephrine, stimulates a pertussis-toxin sensitive Gi-coupled receptor that inhibits adenylate cyclase and production of cyclic adenosine monophosphate (cAMP), decreasing intracellular calcium and thereby reducing insulin secretion.[23] Simultaneous distal reduction in phosphorylation of specific proteins may also be involved in reducing insulin secretion.[15,23] This latter mechanism appears to be independent of Ca^{2+}.[15,23] Activation of SSTR5 on the β-cell of the pancreas also reduces insulin biosynthesis.[15] One study in human volunteers confirms the ability of somatostatin to inhibit the increased insulin response to both glucose and glucagon.[19] Intravenous (IV) infusion of 1 g tolbutamide over 2 minutes caused insulin concentrations to rise and serum glucose concentration to drop sharply. Similarly, in the presence of somatostatin and tolbutamide, administration of IV glucagon caused a rise in glucose concentration without the expected subsequent glucose-stimulated rise in insulin. The effects of somatostatin were short lived. Within 5 minutes of stopping the somatostatin, the insulin-releasing effects of tolbutamide continued, and within 15 minutes the serum glucose concentration fell. Peak insulin concentrations were achieved within 25 minutes.

Studies comparing octreotide to somatostatin in rats and monkeys demonstrate that octreotide is 1.3 times as potent as somatostatin in inhibiting insulin secretion by 50%. Likewise, compared with somatostatin, octreotide was 45 times more potent in inhibiting growth hormone secretion and 11 times more potent in inhibiting glucagon release.[5] Comparable results were found using a hyperglycemic glucose clamp technique.[28] Octreotide blocks the counterregulatory response to the effects of 0.1 unit/kg IV insulin by preventing an increase in glucagon and growth hormone. The effects of octreotide on the responses of adrenocorticotropin, cortisol, prolactin, luteinizing hormone, and follicle- stimulating hormone to insulin-induced hypoglycemia, all

remained intact.[33] In contrast, growth hormone[14] and thyroid-stimulating hormone are significantly inhibited.[33]

PHARMACOKINETICS

The pharmacokinetics of IV and subcutaneous (SC) octreotide were studied in 8 healthy adult volunteers.[30] Subjects received 25, 50, 100, and 200 μg IV octreotide over 3 minutes and 50, 100, 200, and 400 μg SC octreotide in random order. Following IV administration, the distribution half-life averaged 12 minutes, and the elimination half-life ranged from 72 ± 22 minutes to 98 ± 37 minutes and was linear. Vi (volume of distribution of the central compartment) was dose dependent and increased from approximately 5.7 L at 25, 50, and 100 μg IV to 10 L at 200-μg IV doses.[30] The Vd (volume of distribution determined by area under the curve) ranged from 18 ± 6 L to 30 ± 30 L and showed no dose dependency.[30] Renal elimination accounted for approximately 30% of the elimination and was reduced in the elderly and in those with severe renal failure.[40]

After SC administration, bioavailability was 100%, and peak concentrations were achieved within 30 minutes with an absorption half-life of 5–12 minutes. The elimination half-life was 88–102 minutes. Peak plasma concentrations after SC administration ranged from 2.4 ng/mL at doses of 50 μg to 23.5 ng/mL at doses of 400 μg. After IV administration peak plasma concentrations ranged from 9.6 ng/mL at doses of 50 μg to 27.8 ng/mL at doses of 200 μg.[30]

The pharmacokinetics in patients with pathologic conditions may differ from the pharmacokinetics in healthy volunteers as exemplified by a lower peak concentration and a higher steady-state Vd in patients with acromegaly.[40]

The duration of action is variable. When used for tumor suppression, the duration may last up to 12 hours.[40] The duration of action for inhibition of insulin secretion is unknown.

CLINICAL USE FOR INSULIN SUPPRESSION

Octreotide was studied in several clinical conditions, including insulinomas and hypoglycemia of infancy.[2,20,27,46,47] In most instances, octreotide suppressed insulin concentrations, and glucose concentrations rose. However, worsening hypoglycemia is reported when glucagon suppression outlasts insulin suppression.[6,10,18,24,39,46] Another reason for variable effects in these conditions include absence of octreotide susceptible SSTR receptor subtypes.[48] Octreotide currently is used in toxicology for treatment of xenobiotic-induced endogenous secretion of insulin.

In controlled studies of healthy volunteers, octreotide suppressed the release of insulin associated with quinine.[44] Life-threatening hypoglycemia is a well-recognized complication of quinine treatment of *Plasmodium falciparum* malaria. In this setting, hypertonic dextrose and diazoxide therapy are frequently inadequate, with ensuing refractory hypoglycemia. In an investigation of the potential hypoglycemia-sparing effect of octreotide given for treatment of quinine-induced hypoglycemia, healthy adults were given 50 μg/h octreotide or placebo as a continuous IV infusion for 4 hours, followed at the first hour by infusion of 490 mg quinine base.[44] In the control subjects, plasma insulin concentrations rose and serum glucose concentrations fell significantly, whereas in the octreotide group, insulin concentrations fell and glucose concentrations remained constant. This effect of octreotide began within 30 minutes and persisted for 2 hours after octreotide was stopped. Octreotide was used successfully to treat refractory hypoglycemia in a woman receiving 600 mg quinine dihydrochloride IV for malaria.[44]

The efficacy of octreotide against sulfonylurea induced hypoglycemia was demonstrated in an early experimental study. Eight healthy volunteers were given 1.43 mg/kg glipizide orally and randomized to receive either a variable dextrose infusion to remain euglycemic, diazoxide 300 mg IV over 30 minutes and repeated every 4 hours with dextrose, or octreotide 30 ng/kg/min IV continuously.[7] Following administration of glipizide, hypoglycemia of 50 mg/dL was achieved within 30–165 minutes.[7] Insulin concentrations in the diazoxide group were comparable with those in the glipizide group and were 4-5 times higher than in the octreotide group. Four of the 8 patients in the octreotide group did not require supplemental dextrose. At the 5th hour of the protocol, an IV bolus of 50 mL 50% dextrose was given to the octreotide group to study the response to hyperglycemia. Approximately 6.5 hours was necessary for the serum glucose concentration to drop to 85 mg/dL, whereas only 3 hours was necessary in the dextrose and diazoxide groups.[7] Diazoxide infusion was associated with higher norepinephrine concentrations, and epinephrine concentrations were similar in all groups.[7] All xenobiotics were stopped at 13 hours, and serum glucose concentrations fell to < 65 mg/dL within 1.5 hours in subjects who received the dextrose and diazoxide, whereas the serum glucose concentrations remained > 65 mg/dL in 6 of the 8 octreotide subjects for the 4-hour observation period. Without additional octreotide, hypoglycemia continued to recur for as long as 30 hours after the initial glipizide administration.

Several case studies and two case series of 15 patients support the efficacy of octreotide following overdoses of glipizide, glyburide, gliclazide, glimepiride, tolbutamide, and nateglinide. These cases encompass both intentional and unintentional overdoses in children and adults with and without diabetes.[7,9,12,13,16,17,21,22,26,28,34,37,38,45] In these case reports, therapeutic doses ranged considerably, and the most frequent doses were 50–100 μg subcutaneously repeated every 8–12 hours in the adult patients.

ADVERSE DRUG EFFECTS

Octreotide is generally well tolerated, but experience in the toxicologic setting is limited. Adverse reactions occurring with short-term administration usually are local or gastrointestinal. Stinging at the injection site occurs in approximately 7% of patients but rarely lasts more than 15 minutes.[50] Healthy volunteers receiving octreotide noted no side effects when given IV doses of 25 or 50 μg or SC doses of 50 or 100 μg. At higher doses, early transient nausea and later appearing but longer-lasting diarrhea and abdominal pain frequently occur.[29,30] Healthy volunteers were given IV bolus doses of octreotide as high as 1000 μg and infusion doses of 30,000 μg over 20 minutes and 120,000 μg over 8 hours without serious adverse effects. Single doses in healthy volunteers resulted in decreased biliary contractility and bile secretion.[40] Long-term therapy lasting weeks to months results in biliary tract abnormalities.[40,51] Product information warns of the potential for acute cholecystitis, ascending cholangitis, biliary obstruction, cholestatic hepatitis, and pancreatitis.[40]

Octreotide alters the balance among insulin, glucagon, and growth hormone. Serum glucose concentrations must be serially monitored. Hyperglycemia often occurs, but cases of hypoglycemia are reported. A revision in the precautions section of the package labeling states that symptomatic hypoglycemia has occurred in patients with type I diabetes and their insulin requirements will likely be reduced. The most likely explanation is suppression of counter regulatory hormones, in particular when glucagon suppression, is more persistent than insulin suppression.[40]

Other adverse effects reported with long-term administration of octreotide or for octreotide in circumstances other than sulfonylurea induced hypoglycemia include hypothyroidism, cardiac conduction

abnormalities, worsening congestive heart failure (in at-risk patients with acromegaly), bradycardia, pancreatitis, substantial hyperglycemia and bradycardia in an infant with congenital hyperinsulinemia, hypoxemia and pulmonary hypertension in premature neonates, altered fat absorption, and decreased vitamin B_{12} concentrations.[3,4,40] Anaphylactoid reactions are also rarely reported.[40]

Drug interactions are expected with xenobiotics that affect glucose regulation. Octreotide may significantly decrease oral absorption of cyclosporine and increase the bioavailability of bromocriptine. Because octreotide may suppress the activity of the CYP450 enzymes, and in particular 3A4, drugs with a narrow therapeutic indices metabolized by these enzymes should be monitored more closely.[40]

ADMINISTRATION

Both SC and IV administration are acceptable, although the usual route is SC.[40] The SC administration sites should be rotated. For IV infusion, octreotide can be diluted in sterile 0.9% sodium chloride solution or D_5W and infused over 15–30 minutes or by IV bolus over 3 minutes.[40] Rapid IV bolus may be indicated for carcinoid crisis.[40] Refrigeration of octreotide is recommended for prolonged storage, although octreotide is stable at room temperature for 14 days when protected from light. Active warming of refrigerated octreotide is not recommended, although passive warming to room temperature prior to administration is suggested and may reduce the pain of SC administration.[35] Using the smallest volume possible also reduces the pain with SC administration. A depot formula designed to last for 4 weeks is available (Sandostatin LAR Depot). Vapreotide (Sanvar IR) and lanreotide (Somatuline Depot) are analogs of somatostatin which are available in the United States, but are inappropriate for use in the setting of xenobiotic-induced insulin secretion. Although the depot formula is useful for patients with insulinomas, its duration of action far exceeds that of any oral hypoglycemic, making it an inappropriate and unnecessary choice for management of xenobiotic-induced hypoglycemia.

DOSING

No controlled trials have evaluated the optimal dose of octreotide for the management of sulfonylurea overdose. In adults, a 50-μg SC dose of octreotide given every 6 hours is suggested. In children, a dose of 4–5 μg/kg/d SC divided every 6 hours, up to the adult dose, can be used for initial therapy. This pediatric dose is derived from the literature on treatment of persistent hyperinsulinemic hypoglycemia of infancy.[20] In situations where compromised peripheral blood flow is expected, octreotide should be administered intravenously in the same dose but every 4 hours instead of every 6 hours. Further experience in the toxicologic setting should permit a better delineation of dosing recommendations. Several days of therapy may be required, depending on the duration of the offending xenobiotic. All patients must be carefully monitored for recurrent hypoglycemia during octreotide therapy and perhaps for 24 hours following termination of octreotide therapy before discharge. Octreotide is considered a category B drug (Table 30-2), but pregnant women must be carefully monitored for recurrent hypoglycemia. Use of octreotide should not diminish this vigilance.

AVAILABILITY

Octreotide acetate (Sandostatin) injection is available in ampules and multidose vials ranging in concentration from 50–1000 μg/mL. The multidose vials contain phenol.

SUMMARY

Octreotide is useful for treating hypoglycemia induced by xenobiotics such as sulfonylureas and quinine that cause endogenous release of insulin. Octreotide is more effective than diazoxide in suppressing insulin and is much better tolerated.

CHAPTER 49

THYROID AND ANTITHYROID MEDICATIONS

Nicole C. Bouchard

Hypothyroidism and hyperthyroidism are relatively common endocrine disorders. The global incidence of neonatal hypothyroidism is 1 per 3000–4500 births. It is estimated that hypothyroidism affects 1%–5% of US adults. It is more prevalent in whites than people of Hispanic or African American descent. In the elderly, the prevalence of hypothyroidism increases to 15% by age 75. Worldwide, iodine deficiency is the leading cause of hypothyroidism. According to US retail pharmaceutical statistics for prescription drugs, levothyroxine (both generic and Synthroid combined) (T_4) has consistently ranked in the top five for overall total prescription count, with an average 67 million per year. Many cases of intentional and unintentional overdoses with thyroid hormone are reported in both adults and children.[60] Despite the profound effects of thyroid hormones on physiologic homeostasis and the widespread use and access to exogenous thyroid hormone, morbidity, and mortality from overdose is very low.

HISTORY AND EPIDEMIOLOGY

Long before the thyroid was recognized as a functional endocrine gland, it was believed to serve a cosmetic function, especially in women. Egyptian paintings often emphasize the full and beautiful necks of women with enlarged thyroid glands. Early theories on the physiologic function of the thyroid gland included lubrication of the trachea, diversion of blood flow from the brain and protection of women from "irritation" and "vexation" from men.[34] Although poorly defined in historical accounts, symptoms resembling hypothyroidism and myxedema that were successfully treated with ground sheep thyroid were described 500 years ago. In the 16th century, Paracelus described the association between goiter (thyroid gland enlargement) and cretinism.[64] A syndrome of cardiac hyperactivity, goiter, and exophthalmos was first described in 1786.[76] Graves and von Basedow further detailed this syndrome and its relationship to the thyroid gland 50 years later.[31,34,60,64,76,104]

In 1891, injection of ground sheep thyroid extract was formally described as a treatment for myxedema.[34] Shortly afterward, oral therapy was determined to be equally effective. Seaweed, which contains large amounts of iodine, was used to treat goiter (hypothyroidism) in Chinese medicine as early as the 3rd century A.D. In 1863, Trousseau[100] fortuitously discovered a treatment for Graves disease when he inadvertently prescribed daily tincture of iodine instead of tincture of digitalis to a tachycardic, thyrotoxic young woman.

Sir Charles R. Harington described the chemical structure and performed the first synthesis of thyroxine (tetraiodothyronine [T_4]) in 1926.[78] Triiodothyronine (T_3) was not isolated and synthesized until the 1950s.[34] Prior to this, desiccated thyroid gland from animal sources was commonly used to treat hypothyroidism. Despite becoming essentially obsolete in the modern medical community, unprocessed, desiccated thyroid can be easily purchased via the Internet and in health food stores as a thyroid supplement.[89] Armour, a pharmaceutical grade porcine-derived thyroid supplement, is still available by prescription. Unfortunately, the misguided use of both organic and synthetic thyroid supplements as vitality agents, stimulants, and weight-loss aids has become increasingly common. Two epidemics of *hamburger thyrotoxicosis* that occurred in the United States in the mid 1980s secondary to consumption of ground beef contaminated with bovine thyroid gland demonstrated the potential widespread toxicologic sequelae after a community unknowingly ingests thyroid hormone.[39,49] Clinically significant overdose with thyroid hormone preparations are uncommon.

PHARMACOLOGY

■ PHYSIOLOGY

To properly understand the impact of thyroid supplements and antithyroid xenobiotics on the function of the human body, an understanding of thyroid physiology is required. Thyroid function is influenced by the following: (1) the hypothalamus, (2) the pituitary gland, (3) the thyroid gland, and (4) the target organs for the thyroid hormones (Fig. 49–1).

The hypothalamus, viewed by some as the "master gland," is an intermediate between cerebral centers and the pituitary gland. When the hypothalamus receives specific neurotransmitter stimulation, thyroid-releasing hormone (TRH) is produced. TRH is transported through the venous sinusoids to the pituitary gland, which then release thyroid-stimulating hormone (TSH). TSH enters the circulation and stimulates the production and release of the thyroid hormones T_3 and T_4 from the thyroid gland. Thyroid physiology exhibits classic autoregulation or "negative biofeedback" of hormonal function. When adequate thyroid hormones are present, they exert an inhibitory effect on the pituitary gland, leading to diminished production of TSH (Fig. 49–1). Suppression or upregulation of TSH production is a frequently used laboratory marker in the evaluation of hyperthyroidism and hypothyroidism, respectively.

Thyroid hormones are tyrosine molecules with iodine substitutions. Two forms of the hormone are physiologically active: T_3 and T_4 (Table 49–1). Synthesis of thyroid hormones is a multistep process. The amino acid tyrosine is concentrated in the follicles of the thyroid gland, which consist of an epithelial layer surrounding a proteinaceous colloidal substance called thyroglobulin. Thyroglobulin thus contains a large amount of tyrosine. After absorption, iodide (I^-) is concentrated in thyroid cells by an active transport process called *iodide trapping.* Absorbed I^- is then oxidized to iodine (I_2) by thyroid (iodide) peroxidase. Iodine rapidly iodinates tyrosine residues to form monoiodotyrosine (MIT) and diiodotyrosine (DIT). These substituted tyrosine molecules then combine to form T_3 and T_4. The ratio of T_3 to T_4 in thyroglobulin is 1:5. T_3 and T_4 (thyroxine) ultimately are released into circulation from the thyroglobulin matrix.

Iodide trapping can be inhibited pharmacologically by monovalent anions such as thiocyanate (SCN^-), pertechnetate (TcO_4^-), and perchlorate (ClO_4^-). Thyroid peroxidase is inhibited by high concentrations of intrathyroidal iodide and by thioamide drugs. High intrathyroidal iodide concentrations also can inhibit the release of thyroid hormone into circulation (Table 49–2).

Approximately 95% of circulating or peripheral thyroid hormone is T_4; the remainder is T_3. Only 15% of the peripheral T_3 is secreted directly by the thyroid; the balance results from the peripheral conversion of T_4 to T_3. When circulating T_4 enters the cell, it is deiodinated to T_3. Deiodination of the T_4 molecule occurs by monodeiodination of either the outer ring or the inner ring by 5′-deiodinase or 5-deiodinase, yielding 3,5,3′-T_3 and 3,3′,5′-triiodothyronine (reverse
FIGURE 49–1. Thyroid hormone synthesis: its control, metabolism, and molecular structures. PTU = propylthiouracil; SCN⁻ = thiocyanate; TBG = thyroxine binding globulin; TRH = thyrotropin releasing hormone; TSH = thyroid stimulating hormone.

$T_3[rT_3]$), respectively.[56] T_3 has approximately four times greater hormonal activity than T_4, whereas rT_3 is metabolically inactive. T_3 exerts its effects by binding to thyroid hormone receptors inside the nucleus. This interaction with nuclear receptors regulates gene transcription and protein synthesis, which ultimately increases oxygen consumption and underlies the thermogenic effects of thyroid hormones.

Propranolol, corticosteroids, ipodate (contrast agent), starvation, and severe illness inhibit 5′-deiodinase, which results in decreased production of metabolically active T_3 and preferential monodeiodination to metabolically inactive rT_3 leading to a syndrome known as "sick euthyroid" (Table 49–2). This energy-conserving effect allows attenuation of the thermogenic effects of thyroid hormones in times of physiologic stress.[94]

TABLE 49–1. Pharmacokinetic Properties of Thyroid Hormones

Pharmacokinetic Property	T_3	T_4
Oral bioavailability (exogenous drug)	95%	80%
Volume of distribution (L/kg)	40	10
Half-life (days)	1	7
Protein binding (normal adult)	99.96%	99.6%
Relative potency	4	1

■ T_4 AND T_3

Thyroid supplementation for treatment of hypothyroidism is in widespread use both in human and veterinary medicine. Thyroid hormones historically were derived from animal origin, but now are largely produced synthetically. Desiccated and processed porcine thyroid (Armour) contains both T_3 and T_4. Because it is less pharmacologically stable and carries a risk of allergic reaction and thyrotoxicity from T_3, its use has largely been supplanted by the safer synthetic alternatives. Levothyroxine is the preparation of choice because of its low immunogenicity, 7-day half-life, easy dosing regimen and is available IV. Synthroid is the commercial name of the most commonly prescribed form of T_4. Liothyronine (T_3 preparation, Cytomel or Triostat, available PO and IV) and liotrix (combination T_3/T_4 preparations, preparations of Thyrolar, available PO) are synthetic preparations that are seldom used clinically because of their short half-lives, high cost, unique therapeutic indication, and increased risk of thyrotoxicosis.

Steady state with regard to suppression of TSH and elevation of T_4 is reached approximately 6–8 weeks after initiation of therapy. Doses usually are titrated in increments of 12.5 or 25 μg/d after 2–6 weeks based on TSH measurements (see Table 49–3 for typical levothyroxine doses). Different sources suggest that bioequivalence of Synthroid versus generic levothyroxine may or may not be equivalent.[17] As a result, thyroid hormone concentrations and the patient's clinical status should be followed when transitioning between levothyroxine formulations because the switch may present an opportunity for an adverse drug event.

TABLE 49–2. Xenobiotic Interactions: Effects on Thyroid Hormones and Function[6]

Xenobiotic	Interaction	Effect
Dopamine, levodopa, somatostatin	Inhibit TRH and TSH synthesis	No clinical hypothyroidism
Iodides (including amiodarone), lithium, aminoglutethimide	Inhibit thyroid hormone synthesis or release	Hypothyroidism
Monovalent anions (SCN^-, TcO_4^-, ClO_4^-)	Inhibit iodide uptake to thyroid gland	Hypothyroidism
Estrogens, tamoxifen, heroin, methadone, mitotane	Increase TBG	Altered thyroid hormone transport in serum $\uparrow$Total measured thyroid hormone (vs. *free* hormone)
Androgens, glucocorticoids	Decreased TBG	Altered thyroid hormone transport in serum $\downarrow$Total measured thyroid hormone (vs. *free* hormone)
Salicylates, mefenamic acid, furosemide	Displace T_3 or T_4 from TBG	Transient hyperthyroxinemia
Thioamides (methimazole, propylthiouracil)	Inhibit thyroid peroxidase	Decrease thyroid hormone synthesis
Phenytoin, carbamazepine, phenobarbital, rifampin, rifabutin	Induction of hepatic enzymes	$\downarrow$Total thyroid hormone measurements
Iopanoic acid, ipodate, amiodarone, propranolol, corticosteroids, propylthiouracil	Inhibition of 5′-deiodinase	Decrease peripheral conversion of T_4 ($\downarrow T_3$, $\uparrow rT_3$)
Cholestyramine, colestipol, aluminum hydroxide, sucralfate, ferrous sulfate, some calcium preparations, infant soy formula	Interfere with GI absorption of T_4	Decreased oral bioavailability of T_4
Interleukin-α, interleukin-2	Induction of autoimmune thyroid disease	Hyperthyroidism or hypothyroidism

TRH = thyroid-releasing hormone; TSH = thyroid-stimulating hormone; TBG = thyroid-binding globulin; GI = gastrointestinal.

TABLE 49–3. Typical Levothyroxine Doses

Age Group	Dose (μg/kg/d)	Total Daily Dose (μg/d)
Infants <6 mos	8–10	25–50
Infants 6–12 mos	6–8	50–75
Children 1–5 years	5–6	75–100
Children 6–12 years	4–5	100–150
Children >12 years	2–3	Until 150 (adult dose reached)
Adults	1.7	120–150
Elderly	Enhanced sensitivity to thyroxine excess	12.5

PHARMACOKINETICS AND TOXICOKINETICS

Gastrointestinal absorption is thought to occur primarily in the duodenum and ileum. Gastrointestinal absorption can be decreased by variations in intestinal flora and binding by xenobiotics (Table 49–2). In circulation, T_3 and T_4 both are highly but reversibly bound to plasma proteins—approximately 99.6% and 99.97%, respectively, in nonpregnant adults. Thyroxine-binding globulin (TBG) binds approximately two-thirds of the circulating thyroid hormones; albumin and other proteins bind the remainder. It is estimated that only 0.4% of T_3 and 0.04% of T_4 exist in the free form. Exogenously derived thyroid hormones exhibit similar binding characteristics when dosed in a physiologic range. The amount of thyroid hormone bound to proteins varies greatly with different physiologic and pharmacologic conditions, for example, increasing in pregnancy and levothyroxine overdose and decreasing in chronic disease. These changes in protein binding must be considered when measuring total thyroid hormone concentrations in the blood (see Diagnostic Testing). Table 49–1 lists some important pharmacokinetic properties of thyroid hormones.

Thyroid hormones undergo their ultimate metabolism peripherally. Intracellular sequential deiodination accounts for approximately two-thirds of inactivation. Most of the remaining third undergoes hepatic metabolism by glucuronidation or sulfation. Xenobiotics that induce hepatic microsomal metabolism, such as rifampin, phenobarbital, phenytoin, and carbamazepine, increase the metabolic clearance of T_3 and T_4 (Table 49–2).

PATHOPHYSIOLOGY

Thyroid hormones are critical for optimal physiologic growth and function. Thyroid function is the most important determinant of basal metabolic rate (BMR). In addition, the thyroid exercises a permissive effect on many hormones, notably catecholamines and insulin.

Hyperthyroidism is a condition characterized by excess active thyroid hormone. Most aspects of carbohydrate, protein, and lipid metabolism are increased in the presence of thyroid hormone excess. The disorder is characterized by manifestations of increased metabolism such as fever, weight loss, diarrhea, heat intolerance, and diaphoresis, along with tachycardia, widened pulse pressure, tremor, anxiety, other behavioral changes, and sometimes tachydysrhythmias such as rapid atrial fibrillation and high output congestive heart failure.[23,51,86] This constellation of symptoms, called *thyrotoxicosis*, may

result from overproduction of the hormone, increased conversion from T_4 to T_3, or excess exogenous hormone. Graves disease (diffuse toxic goiter), an autoimmune disorder, is the most common cause of excess thyroid hormone secretion. It accounts for approximately two-thirds of cases and often is accompanied by exophthalmos and diffusely enlarged, nontender thyroid gland. Toxic multinodular goiter, toxic thyroid adenoma, iodine or amiodarone exposure (can also cause hypothyroidism, see Table 49–4), thyrotoxicosis factitia, and thyroiditis (eg, postpartum, Hashimoto, DeQuervain) are some other etiologies of hyperthyroidism.[32] Severe thyrotoxicosis accompanied by decompensation is referred to as *thyroid storm* or *thyrotoxic crisis.* Thyroid storm typically occurs when untreated or undertreated hyperthyroidism occurs simultaneously with a physiologic stressor such as trauma, infection, diabetic ketoacidosis or surgery. In early stages patients appear febrile and markedly tachycardic, tremulous, agitated, or psychotic with nausea, vomiting, and diarrhea. As the disease progresses, stupor, coma, and hypotension may ensue. General treatment strategies include early airway control, crystalloid fluid resuscitation, β-adrenergic antagonist administration (mainstay of treatment, propranolol preferred for the added effect of decreased

peripheral conversion of T_4 to T_3), parenteral glucocorticoids if adrenal insufficiency is suspected, and antithyroid medications such as propylthiouracil and methimazole. Mortality in thyroid storm, even with treatment, can approach 20%.[23,84]

As plasma catecholamine concentrations are well established to be normal or decreased in hyperthyroid states, an increase in sensitivity to catecholamines is thought to be responsible for the increased inotropy and chronotropy produced by thyroid hormones.[14,82] Several general mechanisms are proposed for the direct cardiac effects of thyroid hormones, although their relative contributions are uncertain.[3,16,50,99] (1) T_3 increases the number of β-adrenergic receptors in various tissues, including cardiac cells.[16] This process occurs via upregulation of β-adrenergic receptor synthesis at the level of the β-adrenergic gene.[4] (2) T_3 modulates myocyte intracellular signaling mechanisms that lead to increased catecholamine effects. Enhancement of intracellular signaling activity involving protein kinase A, cyclic adenosine monophosphate, G proteins, and increased phosphorylation of thyroid hormone receptor proteins all are implicated to varying degrees.[22,51,80,81,85,92,101] (3) Enhancement of myocardial transmembrane and sarcoplasmic reticulum ion channel function, L-type voltage-gated Ca^{2+} channels,

TABLE 49–4. Common Xenobiotics That Alter Thyroid Function and Cause Clinically Important Effects

Xenobiotic	Effect	Mechanism
Lithium	Goiter (in 37% of patients) Hypothyroidism (in 5%–15% of patients)	Mechanism unclear
Amiodarone (37% iodine by weight)	1. Hypothyroidism (in 25% of patients) 2. Hyperthyroidism, type 1: in patients with preexisting goiters from low iodine intake 3. Hyperthyroidism, type 2: in patients with previously normal thyroid function	1. Inhibition of 5′-deiodinase 2. Type 1: iodine excess stimulates thyroid hormone production 3. Type 2: causes thyroid inflammation
Propranolol	↓Peripheral conversion of T_4 to T_3	Inhibition of 5′-deiodinase
PTU (propylthiourea) or methimazole	Decreased thyroid hormone synthesis ↓Peripheral conversion of T_4 to T_3	Inhibition of thyroid peroxidase Inhibition of 5′-deiodinase
Corticosteroids	↓Peripheral conversion of T_4 to T_3	Inhibition of 5′-deiodinase

Iodine	1. Low dose: transient or no effect
	2. High doses (>10 µg/d):
	  ↓thyroid hormone secretion
	3. Transient thyrotoxicosis (ie, Jod-Basedow effect)
	  With rapid correction of hypothyroidism
	   from iodine deficiency
	   From topical iodine
	4. Delirium
	5. Caustic injury
		1. Transiently stimulates thyroid hormone secretion
		2. Inhibition of thyroid hormone synthesis
		
		3. Increases thyroid hormone synthesis
		
		4. Mechanism unclear
		5. Direct cytotoxic injury to cells

Iodinated contrast material	1. Rapid ↓ peripheral conversion of T_4 to T_3 (adjunctive treatment in thyroid storm) 2. Prolonged suppression of T_4 to T_3 3. Causes thyrotoxicosis and thyroid storm 4. Iodide mumps	1. Inhibition of 5′-deiodinase 2. Mechanism unclear 3. Mechanism unclear 4. Idiopathic, toxic accumulation of iodide
Radioactive iodine	Treatment of hyperthyroidism, causes hypothyroidism	Uptake into thyroid follicles causes local destruction
Anion inhibitors[a]	↓Iodine uptake into thyroid follicle, used in iodide-induced hyperthyroidism	Blocks uptake of iodide into the thyroid gland by competitive inhibition

[a] Also referred to as monovalent anions, ie, thiocyanate (SCN^-), pertechnetate (TcO_4^-), and perchlorate (ClO_4^-).

and accelerated Ca^{2+} entry into the sarcoplasmic reticulum also are suggested.[47,48,69,91] Whether the effects on intracellular signaling represent a direct effect of T_3 on intracellular signaling mediators or T_3 induced-augmentation of the individual β-adrenergic receptor response to catecholamines with a secondary change in postreceptor signaling is unclear.[3]

In addition to these mechanisms, T_3 upregulates synthesis of cardiac thyroid hormone receptors (at TRα and TRβ genes), and the thermogenic effects of thyroid hormones can cause decreased systemic vascular resistance leading to a reflex (and indirect) increase in cardiac output. Comprehensive reviews on this topic explore the more complex cellular aspects of thyroid hormones and their effects on the cardiovascular system.[15,51,74]

Hypothyroidism, a condition characterized by decreased BMR and decreased catecholamine effects, is a common disorder, especially in women and the elderly. Worldwide, dietary iodine deficiency remains the leading cause of hypothyroidism. In certain parts of the world, particularly mountainous regions such as the Andes, Alps, and Himalayas, goitrous hypothyroidism still is endemic. Untreated congenital thyroid deficiency and severe dietary iodine deficiency (goitrous hypothyroidism) in young children result in profound, irreversible mental retardation and dwarfism (also referred to as cretinism). In developed nations, the iodization of salt has essentially eliminated dietary iodine deficiency as a cause of hypothyroidism. In developed nations, hypothyroidism often is autoimmune related, although thyroid function diminishes significantly with age in many patients. Treatment of Graves disease with radioactive iodine typically results in hypothyroidism within 1 year. Thyroiditis (eg, postpartum, Hashimoto, DeQuervain) may cause hypothyroidism (as well as hyperthyroidism) as may exposure to certain xenobiotics such as amiodarone and lithium (see Table 49–4). Myxedema and myxedema coma are potentially life-threatening emergencies that represent extremes of hypothyroidism. Hypothyroidism is not discussed in more detail in this chapter, except to note that treatment of hypothyroid emergencies, especially with T_3, can result in thyrotoxic symptoms. Comprehensive reviews of hypothyroidism are available.[88]

CLINICAL MANIFESTATION

The widespread availability and use of thyroid supplements make thyroid hormone a common xenobiotic in acute intentional and unintentional overdoses. In addition, chronic excess thyroid hormone ingestion is a relatively frequent occurrence. Symptoms of toxicity from exogenous thyroid hormone resemble those of catecholamine excess. Pronounced catecholamine-like effects occur in the cardiovascular system, especially tachycardia, tachydysrhythmias (usually atrial fibrillation or flutter), thromboembolism (from both atrial fibrillation and endothelial activation), and cardiac failure.[23,51,86] Interestingly, although hyperthyroid patients typically are anxious, restless, or agitated, patients with thyroid storm may present with a decreased level of consciousness or even coma.[8,43,54,83,90] Hyperthermia can occur secondary to the thermogenic effects of thyroid hormones and psychomotor agitation. Hyperthermia can be extreme (ie, >106°F [>41°C]). The tachycardia associated with thyrotoxicosis often is disproportionate to the temperature elevation.

■ ACUTE TOXICITY

Acute overdoses with thyroid hormone preparations most commonly occur with oral levothyroxine. Significant ingestions of levothyroxine usually do not manifest clinically until 7–10 days after exposure, but rarely are reported to manifest as early as 2–3 days postingestion.[33,57,84]

The delay of peripheral conversion of T_4 to the metabolically active T_3 and the time required to activate nuclear receptors and protein synthesis account for this clinical latency. Acute overdoses involving preparations containing T_3 can manifest in the first 12–24 hours after exposure.[59]

In children, acute thyroxine overdoses almost universally are benign because of their typically unintentional nature and lower doses ingested. Most children remain asymptomatic or develop only mild symptoms. No deaths have been reported.[20,27,45,55,57,60,95] In a series of 15 patients with unintentional overdose, only 3 children developed mild symptoms 12–48 hours postingestion.[58] Similarly, a case series that involved 41 children (ages 1–5 years) with unintentional ingestions of thyroxine (estimated doses ranged from 40 to 800 μg) found mild symptoms (hyperactive behavior, tachycardia, fever, vomiting, diarrhea, diaphoresis, and flushing) in only 27%. All children had good clinical outcomes. The degree of symptoms did not correlate with the amount ingested or measured serum thyroxine concentrations (measured 1–5 hours postingestion) for most cases in that series (see Diagnostic Testing).[27] Two other series involving 78 and 92 cases of unintentional ingestions in children found that mild symptoms developed in only 4 and 8 patients, respectively.[57,102] A report involving an intentional ingestion of 9900 μg in a 13-year-old boy treated empirically with activated charcoal, dexamethasome, and oral propranolol described only mild tremors and anxiety.[93] Only two cases of severe toxicity in children are reported: one child without a history of a seizure disorder had two seizures 7 days after a levothyroxine ingestion (18,000 μg),[53] and another child became gravely ill for a 12-hour period (blood pressure, 120/68 mm Hg; pulse, 200 beats/min; temperature 104°F [40°C]) 6 hours after ingesting a large amount (3.2 g, or 50 grains) of a desiccated thyroid preparation containing both T_3 and T_4.[58]

Ingestions in adults have a wide range of toxicity. Many patients are asymptomatic or mildly symptomatic.[29,61,72] Severe sequelae occur more frequently in adults than in children. Symptoms resemble thyrotoxicosis and, in extreme cases, thyroid storm. Hyperthermia,[33,55,90] dysrhythmias,[5,55,90] and severe agitation[33] are well described. Hemiparesis,[8] muscle weakness,[8,90] coma,[8,55,90] respiratory failure,[25] sudden death,[7] myocardial infarction,[7] cardiac failure,[8] focal myocarditis,[7] rhabdomyolysis with muscle necrosis,[8] delayed palmar desquamation (>2 weeks postingestion),[8,90] and hematuria[33] are also described. Because patients are expected to be asymptomatic shortly after ingestion and laboratory tests correlate poorly with the degree of symptoms, clinical and laboratory findings early in the course of the ingestion are not reliable indicators of which patients will become ill (see Diagnostic Testing).

■ CHRONIC TOXICITY

Following chronic excessive thyroid hormone ingestion, patients may present with thyrotoxicosis or a have a more subtle and insidious presentation. Classically, chronic ingestion of excess thyroid hormone occurs in patients with hypothyroidism, psychiatric disorders, and eating disorders. Persons who ingest thyroid hormones chronically may develop significant weight loss, anxiety, and accelerated osteoporosis.[71] More severe manifestations, such as cardiac dysrhythmias, tachycardia, cardiac failure, and psychosis, also occur. As in patients with hyperthyroidism, intercurrent illness and physiologic stressors can trigger thyroid storm in these patients.

Numerous miniepidemics of hyperthyroidism and thyrotoxicosis have resulted from the consumption of ground meat containing neck muscle contaminated with thyroid gland.[18,39,49] Investigators in one of these epidemics had three volunteers consume a single large portion of "well-cooked" epidemic-implicated ground beef that previously had been frozen. Although all volunteers remained asymptomatic, the

mean serum peak T_4 (8–12 hours postingestion) was elevated ~15 µg/dL, and TSH remained undetectable for 4–17 days.[39] The practice of gullet trimming (using larynx muscles for beef) that led to these outbreaks has since been prohibited in US slaughter houses. However, the risk for sporadic cases remains, especially when laryngeal muscles are used or when farmers and hunters butcher their own meat.[75] Until an exogenous source of thyroid hormone is suspected or identified, such patients often are misdiagnosed with painless thyroiditis or thyrotoxicosis factitia.

Thyrotoxicosis factitia is a symptomatic disorder that mimics physiologic disease. It occurs with intentional chronic ingestion of exogenous thyroid hormone. The pattern of ingestion typically is surreptitious and maladaptive. Patients frequently have comorbid psychiatric disorders, such as Munchausen syndrome or eating disorders, or are taking thyroid hormone for secondary gain.[35] Patients with thyrotoxicosis factitia tend to be either healthcare professionals with access to medications or prescriptions or persons with access to thyroid medications being taken by relatives or friends.[28,35,65]

In recent years, thyroid hormones have gained popularity among dieters and athletes who use the hormones as weight-loss aids and as stimulants. Severe consequences can occur. Sudden death was reported in three patients suspected of chronic ingestion of thyroid hormone for weight loss and energy enhancement.[7] In 2002, the heavily promoted Singaporean diet pill (Slim 10) was linked to hepatotoxicity and hyperthyroidism in numerous patients.[38] Investigators found the proprietary herbal preparation was adulterated with significant amounts of the undeclared ingredients T_4, T_3 (from thyroid gland extract), and fenfluramine (an FDA-banned drug). The medication was promptly withdrawn and the manufacturers convicted under the Singapore Poisons Act.[38] Similar cases were reported from Hong Kong, Japan, and France following ingestion of "slimming pills" containing animal thyroid extract.[73,79] Unfortunately, thyroid hormone–containing supplements are promoted and are readily available to the general public without a prescription through the Internet and in stores selling nutritional supplements (Chap. 44).[89]

DIAGNOSTIC TESTING

Traditionally, thyroid testing involved combinations of measurement of total T_4 and some measurement of hormone binding (T_3 uptake). Free T_4 and T_3 also can be measured by equilibrium dialysis (*free* T_4), analogue assays (ie, competitive analogs of either free T_3 or free T_4 that competitively bind for spaces on the serum-binding proteins), and antibody capture assays (ie, sequential assays that capture a representative portion of the free fraction of thyroid hormone). Assessment of pituitary production of TSH has improved greatly in recent years. Supersensitive TSH assays can readily detect suppression of TSH production. TSH is now the primary test for screening thyroid function. Suppressed or elevated concentrations of TSH can be reflexively followed up with a free T_4 assay and, if necessary, a free T_3 assay (Table 49–5).

The clinical manifestations of thyrotoxicosis and thyroid storm are well known to occur at normal, low, moderate, and high concentrations of T_3 and T_4.[10] This lack of correlation between symptoms and serum concentrations is also true for exogenous thyroid hormone ingestion.[8,27,33,39,53,57,66,72,105] In a large case series of children with unintentional ingestions of thyroxine estimated to be between 40 and 800 µg, serum T_4 concentrations were drawn in 11 (1–5 hours postingestion). Serum T_4 concentrations were normal in five of these children and were slightly elevated in six (mean 16 µg/dL). In this series, one infant who was estimated to have ingested 4500 µg had a significantly higher concentration (55 µg/dL at 4.5 hours) but developed only a transient episode of diaphoresis and a "staring spell" 7 days postingestion. Another child

TABLE 49–5. Diagnostic Tests for Thyroid Hormone and Thyroid Function

Diagnostic Test	Normal Values[a]	Comments
TSH	0.5–5.0 µIUnits/mL	Available assays with respective detection limits: First generation 1.0 IUnits/L Second generation 0.1 IUnits/L Third generation 0.01 IUnits/L
Total T_4 by RIA	5–12 µg/dL (64–153 nmol/L)	↑In pregnancy, estrogens, oral contraceptives
Total T_3 by RIA	40–132 ng/dL (1.1–2.0 nmol/L)	↑In pregnancy, estrogens, oral contraceptives
Free T_4	0.7–1.86 ng/dL (9–24 pmol/L)	↑In hyperthyroidism, exogenous thyroxine ingestion
Free T_3	0.2–0.52 ng/dL (3–8 pmol/L)	↑In hyperthyroidism, exogenous thyroid hormone (T_3 or T_4)

[a] Interlaboratory and interassay variations may occur.

RIA = radioimmunoassay; TSH = thyroid-stimulating hormone.

who ingested an estimated 4200 µg had a concentration of 12 µg/dL and developed significant tachycardia and hyperthermia.[28] A young child (estimated ingestion 18,000 µg levothyroxine) had a serum T_4 concentration of 117 µg/dL 8 hours postingestion and 38 µg/dL on day 7, when he was symptomatic.[53] In an adult with a massive ingestion of levothyroxine (720,000 µg), serum T_4 concentrations were greater than 30 µg/dL and free T_4 greater than 13 ng/dL (normal 0.7–1.86 ng/dL). In this case, TSH remained undetectable until day 32 postingestion.[33] Overall, the observed symptoms following thyroid hormone ingestion correlate poorly with the amount ingested or with measured serum T_4 concentrations. Prolonged suppression of TSH is common following ingestion of excess thyroid hormone.

Routine analysis of laboratory thyroid function tests in the setting of acute thyroid hormone overdose likely will not affect management. Analysis of thyroid hormone concentrations is indicated only if confirmation of a suspected ingestion is desired and in massive ingestions when early and severe symptoms may occur. Suppression of TSH and elevated thyroid hormone concentrations with a low serum thyroglobulin concentration may help to differentiate between thyrotoxicosis factitia and true endogenous disease.[65]

MANAGEMENT

■ GENERAL

Based on the existing literature, conservative management is adequate in most cases of acute unintentional thyroxine ingestions in both adults and children. Most children with acute overdose are managed with home observation and follow-up appointments. In cases where the acute thyroxine dose is estimated to be greater than 4000 µg, patient follow-up by regular telephone contact for 10 days is suggested.[27] Historically, most children with unintentional ingestions have been treated with GI decontamination with activated charcoal and/or syrup

of ipecac, or by gastric lavage,[27,45,53,55,57,60] but these procedures probably are unnecessary. Based on two large series of unintentional ingestions in children in which no toxicity was observed in the vast majority of cases, clinically significant toxicity is not expected with estimated ingestions less than 4000 μg.[27,102] Because children almost uniformly develop no more than minor symptoms, activated charcoal administration should be considered only if the ingestion is greater than 5000 μg thyroxine. Aspiration risks are minimal in awake, alert children who are able to protect their airways and take activated charcoal orally, without nasogastric tube placement.[55,102] By extension, adults with acute ingestions greater than 5000 μg thyroxine also should be treated with activated charcoal. Except in early presentations with massive thyroxine ingestions (>10,000–50,000 μg) in suicidal adults or ingestions of preparations containing large amounts of T_3, gastric emptying procedures such as induced emesis and orogastric lavage are unwarranted.[8,33] Similarly, patients with massive ingestions (>10,000–50,000 μg) or ingestion of T_3-containing products should be admitted for observation in anticipation of developing significant symptoms.[8,33,53,58]

Treatment should be based on the development of symptoms and should include rehydration, airway protection, and control of sympathomimetic symptoms, mental status alterations, and hyperpyrexia. β-Adrenergic antagonism with propranolol has been used for sympathomimetic symptoms in numerous cases.[24,45,53,57,72,95] Empirical treatment with β-adrenergic antagonists is not recommended. Treatment is only indicated for clinically significant tachycardia, dysrhythmias, and other symptoms of catecholamine-like excess.[24]

■ AGITATION

If sedation is required, parenteral benzodiazepines and barbiturates are recommended. Rapid-acting benzodiazepines such as midazolam, or diazepam should be used to control severely agitated or symptomatic patients. Phenobarbital should be considered as a sole agent in intubated patients or as an adjunct in patients requiring sedation because it offers the added theoretical benefit of inducing enhanced hepatic elimination of thyroxine (Table 49–2). Because of the general risks of sedation and the lack of evidence regarding the clinical use of enhanced hepatic elimination from phenobarbital, sedation with phenobarbital for the sole purpose of enhanced elimination is not indicated. Sedation with antipsychotics such as haloperidol and droperidol should be avoided because their significant anticholinergic properties can exacerbate thyrotoxic symptoms. In addition, the tendency for this class of drugs to prolong the QT interval and predispose to malignant dysrhythmias is of concern in the already catecholaminergic patient. Antipsychotics should be reserved for medically stable patients with psychiatric behavior.

■ CATECHOLAMINE-LIKE EXCESS AND CARDIOVASCULAR SYMPTOMS

The principal therapeutic role of β-adrenergic antagonists in hyperthyroidism is antagonism of β-receptor–mediated effects.[71] In addition to these sympatholytic effects, β-adrenergic antagonists inhibit 5′-deiodinase, thereby decreasing peripheral conversion of T_4 to T_3 (Table 49–2). The clinical significance of decreased peripheral conversion in the setting of overdose is unknown. Propranolol is the most frequently used β-adrenergic antagonist in thyrotoxic patients.[27,45,53,57,72,95] Parenteral β-adrenergic antagonists should be used when symptoms are severe or when rapid control of heart rate is required. Starting doses of 1–2 mg IV propranolol every 10–15 minutes are recommended. High doses have been reported in massive thyroxine overdose, where a patient received 23 mg propranolol IV over 1 hour on initial presentation, then required an average of 30 mg/d IV for 5 more days.[33] Oral propranolol

can be used for persistent symptoms in patients who are both hemodynamically and medically stable and are not acutely agitated. High oral doses in the range of 20–120 mg every 6 hours may be required. Other β-adrenergic antagonists likely will be effective, provided they *do* have intrinsic sympathomimetic activity (ie, partial agonism at β-adrenergic receptors), such as acebutolol, oxprenolol, penbutolol, and pindolol (Chap. 61). Continuous electrocardiographic and hemodynamic monitoring are indicated when parenteral β-adrenergic antagonists are used or when patients require hospitalization.

When β-adrenergic antagonists are contraindicated, as in patients with asthma or severe congestive heart failure, calcium channel blockers can be used as an alternative. Among calcium channel blockers, diltiazem is the most studied for the management of thyrotoxicosis.[68,87] A double-blind, crossover trial that compared propranolol to diltiazem for thyrotoxic symptoms found that diltiazem was well tolerated and appeared as effective as propranolol.[68] Another study successfully used diltiazem as the sole agent for treatment of cardiovascular symptoms in 11 thyrotoxic patients.[87] Oral doses of 60–120 mg diltiazem 3–4 times daily or 5–10 mg/h parenterally have been used.[68,87] A possible explanation for the efficacy of calcium channel blockers in thyrotoxicosis is that thyroid hormone enhances Ca^{2+} uptake by L-type voltage-gated Ca^{2+} channels, accelerates Ca^{2+} entry into the sarcoplasmic reticulum, and increases cellular Ca^{2+} storage capacity.[47,48,69,91] The net effect of these changes is increased inotropy and chronotropy. Calcium channel blockers, particularly diltiazem and verapamil, attenuate these effects. Use of parenteral β-adrenergic antagonists in combination with parenteral calcium channel blockers is contraindicated because of the risk for profound hypotension and cardiovascular collapse (Chap. 61).

■ HYPERTHERMIA

Antipyretics are recommended for hyperpyrexia, with acetaminophen being the drug of choice. Aspirin, particularly high doses (1.5–3 g/d), should be avoided because it carries a theoretical risk of increased thyrotoxicity from displacement of T_3 and T_4 from TBG (Table 49–2). Note, however, that hyperthermia, especially extreme hyperthermia (>106°F [>41°C]), most likely is secondary to psychomotor agitation and excess heat production from the hypermetabolic, catecholaminergic, thyrotoxic state. Extreme hyperthermia should be considered a medical emergency and should be rapidly and aggressively treated with active external cooling with ice baths and with β-adrenergic antagonism, sedation with benzodiazepines and/or barbiturates, and endotracheal intubation with paralysis if necessary (Chap. 15).

■ OTHER THERAPIES

Bile acid sequestrants, such as cholestyramine and colestipol, and aluminum hydroxide (antacids) and sucralfate bind to exogenous T_4 and decrease GI absorption (Table 49–2). Because the evidence supporting their effectiveness is poor, they are not routinely recommended for thyroid hormone overdose.[55]

Oral iodine-containing contrast media is known to decrease peripheral conversion of T_4 to T_3. Doses of 1–2.5 mg/kg iodine PO daily are routinely used for thyroid storm (oral drops commonly referred to as saturated solution KI [SSKI]). Thioamides, such as propylthiouracil (PTU) and methimazole, and the corticosteroids are thyroid gland inhibitors that are used for treatment of non–drug-related hyperthyroidism. In addition, thioamides inhibit peripheral conversion of T_4 to T_3. Evidence from limited case reports suggests poor efficacy of both thioamides and corticosteroids in acute overdose[8,25,55] (see Thioamides and Iodides).

Although use of antithyroid drugs such as PTU, corticosteroids, and iodine contrast media in thyroxine overdose has theoretical benefits, these drugs are unvalidated, potentially harmful, and unlikely to offer

additional benefit, or be superior to conventional therapy with activated charcoal, β-adrenergic antagonism, and sedation. These treatments are not recommended as adjunctive therapies for treatment of exogenous thyroxine overdose.

■ EXTRACORPOREAL DRUG REMOVAL

Extracorporeal drug removal procedures, such as plasma exchange or plasmapheresis, exchange transfusion (in children), and charcoal hemoperfusion, have been used in extreme cases of thyroid hormone overdose and thyroid storm.[1,8,9,25,40,55,59,66,70,97,103] Overall, results regarding improvement of clinical condition and plasma clearances of thyroid hormones with these methods are conflicting. The largest series of acute ingestions involved six patients who became critically ill after massive thyroxine ingestions of prescribed capsules containing a 1000-fold concentration excess of thyroxine (dose range 50,000–125,000 μg/d for 2–12 days). Charcoal hemoperfusion and plasmapheresis were used in all patients. Plasmapheresis was found to be more effective than hemoperfusion in the extraction of thyroxine. The authors suggest this intervention may shorten the duration of thyrotoxicosis. Rebound elevations in plasma concentrations occurred 24 hours later, suggesting redistribution between extravascular and intravascular compartments.[8] This redistribution is expected given the large volume of distribution for thyroid hormones (Table 49–1). There may be a role for early plasmapheresis in the exceptional situation of a known massive ingestion of thyroid hormone. Because the outcomes from most ingestions of thyroid hormone will be favorable with good supportive care, sedation, and β-adrenergic antagonism, the risks of plasmapheresis should be evaluated on a case-by-case basis after consultation with a medical toxicologist.

XENOBIOTICS WITH ANTITHYROID EFFECTS

■ THIOAMIDES

Antithyroid drugs are used to decrease the amount of thyroid hormone in hyperthyroid states, most commonly in Graves disease. Thioamides are a group of chemicals with the basic structure of R-SCN. Methimazole and propylthiouracil (PTU) are the two principal thioamides used for treatment of hyperthyroidism. Carbimazole, which is bioactivated methimazole, is available in Europe and China. Methimazole and PTU both inhibit the activity of thyroid peroxidase in the thyroid gland.[98] PTU has the added effect of inactivating 5′-deiodinase, which decreases the peripheral conversion of T_4 to the metabolically more active T_3.[19,56] Because thioamides act primarily by decreasing thyroid hormone synthesis (vs. release), a lag time of 3–4 weeks may occur before T_4 is depleted. The oral bioavailability of PTU is 50%–80%. It is rapidly absorbed from the GI tract and may undergo first-pass effect by the liver. Although its plasma half-life is only 1.5 hours, its effects are long-lasting because of accumulation in the thyroid gland. PTU is inactivated by glucuronidation and is renally eliminated. Methimazole is completely absorbed, is concentrated in the thyroid, and is more slowly eliminated than PTU (48 vs. 24 hours). Doses of PTU are in the range of 100 mg orally every 6–8 hours. Methimazole can be given 30 mg PO daily. Although PTU is 10 times less potent than methimazole, it is more commonly used. The indications for its use are mild-to-moderate hyperthyroidism.

The two thioamides traverse the placenta (methimazole more than PTU) and should not be administered during pregnancy. However, they are minimally secreted in breast milk. Adverse effects occur in 3%–12% of patients taking thioamides. The most common adverse effect is a maculopapular pruritic rash. Methimazole, PTU, and, to a lesser extent, carbimazole can cause immune-mediated, dose-related, and age-related agranulocytosis and neutrophil dyscrasias.[58,62,67,77] This potentially life-threatening adverse effect can be treated by administration of granulocyte colony-stimulating factor.[5] Premature withdrawal of thioamides can lead to rebound symptoms and thyrotoxic states.[52]

There are little data regarding overdose with thioamides. A 12-year-old girl with a previous thyroidectomy, who was estimated to have ingested 5000–13,000 mg PTU, developed only a transient decreased T_3 concentration and elevated alkaline phosphatase concentration (7350 mU/mL).[44] The absence of a functioning thyroid gland may have contributed to the benign course in this patient. No other serious sequelae have been associated with acute overdose of thioamides.

■ IODIDES

Prior to the development of thioamides, iodide salts were the principal treatment for hyperthyroidism. Iodides decrease thyroid hormone concentrations by inhibiting formation and release. In thyroid storm, high-dose iodides (>2 g/d) decrease thyroid hormone release and produce substantial improvements by 2–7 days. Common sources of iodides include calcium iodide, sodium iodide, potassium iodide (KI; pharmaceutical preparations, iopanoic acid, Lugol's solution [iodine + KI solution], oral drops [SSKI]), and methyl iodide (industrial preparations).

The adverse reaction to chronic ingestion of small or excessive amounts of iodide salts, termed *iodism,* is characterized by cutaneous rash, laryngitis, bronchitis, esophagitis, conjunctivitis, drug fever, metallic taste, salivation, headache, and bleeding diathesis. Immune-mediated hypersensitivity symptoms consisting of urticaria, angioedema, eosinophilia, vasculitis, arthralgia, lymphadenitis, and rarely anaphylactoid reactions may occur. Chronic iodide therapy has produced goiters, hypothyroidism, and rarely hyperthyroidism. As much as 10 g sodium iodide has been administered IV without development of signs or symptoms of toxicity.

Iodide (I^-), unlike iodine (I_2) (Chap. 102), is not a caustic. Potassium iodide is added to table salt to form iodized salt for prevention of goiter. It also is used as a prophylactic agent after exposure to large amounts of nuclear fallout to prevent uptake of radioactive iodine into the thyroid gland (see Antidotes in Depth A42: Potassium Iodide) and is the most commonly used iodide for thyroid suppression in hyperthyroidism. Iodide mumps is a well-described but rare disorder characterized by severe sialadenitis (or parotitis),[46] allergic vasculitis, and/or conjunctivitis following administration of ionic and nonionic iodine-containing contrast media and oral iodide salts (Table 49–4).[12,13,45] Although the mechanism remains unclear, it is thought to be idiosyncratic or secondary to iodide accumulation and subsequent inflammation in the ductal systems of the salivary gland. Symptoms tend to occur within 12 hours and resolve spontaneously within 48–72 hours.[12]

Iodides should be avoided in pregnancy because they readily cross the placenta. Severe fetal complications, such as cretinism and death from respiratory failure secondary to obstructive goiter, are reported.[21,41,63] Iodide salts adsorb to activated charcoal.

Methyl iodide is a methylating agent used in the chemical and pharmaceutical industry, as a reagent in microscopy, as a catalyst in production of organic lead compounds, as an etching agent, as a component in fire extinguishers, and formerly as a soil fumigant. Methyl iodide toxicity from inhalation is associated with early pulmonary congestion, lethargy, and renal failure. It also is associated with delayed cerebellar degeneration, multifocal neuropathies (cranial nerve and spinal), parkinsonian symptoms, and late and persistent psychiatric symptoms (months to years).[2,42] Chronic repeated overexposures have led to misdiagnoses such as multiple sclerosis. The toxicity is similar to that of the monohalomethanes (Chap. 116).

SUMMARY

Despite the prevalence of thyroid disorders in the general population and the widespread use of levothyroxine, remarkably little morbidity and mortality associated with overdose from thyroid hormones is reported. Most unintentional ingestions in children are benign, and they can be observed as outpatients for 5–10 days. Intentional ingestions in adults may result in severe symptoms that require ICU management. Supportive care with sedation, cooling measures, and β-adrenergic antagonism are adequate in most cases. Chronic ingestions may produce more severe symptoms as they may present more insidiously or are complicated by thyroid storm. Unregulated dietary supplements containing thyroid hormone used for weight loss and athletic enhancement are becoming increasingly available to consumers via the Internet and in health food or supplement stores. Clinicians should suspect exogenous thyroid hormone exposure in patients with thyrotoxicosis and suppressed TSH concentrations.

CHAPTER 50

ANTIHISTAMINES AND DECONGESTANTS

Anthony J. Tomassoni and Richard S. Weisman

Antihistamines and decongestants rank highly among the top 40 prescription and nonprescription xenobiotics used in the United States. Inappropriate use and unrecognized dangers associated with their use have posed significant public health problems. Their ready availability, singly and in combination with each other and with analgesics and antipyretics, coupled with widespread public impression that nonprescription and herbal xenobiotics are "safe," contributes to their frequent use, misuse, and potential abuse.

HISTORY AND EPIDEMIOLOGY

Recreational use of antihistamines and decongestants as "legal highs" has gained in notoriety over the past several years, and nonprescription sympathomimetics have been used as precursors in the synthesis of illegal stimulants. While the rates of potential adverse events are perceived as low, the issue takes on added significance when the magnitude of the exposure rates for these xenobiotics is considered: in a survey of 2590 participants distributed across the United States, 8.1% of adult participants reported taking pseudoephedrine within the past week, and 4.4% reported the use of diphenhydramine within the same time period[47] (Table 50–1).

Despite well-designed and carefully monitored studies prior to US Food and Drug Administration (FDA) approval of medications, only half of newly discovered serious adverse drug events (ADEs) are detected and reported in the Physicians' Desk Reference within 7 years of drug approval.[52] This suggests that increased efforts to detect and report ADEs via improved postmarketing surveillance are required. The quality and timeliness of current toxicovigilance efforts may be hampered by many variables including low reporting rates, variable data quality in reports, and the effects of media attention on spontaneous reporting systems—factors well-known to clinical toxicologists and poison centers. The potential impact of surveillance system inadequacies on public health is dramatically illustrated by the delayed recognition of the risk of intracranial hemorrhage associated with the use of phenylpropanolamine.[48]

Recent information regarding potential hazards of antihistamine or decongestant use has catalyzed new review, regulations and withdrawal of some xenobiotics from the market. The Combat Methamphetamine Act signed into law in 2006 limiting methamphetamine precursor availability and additional precautions in pharmacies (such as dispensing limits for nonprescription quantities and storage of the medications behind pharmacy counters) has attempted to reduce potential harm associated with these xenobiotics.

ANTIHISTAMINES

■ HISTORY AND EPIDEMIOLOGY

What subsequently became known as H_1 receptor antagonists were introduced into clinical use in the early 1940s with pyrilamine as the first medication. Antihistamines are available worldwide, and many

do not require a prescription. The class of medications continues to find widespread application in the treatment of anaphylaxis, allergic rhinitis, urticaria, and other histamine-mediated disorders. They are often used for symptomatic relief of allergy symptoms and are included in many combination cold and cough preparations. First-generation (sedating) antihistamines are also marketed as sleep aids, sometimes in combination with analgesics such as acetaminophen. First-generation H_1 receptor antagonists are commonly ingested in suicide attempts, most likely because of their ready availability and because of the many formulations marketed as "sleeping pills."[65] Second- and third-generation H_1 receptor antagonists, marketed beginning in the mid-1980s, are not sedating and less frequently implicated in suicide attempts.

Both poison center and clinical experiences suggest that recreational use of antihistamines may be increasing. It is unclear whether the increased use results simply from inclusion of antihistamines in cold preparations containing the widely abused cough suppressant dextromethorphan (Chap. 38). The second-generation (nonsedating) antihistamines terfenadine and astemizole are associated with cardiac dysrhythmias and are no longer approved for use in the United States (Chap. 138). Absolute risk of developing ventricular dysrhythmias as a result of nonsedating antihistamine use has been estimated to be 1 in 57,000 prescriptions.[17]

Unintentional exposures to antihistamine-containing preparations are common. Review of the annual reports of the American Association of Poison Control Centers underscores the frequency of antihistamine exposures. Of a total of 2,482,041 human exposure calls voluntarily reported in 2007, antihistamines alone accounted for 79,157 making antihistamines 15th among classes of poison exposures overall and 10th among children (39,686 exposure calls).[8] Additional exposures related to cough and cold medications will be considered in the decongestants section. While reporting is not comprehensive, poison center data suggest that the prevalence of unintentional antihistamine exposure is increasing: antihistamines ranked 13th among children in 2001 accounting for only 67,053 of 2,267,979 human exposure calls.[55] National Association of Medical Examiners data reported 14,000 fatalities involving children younger than 6 years annually.[44] Liquid formulations attractive to children are available, and diphenhydramine or another antihistamine is occasionally administered as a sedative by parents and daycare workers.[3] Although ingestion is the usual route of exposure, exposure to topical preparations containing antihistamines can also cause toxicity.[39]

■ ANATOMY AND PHYSIOLOGY OF THE HISTAMINE RECEPTOR SYSTEM

The numerous functions of histamine and its receptors in the nervous system, immune system, and other organ systems are continually being appreciated. Four types of histamine receptors are recognized and designated H_1, H_2, H_3, and H_4. All are helical transmembrane molecules that transduce extracellular signals via G proteins to intracellular second-messenger systems.[70]

H_1 receptors are most commonly associated with mediation of inflammation. These receptors are located in the CNS, heart, vasculature, airways, sensory nerves, gastrointestinal smooth muscle cells, immune cells, and adrenal medulla. The functions of histamine and the H_1 receptor include control of the sleep–wake cycle, cognition, memory, and endocrine homeostasis. H_1 receptor stimulation also causes vasodilation, increases vascular permeability and bronchoconstriction, and decreases atrioventricular nodal conduction when histamine is present.

Through H_1 receptors, histamine interacts with G proteins in the plasma membranes. Stimulation of H_1 receptors results in increased synthesis by phospholipases A_2 and C, inositol-1,4,5-triphosphate and several diacylglycerols (DAGs) from phospholipids located in cell membranes.

Rank	Drug	1-Week Prevalence (%)
4	Pseudoephedrine HCl	8.1
6	Diphenhydramine HCl	4.4
13	Chlorpheniramine maleate/tannate	2.9
17	Loratidine	2.5
35	Fexofenadine	1.3
36	Doxylamine succinate	1.2

From Kaufman DW, Kelly JP, Rosenberg L, et al. Recent patterns of medication use in the ambulatory adult population of the United States. The Slone Survey. *JAMA*. 2002;287:337-344. With permission.

Inositol-1,4,5-triphosphate causes release of calcium, which then activates calcium–calmodulin-dependent myosin light-chain kinase, resulting in enhanced cross-bridging and smooth muscle contraction. The active and inactive forms of this receptor subtype are in equilibrium at baseline, and histamine shifts the equilibrium to the active conformation.[70]

H_2 receptors are located in cells of the gastric mucosa, heart, lung, CNS, uterus, and immune cells. H_2 receptor stimulation is mediated by adenyl cyclase activation of cyclic adenosine monophosphate (cAMP)-dependent protein kinase in smooth muscle and in parietal cells of the stomach and results in increased gastric acidity through stimulation of the H^+-K^+-ATPase pump causing release of H^+ into the gastric lumen.[37,70] The action of histamine on H_2 receptor results in increased gastric acid secretion, increased vascular permeability, and other effects.

H_3 receptors are found in neurons of the central and peripheral nervous systems, airways, and the GI tract. The action of histamine on H_3 receptors of the CNS decreases further release of histamine, acetylcholine, dopamine, and serotonin.[82] H_3 receptors partly act to prevent excessive bronchoconstriction and also are implicated in control of neurogenic inflammation and proinflammatory activity.[53] No H_3 receptor antagonists are commercially available. Some prototypical drugs include clobenpropit, ciproxifan, and thioperamide. Due to nootropic (cognitive enhancement) and stimulant effects it has been suggested that H_3 antihistamines might play a future role in the treatment of ADHD, depression, or dementia.

H_4 receptors are located in leukocytes, bone marrow, spleen, lung, liver, colon, and hippocampus. The H_4 receptor has apparent roles in the differentiation of myeloblasts and promyelocytes, and in eosinophil chemotaxis.[37,70] Due to their association with mast cells and eosinophils, future H_4 antagonists may play a part in the treatment of allergic rhinitis, asthma and rheumatoid arthritis.

This chapter focuses on H_1 and H_2 antihistamines, since no H_3 or H_4 receptor active pharmaceuticals are presently in clinical use.

■ PHARMACOLOGY

Histamine Antagonists All known H_1 histamine antagonists function as inverse agonists and not simply reversible competitive antagonists.[70] Rather than preventing the binding of histamine to its receptor as in a classical competitive antagonist model, H_1 histamine antagonists stabilize the inactive form of the H_1 receptor and shift the equilibrium to this inactive conformation.[70] However, for consistency with the medical literature and the current clinical use of these drugs, we use the terms H_1 antihistamine and histamine antagonist rather than inverse agonist to describe agents of this class.

Agonists and antagonists that act at each of the four histamine-modulated receptor sites have been identified. Antiallergic and antiinflammatory activities of the H_1 antihistamines involve multiple mechanisms. For example, inhibition of the release of mediators from mast cells or basophils may involve a direct inhibitory effect on calcium-ion channels, thereby reducing the inward calcium current activated when intracellular stores of calcium are depleted. Inhibition of the expression of cell adhesion molecules and eosinophil chemotaxis may involve downregulation of the H_1 receptor-activated nuclear factor (κB) which binds to promoter or enhancer regions of genes that regulate the synthesis of proinflammatory cytokines and adhesion proteins.[70]

Six major classes of H_1 antihistamines are traditionally recognized based on molecular structure. The classes were initially populated by first-generation derivatives of ethylenediamine, ethanolamine, alkylamines, phenothiazines, piperazines, and piperidines (Fig. 50–1).[70]
FIGURE 50–1. Structures of histamine and diverse H_1 receptor antagonists.

Many of the classic antihistamines are substituted ethylamine structures with a tertiary amino group linked by a two- or three-carbon chain with two aromatic groups. This structure differs from histamine by the absence of a primary amino group and the presence of a single aromatic moiety.

In some respects, a more functional classification stratifies H_1 antihistamines by sedating properties and ability to cross the blood–brain barrier. So-called first-generation antihistamines readily penetrate the blood–brain barrier and produce CNS effects including sedation and performance impairment. In contrast, second-generation or nonsedating H_1 antihistamines are peripherally selective and have a higher therapeutic index. Central effects of the first-generation H_1 antihistamines likely result from their high lipophilicity or lack of recognition by the P-glycoprotein efflux pump on the luminal surfaces of vascular endothelial cells in the CNS.[13,70] Some first-generation H_1 antihistamines also bind to muscarinic and perhaps to α-adrenergic receptors (Table 50–2).

Second-generation H_1 antihistamines do not penetrate the CNS well because of their hydrophilicity, their relatively high molecular weight, and recognition by the P-glycoprotein efflux pump on the luminal surfaces of vascular endothelial cells in the CNS. Furthermore, the second-generation H_1 antihistamines cetirizine, fexofenadine, loratadine, azelastine (nasal spray), and ebastine have lower binding affinities for the cholinergic, α-adrenergic, and β-adrenergic receptor sites than do the first-generation antihistamines.

Careful prescribing practice may lead to a preference for second-generation H_1 antihistamines in patients whose activities are safety-critical and may be affected by any psychomotor impairment, for example, those who operate motor vehicles.[33,58] Despite this seemingly straightforward precaution, care must be exercised in the selection and use of second-generation H_1 antihistamines since some subjective or objective sedation may still result from their use. Furthermore, it has been posited after meta-analysis that the line between sedating and nonsedating H_1 antihistamines may be blurry, with some studies suboptimally constructed and lacking in distinction between medication side effects and the effects of the condition being treated.[5,78] Overall, it appears that the relative incidence of anticholinergic and CNS adverse effects caused by second-generation H_1 antihistamines may be similar to that produced by placebo.[16] However, some patients report sedation, especially if higher-than-recommended dosages are taken, particularly

with cetirizine.[16,78] Table 50–3 lists the peripheral selectivity of the antihistamine that is principally defined by the relative absence of anticholinergic and sedative properties of the H_1 antihistamines.

Using recommended doses of antihistamines, PET scanning shows that first-generation antihistamines occupy more than 70% of the H_1 receptors in the frontal cortex, temporal cortex, hippocampus, and pons. In contrast, the second-generation antihistamines occupy less than 20%–30% of the available CNS H_1 receptors.[77,78] Given the relatively limited anticholinergic effects of the second-generation antihistamines, antihistamine therapy for patients with seasonal asthma has been reintroduced and has proved efficacious.

Some H_1 antihistamines have relatively unique properties that may lead to special uses or marketing. Diphenhydramine and promethazine have local anesthetic properties although higher concentrations are necessary to achieve this effect. Diphenhydramine and doxylamine find frequent application in nonprescription sleeping medications due to their sedative effects. Diphenhydramine and dimenhydrinate have relatively strong antimuscarinic activity and have been used for the management of motion sickness. Oxatomide, a sedating H_1 antihistamine, may possess mast-cell stabilizing properties possibly mediated via calcium-channel blockade and has been associated with dyskinesia. In a test of wheal suppression, fexofenadine had the earliest onset of action while levocetirizine showed maximal inhibition of wheal response at 3 and 6 hours.[18]

H_2 Receptor Antagonists These structural analogs of histamine are highly selective and competitively inhibit the H_2 receptor site. Cimetidine is the original antihistamine in this class; it retains the imidazole ring of histamine (Fig. 50–2). Although newer antihistamines such as ranitidine and famotidine have replaced this ring with a furan or thiazole group, respectively, they retain significant structural similarity to histamine.

The effectiveness of H_2 receptor antagonists in the treatment of gastroesophageal reflux disease is improved further by their concomitant alteration in the response of parietal cells to acetylcholine and gastrin, two other stimulants for gastric acid secretion (Fig. 50–3). Of note, H_2 receptor antagonists have little effect elsewhere in the body, and they have weak CNS penetration secondary to their hydrophilic properties. Though effective in the treatment of *H. pylori*-mediated disease when used in conjunction with appropriate antibiotics, a proton pump inhibitor was used in lieu of an H_2 blocker.

TABLE 50–2. Common Effects of H_1 Antihistamines

Effector	Effect	Comment
H_1 receptors	Decreased CNS neurotransmission resulting in increased appetite, potential weight gain, sedation, impaired psychomotor and cognitive function, dyskinesia, agitation	Observed with first-generation drugs; cetirizine 10 mg or greater dose is associated with sedation in some patients
Ion channels	Electrocardiographic QT interval prolongation; sodium channel blockade; resultant ventricular dysrhythmias; I_{Kr}, I_{Na} and other channels may be affected	Terfenadine and astemizole withdrawn from the US market for this reason. Diphenhydramine has CA like effects
Muscarinic receptors	Antimuscarinic (anticholinergic) effects including flushing, hyperthermia via impaired cooling/sweating, dry mouth, dry eyes, sinus tachycardia, mydriasis, agitation/hallucination, reduced GI motility, urinary retention, sinus tachycardia	Insignificant with second-generation agents
α-Adrenergic receptors	Hypotension, orthostasis and reflex tachycardia	No serious effect likely
Serotonin receptors	Increased appetite	

TABLE 50–3. Pharmacologic Characteristics of H_1 Antihistamines

Antihistamine	Anticholinergic Class	Sedation	Duration of Action (h)	Typical Adult Dose
Acrivastine	Alkylamine	+	6–8	8 mg tid
Brompheniramine	Alkylamine	++	4–6	4 mg qid
Chlorpheniramine	Alkylamine	++	4–6	4 mg qid
Dexbrompheniramine	Alkylamine	++	12	3–12 mg bid
Dexchlorpheniramine	Alkylamine	++	3–6	4–6 mg tid
Dimethindene	Alkylamine	++	8	1–2 mg tid
Pheniramine	Alkylamine	++	4–6	5–15 mg q4h
Triprolidine	Alkylamine	++	4–6	2.5 mg qid
Carbinoxamine	Ethanolamine	++++	3–6	4–8 mg qid
Clemastine	Ethanolamine	++++	12–24	2 mg bid
Dimenhydrinate	Ethanolamine	++++	4–6	50–100 mg qid
Diphenhydramine	Ethanolamine	++++	4–6	25–50 mg qid
Doxylamine	Ethanolamine	++++	6	7.5–12.5 mg qid
Phenyltoloxamine	Ethanolamine	++++	4–8	7.5–25 mg tid
Tripelennamine	Ethylenediamine	+++	4–6	25–50 mg qid
Promethazine	Phenothiazine	++++	4–6	12.5–25 mg qid
Trimeprazine	Phenothiazine	++++	4–6	2.5 mg qid
Buclizine	Piperazine	++	4–6	50 mg bid
Cetirizine	Piperazine	+	12	5–10 mg qid
Hydroxyzine	Piperazine	++	6–8	25 mg qid
Levocetirizine	Piperazine	0	24	5 mg daily
Meclizine	Piperazine	++	6–8	25 mg tid
Azatadine	Piperidine	+	12	1–2 mg bid
Desloratadine	Piperidine	0	24	5 mg daily
Fexofenadine	Piperidine	+	12	60 mg bid
Loratadine	Piperidine	+	8–12	10 mg daily

FIGURE 50–2. Structures of H_2 receptor antagonists.
Reports on the effect of H_2 antihistamines on ethanol metabolism yield conflicting results. Definitive studies have not been performed, but at this time any effect at clinically relevant doses of alcohol appears insignificant.[31] Questions remain regarding the effect of H_2 antagonist induced accelerated gastric emptying time on ethanol kinetics as well as their effects on gastric alcohol dehydrogenase and hepatic cytochromes. Interindividual variability of the effects of H_2 antagonists on ethanol metabolism and the magnitude of the effect caused by different H_2 antagonists remain to be elucidated.[31,76]

■ PHARMACOKINETICS AND TOXICOKINETICS

H_1 Receptor Antagonists The antihistamines are generally well absorbed following oral administration, and most achieve peak plasma concentrations within 2–3 hours. Although less well studied, dermal absorption appears to be consequential, especially with extensive or prolonged application to abnormal skin.[60] The maximum antihistaminic effect

FIGURE 50–3. Schematic representation of a gastric parietal cell demonstrating the mechanism of hydrogen ion secretion into the lumen. Gastric acid is modulated by both calcium-dependent and cyclic adenosine monophosphate (cAMP)-dependent pathways. Histamine binding to the H_2 receptor increases gastric acidity by increasing cAMP. Both acetylcholine and gastrin increase gastric acidity by increasing the influx of calcium. Acetylcholine binds at the muscarinic$_3$ (M_3) receptor, whereas gastrin binds at the cholecystokinin B (CCK_B) receptor.

occurs several hours after peak serum concentrations. The duration of action ranges from 3 hours to 24 hours, which is much longer than predicted from the serum elimination half-lives of the antihistamines. Hepatic metabolism is the primary route of metabolism for antihistamines.[63] Many Asian patients can acetylate therapeutic concentrations of diphenhydramine to a nontoxic metabolite twice as rapidly as Caucasian patients, making Asians much less sensitive to both the psychomotor and sedative effects.[74] Alterations in usual dosages may be required for patients taking other medications, those with hepatic or renal dysfunction, the young, and the elderly. Such modifications often must be made empirically because formal studies and recommendations for many agents are lacking. In a recent study, desloratidine doses of 1 and 1.25 mg in children between the ages of 6 months and 2 years were found to provide a single dose target exposure (AUC) comparable with that experienced by adults receiving the recommended 5 mg dose.[31] Recognized pharmacokinetic drug interactions involving the H_1 antihistamines are generally caused by modulation of CYP450 metabolism (most often CYP2D6 or CYP3A4), or via interference with active transport mechanisms such as P-glycoprotein or organic anion transporter polypeptide (OATP).[4,70] The currently available second-generation H_1 antihistamines undergo fewer clinically relevant pharmacokinetic interactions than the first-generation H_1 antihistamines.

H_2 Receptor Antagonists Cimetidine is the prototypical H_2 receptor antagonist. Cimetidine is rapidly and completely absorbed following

oral administration. Cimetidine has a volume of distribution of approximately 2 L/kg, with 13%–25% protein binding.[1] Up to 75% of cimetidine is eliminated unchanged in the urine, 15% is metabolized by the liver, and 10% is eliminated unchanged in the stool. The elimination half-life in patients with normal renal function is approximately 2 hours, but the half-life is substantially prolonged with impaired renal function.[1] Cimetidine is responsible for numerous drug–drug interactions because it can inhibit cytochrome P450 activity, thereby impairing hepatic drug metabolism. It can reduce hepatic blood flow, resulting in decreased clearance of drugs that are highly extracted by the liver. None of the other currently available H_2 receptor antagonists inhibit the cytochrome P450 oxidase system.[59] Additionally, by altering gastric pH, cimetidine and all the other H_2 antagonists may alter the absorption of acid-labile xenobiotics. Finally, cimetidine and ranitidine are associated with myelosuppression particularly when administered with xenobiotics capable of causing bone marrow suppression.[2] Table 50–4 lists the pharmacologic properties of H_2 receptor antagonists.

■ CLINICAL MANIFESTATIONS

H_1 Receptor Antagonists Although dry mouth and mydriasis are common adverse therapeutic effects, sedation is of the greatest concern. Therapeutic antihistamine use has been described by investigators to be as incapacitating as ethanol intoxication when operating motor

TABLE 50–4. Pharmacology of Histamine H_2 Receptor Antagonists

Drug	Typical Adult Dose (mg)	Half-Life (hours)	Urinary Elimination (%)
Cimetidine	800	2.0	62
Ranitidine	300	2.1	69
Nizatidine	300	1.3	61
Famotidine	40	2.6	67

vehicles.[33] Compared with adults, children may more commonly present with excitation and irritability and may be more prone to hallucinations and seizures. Chlorpheniramine is both a serotonin reuptake inhibitor and a postsynaptic 5-HT_{1A} receptor agonist.[45] Agonism of 5-HT_{1A} receptors has been associated with seizures. Though uncommon, metabolic acidosis followed by seizure has resulted from abuse of a chlorpheniramine-containing cold medication.[61]

The clinical manifestations of H_1 antihistamine overdose are largely extensions of their therapeutic and adverse effects. Following overdose with a first-generation H_1 antihistamine, patients typically present with CNS depression and an anticholinergic syndrome (Chap. 3). Findings typically include mydriasis, tachycardia, hyperthermia, dry mucous membranes, urinary retention, diminished bowel sounds, and altered mental status including disorientation and hallucinations (Table 50–3). The skin may appear flushed, warm, and dry. Hyperthermia correlates with the extent of agitation, ambient temperature and humidity, and length of time during which the patient cannot dissipate heat because of anticholinergic-mediated reduction in sweating.

Some patients with high therapeutic dosing or following overdose develop the central anticholinergic syndrome, in which CNS anticholinergic effects, such as hallucinations, outlast peripheral anticholinergic effects. At a later stage of ingestion the lack of tachycardia, skin changes, or other peripheral anticholinergic manifestations complicates obtaining the correct diagnosis for antihistamine-poisoned patients unless there is a clear exposure history.[29,83] Ingestion of second-generation H_1 antihistamines usually does not result in significant CNS depression or anticholinergic effects.

Cardiotoxicity associated with terfenadine and astemizole may result from accumulation of drug in cardiac tissue after inhibition of drug elimination (eg, terfenadine–ketoconazole interaction) and may be exacerbated by electrolyte (eg, Ca^{2+}) imbalances or concomitant use of another ion channel blocker.[6,35] Newer second-generation H_1 antihistamines are less dysrhythmogenic.

In a review of 136 patients with diphenhydramine overdose, somnolence, lethargy, or coma occurred in approximately 55% of patients, whereas 15% experienced a catatonic stupor.[49] Several reports suggest that young children experience more respiratory complications, CNS stimulation, anticholinergic effects, and seizures than do adult patients.[62] In a placebo-controlled study comparing the CNS effects of first- and second-generation H_1 antihistamines, the second-generation antihistamines caused less cognitive dysfunction and somnolence.[16,36] Results of a study of 100 patients in a sample of 2074 antihistamine users reporting excessive daytime sleepiness after use of H_1 antihistamines (predominantly chlorpheniramine) suggest that the presence of the CYP2D6*10 allele is a risk factor for development of H_1 antihistamine–induced ADEs.[67] A retrospective review of 146 adults and children found that cetirizine overdose is relatively free of CNS or cardiotoxicity

when compared with older generation H_1 antagonists.[75] This finding was corroborated in the simulated driving model, in which loratadine produced significantly less impairment than diphenhydramine.[33] Use of diphenhydramine compared with loratadine in a work setting results in significantly higher injury rates.[25]

Sinus tachycardia is a consistent finding following overdose with an H_1 antihistamine with anticholinergic effects. Both hypotension and hypertension may occur.[56] These findings probably relate more to the patient's age, volume status, and vascular tone than to a specific class of antihistamines. As a result of sodium channel blockade following a large diphenhydramine overdose, prolongation of both the QRS complexes and QT intervals may occur.[43,68,79] Of note, postmortem findings are generally limited to pulmonary and visceral edema, suggesting cardiogenic causes of death.[46]

Mydriasis develops at both therapeutic and toxic doses, with most patients describing blurred vision and/or diplopia. Both vertical and horizontal nystagmus may occur in patients with diphenhydramine overdose. Other CNS effects include seizures, hallucinations, acute extrapyramidal movement disorders,[24] and psychoses.

Rhabdomyolysis can occur in patients with extreme agitation or seizures following an H_1 antihistamine overdose.[27] Rhabdomyolysis is commonly noted in patients who overdose with doxylamine, even in the absence of trauma or any of the other common etiologies such as seizures, shock, or crush injuries.[41,50,54] The mechanism remains undefined. A prospective study found that 87% of patients who ingested more than 20 mg/kg of doxylamine developed rhabdomyolysis, and this dose was the best predictor of this complication.[41] Rhabdomyolysis is reported as a rare adverse event following diphenhydramine overdose.[22]

Topical application of some antihistamines, particularly to children with skin lesions such as varicella, may produce classic systemic anticholinergic toxicity.[60] Promethazine and other H_1 antihistamines are associated with sudden infant death syndrome, although causality is not yet proven.[64] Cetirizine, a second-generation H_1 antihistamine, is suggested as safer for infant use, but further study is warranted.[71] Other adverse effects include pancytopenia and jaundice.

Elderly patients are more susceptible to adverse events because renal and hepatic dysfunction, which are more common in the elderly, delay antihistamine metabolism.[36] Several infants who died of diphenhydramine overdose had serum concentrations lower than expected for fatality in adults suggesting a reduced threshold for toxicity.[3] All H_1 antihistamines cross the placenta, and some are teratogenic in animals. First- and second-generation agents fall into FDA categories B and C and should be individually addressed, avoiding or minimizing exposure when possible (see Chap. 30). Because of their antimuscarinic effects, first-generation antihistamines are generally contraindicated in patients with glaucoma or benign prostatic hypertrophy.

Rare effects include fixed-drug rash, urticaria, photosensitivity, hyperthermia, transaminitis, or agranulocytosis.

H_2 Receptor Antagonists Acute toxic effects appear to be extremely rare, even after large (20 g) oral ingestions of H_2 receptor antagonists.[40] Patients may develop tachycardia, dilated and sluggishly reactive pupils, slurred speech, and confusion.[73,80] Bradycardia, hypotension, and cardiac arrest follow rapid intravenous administration of cimetidine in seriously ill patients.[69] Famotidine and ranitidine produce even fewer dose-related toxicities in overdose. In addition, they are less likely than cimetidine to induce or inhibit the cytochrome P450 enzyme system, thereby producing fewer drug–drug interactions.[38]

■ MANAGEMENT

Patients who will develop severe complications may be initially indistinguishable from those who will have a benign course. The patient's

vital signs and mental status must be monitored. The individual should be attached to a cardiac monitor and observed for signs of sodium channel blockade (increased QRS complex duration), potassium channel blockade (prolonged QT interval), and related dysrhythmias, as well as for seizures. Assessment of the serum acetaminophen concentration is important because many analgesics and cough and cold products contain acetaminophen. Other laboratory studies should be obtained as indicated by history or physical signs and symptoms, such as creatine kinase in patients with seizures or doxylamine overdose. Measurement of antihistamine concentrations in body fluid is not readily available and is generally unnecessary for clinical assessment and management. Serum pregnancy tests should be obtained after ingestions by women of childbearing age.

Gastrointestinal decontamination should be undertaken with care to avoid aspiration. The use of oral activated charcoal, while effective if administered immediately, may be considered even after a short delay.[30] Orogastric lavage is rarely indicated except in patients presenting rapidly after a massive overdose of a first-generation H_1 antihistamine. Serial assessments of the patient's vital signs, particularly temperature, and mental status should be made. The potential for clinical deterioration necessitates management of symptomatic patients in a monitored environment.

■ SPECIFIC THERAPY

H_1 Receptor Antagonists Hypotension generally responds to isotonic fluids (0.9% sodium chloride solution or lactated Ringer solution). If the desired increase in blood pressure is not attained, dopamine or norepinephrine can be titrated to achieve an acceptable blood pressure. In one instance, cardiogenic shock and myocardial depression resulting from a 10-g ingestion of pyrilamine maleate could only be reversed with an intraaortic balloon counterpulsation device.[28] This approach is a rarely needed but potentially useful intervention. Agitation, psychosis, or seizure generally responds readily to titration of a benzodiazepine such as diazepam or lorazepam. Cooling via evaporative methods (tepid mist via spray bottle or similar device; fan) is generally sufficient, but patients with severe hyperthermia should receive more rapid cooling using an ice bath. Hyperthermic patients should be monitored for development of disseminated intravascular coagulation and other complications. Seizures should be treated with an intravenous benzodiazepine such as lorazepam 1–2 mg (0.05–0.1 mg/kg in children) or diazepam 10 mg (0.2–0.5 mg/kg in children) with repeated dosing as necessary. Recurrent seizures refractory to the benzodiazepine should be treated with propofol or general anesthesia. In addition, proper fluid management and urinary alkalinization may be necessary to prevent myoglobin-induced nephrotoxicity.

The sodium channel–blocking (type IA antidysrhythmic) properties of diphenhydramine and other antihistamines may lead to wide-complex dysrhythmias that resemble those that occur after cyclic antidepressant overdose (Chap. 73). Hypertonic sodium bicarbonate may reverse diphenhydramine or other antihistamine-associated conduction abnormalities[68] (see Antidote in Depth A5: Sodium Bicarbonate). Type IA (quinidine, procainamide, disopyramide), IC (flecainide), and III (amiodarone, sotalol) antidysrhythmics are contraindicated because of their capacity to prolong the QT interval.

Physostigmine may effectively reverse the peripheral or central anticholinergic syndrome if clinically indicated. In a retrospective comparison of physostigmine and benzodiazepines, physostigmine was found to be safer and more effective for treating anticholinergic agitation and delirium.[9] Physostigmine can reverse both peripheral and central anticholinergic effects. Contraindications to physostigmine use include wide QRS complexes or bradycardia noted by electrocardiography, asthma, and pulmonary disease.

The primary benefits of physostigmine use in patients with antihistamine overdose include restoration of gastrointestinal motility, elimination of agitation, and possible obviation of the need for CT scan or lumbar puncture if the patient regains a normal mental status and can provide a clear history. The anticipated benefits of physostigmine must outweigh the potential risks prior to its use.

Prior to administering physostigmine, the patient should be attached to a cardiac monitor, and secure intravenous access should be established. Physostigmine (1–2 mg in adults; 0.5 mg in children) should be administered by *slow* intravenous push with continuous monitoring of vital signs, electrocardiogram, breath sounds, and oxygen saturation by pulse oximetry. The initial dose of physostigmine can be repeated at 5- to 10-minute intervals if anticholinergic symptoms are not reversed and cholinergic symptoms such as salivation, diaphoresis, bradycardia, lacrimation, urination, or defecation do not develop. When improvement occurs as a result of physostigmine, readministration of physostigmine at 30- to 60-minute intervals may be necessary. Alternatively, sedation with benzodiazepines may be preferable once the diagnosis is confirmed. A dose of intravenous atropine that is half the dose of physostigmine should be available at the patient's bedside to treat cholinergic toxicity if it occurs (Antidotes in Depth A12: Physostigmine Salicylate).

H_2 Receptor Antagonists Patients who overdose on an H_2 antihistamine in general require no formal gastrointestinal decontamination given their uniformly good outcome. Administration of oral activated charcoal 1 g/kg is acceptable, particularly if co-ingestants are suspected. Monitoring for uncommon complications and assessment for co-ingestants, particularly acetaminophen, should be performed as clinically indicated.

DECONGESTANTS

■ HISTORY AND EPIDEMIOLOGY

Decongestants are sympathomimetics that act on α-adrenergic receptors, producing vasoconstriction, shrinking swollen mucous membranes, and improving bronchiolar air movement. Ephedrine, the first xenobiotic of this class to be used pharmaceutically, is derived from *Ephedra* spp plants. Ephedrine was used in China for at least 2000 years before it was introduced into Western medicine in 1924. Phenylephrine was introduced into clinical medicine in the 1930s (see Fig. 50–4). Several topical imidazoline decongestants have since been developed for clinical use.

Despite many years of widespread decongestant use in the United States and sporadic case reports of adverse effects, the magnitude and public health significance of adverse effects of this class of medications has only recently been appreciated. Premarketing studies of medications lack the power to detect rare adverse effects. Since 1969, 22 spontaneous reports of hemorrhagic stroke associated with phenylpropanolamine use were received by the FDA. Additionally, over
FIGURE 50–4. Structures of ephedrine and phenylpropanolamine.

30 cases were reported in the literature since 1979. Statistical analysis published in 2000 confirmed that PPA is an independent risk factor for hemorrhagic stroke in women.[48] The FDA recommended removal of phenylpropanolamine (PPA) from the market in 2000 due to its association with intracranial hemorrhages. Many manufacturers took steps to remove or reformulate PPA-containing products well before the FDA's rulemaking process could be completed.

Recreational use of ephedrine-containing stimulants is common, and combinations of these xenobiotics with caffeine or other herbs may be marketed as "herbal ecstasy" (Chap. 39). The sale of dietary supplements containing Ephedra (ephedrine alkaloids) was banned by the FDA in 2004 because of concerns over their cardiovascular effects, including hypertension, seizures, stroke, and dysrhythmias.[32] Xenobiotics that contain chemically synthesized ephedrine, traditional Chinese herbal remedies, and herbal teas are not covered by the rule.[26]

In children, intentional and unintentional exposures to cough and cold medicines are common with approximately 10% of US children taking a decongestant, antitussive, expectorant or a combination medication in any week,[81] probably driven by caregivers' desire to improve comfort and sleep for those under their care and for themselves as well. Popular mythology suggests that expectorants or decongestants will depress cough and relieve congestion while antihistamines will promote sleep. In reality, these medications have not been shown to be effective and increase the frequency of adverse events related to exposure. In an effort to retain selected drugs on the nonprescription market, the FDA developed a nonprescription monograph rule allowing some medications in use before 1972 to remain on the market without new clinical trials. As such, many nonprescription decongestants, antihistamines, and expectorants have remained available for children, without adequate safety or efficacy data in those under the age of 6 years. More recently, decongestants and cough and cold medicines have come under scrutiny.[15] Despite their widespread use, reviews of nonprescription medications for cough in adults and children by the Cochrane Collaboration in 2008 found no evidence for the effectiveness of non prescription medications in acute cough.[72] Conclusions are similar regarding the use of antihistamines or decongestants in otitis media.[14] It has also been suggested that the majority of any perceived benefit of cough suppressants may be due to sensory impact of sweetness and the placebo effect.[20]

In one study, three deaths in children under 2 years of age were associated with the use of cough and cold medications resulting in high pseudoephedrine concentrations. Additional nonfatal adverse events also occurred in the children during that study period.[12] In another study postmortem analysis of unexpected infant fatalities yielded ten deaths (ages 17 days to 10 months) associated with the use of cough and cold medicines.[66] In response to new information and concerns, the FDA has taken enforcement action to stop the production of unapproved medications and has required labeling changes on other medications aimed toward young children.

PHARMACOLOGY AND PHARMACOKINETICS

Decongestants are pharmacologically active following topical or oral administration. Absorption from the gastrointestinal tract is rapid, with peak blood concentrations occurring within 2–4 hours of ingestion. Oral decongestants can affect the cardiovascular, urinary, central nervous, and endocrine systems. The decongestants phenylephrine, pseudoephedrine, ephedrine, and phenylpropanolamine reduce nasal congestion by stimulating the α-adrenergic receptor sites on vascular smooth muscle.[42] This process constricts dilated arterioles and reduces blood flow to engorged nasal vascular beds. The α_1-adrenergic-mediated decrease in volume ultimately lowers

resistance to airflow. Prolonged topical administration may produce rebound congestion upon discontinuation; possible mechanisms include desensitization of receptors and mucosal damage. This damage is thought to be caused by α_2-adrenergic-mediated arteriolar constriction resulting in decreased nutritional supply to the mucosa. Therefore, selective α_1-adrenergic agonists may cause less mucosal damage.

Phenylephrine is a powerful $\alpha_{1,2}$-adrenergic receptor agonist with very little β-adrenergic agonist activity. Pseudoephedrine and ephedrine are mixed-acting (Idirect and indirect) nonspecific $\alpha_{1,2}$- and $\beta_{1,2}$-adrenergic receptor agonists. Pseudoephedrine is the D-isomer of ephedrine and has only 25% of the adrenergic receptor activity of ephedrine.[19] Phenylpropanolamine is an $\alpha_{1,2}$-adrenergic receptor stimulant devoid of β-adrenergic receptor activity. Phenylpropanolamine can directly stimulate $\alpha_{1,2}$ receptors and can indirectly stimulate these receptors by causing norepinephrine release (Table 50–5).

The imidazoline (I) category of sympathomimetics is generally reserved for topical application and the imidazolines are used for their local effects in the nasal passages and the eye. The more common medications include oxymetazoline hydrochloride, tetrahydrozoline hydrochloride, and naphazoline hydrochloride (Fig. 50–5). The imidazolines are rapidly absorbed from the gastrointestinal tract and mucous membranes. The elimination half-lives range from 2 to 4 hours. Their vasoconstrictor effects are mediated by their actions as α-adrenergic agonists, with binding to α_2 receptors on blood vessels. The α_1-mediated vasoconstriction is complemented by an additive effect of preferential binding to α_2 receptors located on resistance vessels regulating blood flow. In addition, these medications show high affinity for imidazoline receptors, which are located in the ventrolateral medulla and some peripheral tissues. Stimulation of imidazoline receptors produces a sympatholytic effect that results in bradycardia and hypotension. All imidazoline preparations have a relatively rapid onset of action, with 60% of maximum effectiveness after only 20 minutes. Oxymetazoline is the only medication with a duration of action more than 8 hours. The other preparations have an average duration of action of approximately 4 hours.

The imidazoline decongestants such as oxymetazoline and naphazoline are pure central and peripheral α_2-adrenergic receptor agonists; tetrahydrozoline stimulates α_2 receptors and H_2 receptors. These medications are primarily used as nasal decongestants. Tetrahydrozoline is available without a prescription as an ophthalmic preparation to decrease conjunctival injection.

TABLE 50–5. Pharmacologic Characteristics of Decongestants

Decongestant	Class	Duration of Action	Receptor Activity
Naphazoline	Imidazoline (I)	8 h	α_2, and I
Oxymetazoline	Imidazoline	6–7 h	α_2, and I
Tetrahydrozoline	Imidazoline	4–8 h	α_2, and I
Xylometazoline	Imidazoline	5–6 h	α_2, and I
Ephedrine	Sympathomimetic	3–5 h	$\alpha_{1,2}$ and $\beta_{1,2}$
Phenylephrine	Sympathomimetic	1 h	$\alpha_{1,2}$
Phenylpropanolamine	Sympathomimetic	12 h (sustained release)	$\alpha_{1,2}$
Pseudoephedrine	Sympathomimetic	3–4 h	$\alpha_{1,2}$ and $\beta_{1,2}$
FIGURE 50–5. Structures of imidazoline and the imidazoline decongestants, tetrahydrozoline, and oxymetazoline.

DRUG OVERDOSE

■ CLINICAL MANIFESTATIONS

Following a decongestant overdose, most patients present with CNS stimulation, hypertension, tachycardia, or reflex bradycardia (in response to pure α_1-adrenergic agonist-induced hypertension only). Approximately 4–5 times the recommended dose of pseudoephedrine,[19] but less phenylpropanolamine, may be required to cause hypertension.[21] An increase in sinus dysrhythmias is reported in adults with ingestion of 120 mg pseudoephedrine and moderate exercise.[7] Headache was the most common initial symptom (39%) reported by patients who later developed severe toxicity.[51] In 45 patients who developed hypertensive encephalopathy from phenylpropanolamine ingestion, 24 patients developed intracranial hemorrhages, 15 developed seizures, and 6 died.[51] Seizures, myocardial infarction, bradycardia, atrial and ventricular dysrhythmias, ischemic bowel infarction, and cerebral hemorrhages are reported, even with therapeutic dosing.[10,23,57] In a review of 500 reports of adverse reactions from patients who had ingested ephedrine and associated stimulants as dietary supplements, 8 fatalities from myocardial infarction and cerebral hemorrhage were reported.[11] Symptoms of toxicity from decongestants usually resolve within 8–16 hours. However, symptoms may persist for more than 24 hours if a sustained-release product is ingested. Little organized information is available regarding the use of decongestants by those with hypertension; these agents are best avoided in patients with hypertension.

When ingested, the imidazoline decongestants naphazoline, oxymetazoline, tetrahydrozoline, and xylometazoline are potent central and peripheral α_2-adrenergic and imidazoline receptor agonists. In overdose, they can cause CNS depression, and initial brief hypertension followed by hypotension, bradycardia, and respiratory depression.[34] Children are particularly sensitive to the effects of the imidazoline decongestants.

■ MANAGEMENT

Extreme agitation, seizures, tachycardia, hypertension, and psychosis should initially be treated with administration of oxygen and intravenous benzodiazepines, expeditiously titrated upward to effect. A patient who remains hypertensive or is believed to have chest pain of ischemic origin (ECG indicated) should be treated with phentolamine, an α-adrenergic antagonist, or nicardipine, but β-adrenergic antagonists should be avoided due to concern for unopposed α-adrenergic effects.

A patient with a focal neurologic deficit or an abnormal neuropsychiatric examination following decongestant ingestion should be evaluated for cerebral hemorrhage by noncontrast head CT scan and, if indicated, subsequent lumbar puncture to exclude subarachnoid hemorrhage.[51]

Patients who have overdosed on a decongestant generally should receive 1 g of activated charcoal per kilogram body weight as a single dose. Activated charcoal administration may be beneficial several hours after ingestion of sustained-release decongestant preparations, and serial doses of activated charcoal may be considered in this context.

Ventricular dysrhythmias from decongestants should be treated with standard doses of lidocaine or amiodarone. Refractory dysrhythmias may require antiadrenergic therapy with propranolol, but only after pretreatment with phentolamine or another vasodilator, if possible, or with strict expectant management of the patient's blood pressure. Patients who develop hypertension following propranolol should immediately receive phentolamine. Phenylpropanolamine may cause hypertension with a reflex bradycardia and atrioventricular block that is responsive to standard doses of atropine. Atropine must be used with caution because it can cause a dangerous increase in blood pressure as the reflex bradycardia reverses. Therefore, a direct-acting vasodilator such as phentolamine is preferred because the stimulus for the bradycardia is corrected with reversal of the hypertension. Imidazoline-induced hypertension rarely requires therapy, but in the setting of symptomatic hypertension a short-acting α-adrenergic antagonist such as phentolamine may be administered.[84] However, the hypertension is generally transient and followed by hypotension that raises the risk of antihypertensive therapy.

SUMMARY

The popularity and availability of antihistamines and decongestants make them readily accessible for deliberate or unintentional ingestions in both adults and children. Recreational use of these agents may lead to exposure to substantial doses of these medications. Fortunately, nearly all patients exposed to excessive doses of members of these classes of xenobiotics that are currently available in the United States do well if they receive treatment early in the course of ingestion. While serious complications and deaths do result from exposure to these medications, nearly all exposed patients treated with activated charcoal, continuous assessment, supportive care, management of abnormal vital signs, electrocardiography, cardiac monitoring, and continuous observation of mental status generally have an excellent outcome with little risk of adverse sequelae. Familiarity with the more severe complications of antihistamine and decongestant overdoses results in early and appropriate interventions to reduce both morbidity and mortality from these exposures.

ANTIDOTES IN DEPTH (A12)

PHYSOSTIGMINE SALICYLATE

Mary Ann Howland

Physostigmine is a carbamate that reversibly inhibits cholinesterases in both the peripheral nervous system and the central nervous system (CNS).[45] The tertiary amine structure of physostigmine permits CNS penetration and differentiates it from neostigmine and pyridostigmine, from the quaternary amines that have limited ability to enter the CNS. The inhibition of cholinesterases prevents the metabolism of acetylcholine, allowing acetylcholine to accumulate and antagonize the anticholinergic effects of xenobiotics such as atropine, scopolamine,[53] and diphenhydramine. Although physostigmine previously was used as an antagonist to the anticholinergic effects of the cyclic antidepressants and the phenothiazines, this use is no longer recommended because of a poor risk-to-benefit ratio given the potential for exacerbation of life-threatening cardiotoxicity. A review of 30 years of the literature reassessed and questioned the contraindication to physostigmine use for cyclic antidepressant ingestions. The review concluded that the safety of physostigmine use for seizures or cardiotoxicity was difficult to predict, but the author still did not recommend physostigmine use in the setting of cyclic antidepressant toxicity.[44] Similarly, physostigmine has a poor risk-to-benefit ratio in the management of presumed γ-hydroxybutyrate (GHB) toxicity.[47,54] A study in rats given GHB revealed that physostigmine did not effect arousal but increased the risk of physostigmine-induced toxicities of fasciculations and seizures.[4]

Atypical antipsychotics have complex pharmacologic effects. Although some atypical antipsychotics such as olanzapine have significant antimuscarinic side effects, the benefit of treating these anticholinergic effects with physostigmine in the often confusing overdose setting must be weighed against the potential risks of exacerbating cardiotoxicity.[46,52]

HISTORY

The history of physostigmine dates to antiquity and the Efik people of Old Calabar in Nigeria.[17,20,23,45] The chiefs in this area used a poisonous concoction made from the beans of an aquatic leguminous perennial plant found in the area to deliver the *esere ordeal*. Esere was the word used to represent both the bean and the ritual used to test the innocence or guilt of an accused person. They also believed that the esere had the power to detect and kill those persons practicing witchcraft. Supposedly, innocent persons quickly swallowed the poison, which caused immediate emesis.[23] Vomiting allowed them to survive without therapy or to be given an antidote of excrement in water. The guilty, however, hesitated swallowing, leading to speculation that sublingual absorption led to severe systemic symptoms

without the benefit of vomiting. These persons were noted to develop mouth fasciculations and died foaming at the mouth. Daniell, a British medical officer stationed in Calabar, brought samples of the bean and the plant back to England in 1840.[23] John Balfour, a professor of medicine and botany at the Edinburgh Medical School, is credited with characterizing the plant, which became known as *Physostigma venenosum Balfour* (family Leguminoseae) in 1857. The active alkaloid was isolated by Jobst and Hesse in 1864 and was named physostigmine. Independently, one year later Vee and Leven also isolated the active alkaloid and named it eserine.

Christison performed the first toxicologic studies, including self-experimentation with increasing doses of the seed. Fraser, Christison's student and successor, originated the concept of antagonism from his experiments with physostigmine and atropine. Fraser plotted the dose relationships between the effects of atropine versus physostigmine on various organs such as the eye and the heart, demonstrating the antidotal effects of atropine for the lethal effects of physostigmine.[17] Subsequent experiments with physostigmine led to the development of the theory of neurohumoral transmission.[20] By the 1930s physostigmine was already used as a miotic for patients with glaucoma, a treatment for myasthenia gravis, for reversal of the paralytic effects of curare, an antidote to atropine, and an insecticide.

CHEMISTRY AND AFFINITY FOR CHOLINESTERASE

Figure 113–4 shows the general formula for carbamate inhibitors. Figure A12-1A through C shows the chemical structures of physostigmine ($C_{15}H_{21}O_2N_3$), a tertiary amine, and neostigmine, a quaternary amine. Like acetylcholine, physostigmine is a substrate for the cholinesterases (choline ester hydrolases), erythrocyte acetylcholinesterase and plasma cholinesterase. Both acetylcholine and physostigmine bind to cholinesterases to form a complex. Then a part of the substrate known as the *leaving group* (ie, choline for acetylcholine) is removed, and the remaining acetylated (for acetylcholine) or carbamoylated (for physostigmine) enzyme is hydrolyzed, regenerating the enzyme and freeing the acetate or carbamate groups, respectively (Figs. 113-2 and 113-3). For acetylcholine, the process is extremely quick, with a turnover time of 150 msec. In contrast, the half-life for hydrolysis of the carbamoylated enzyme is 15 to 30 minutes.[45] The I_{50} (molar concentration that inhibits 50% of the enzyme) of physostigmine is 2.3×10^{-7} M for acetylcholinesterase, which is much weaker than for other carbamates at 1×10^{-10} M or many organic phosphorus compounds at 1×10^{-11} M.[21] Only the S-isomer inhibits cholinesterases, with plasma cholinesterase just a little more sensitive than acetylcholinesterase.[3] Newer pharmaceuticals used in patients with Alzheimer disease[11] show selectivity for the CNS and for acetylcholinesterase. They include tacrine, donepezil, and galantamine, which are reversible cholinesterase inhibitors, and rivastigmine, a pseudo-irreversible or slowly reversible inhibitor. These pharmaceuticals and neostigmine[22] have undergone limited study for reversal of anticholinergic poisoning.[11,22,26,39]

C. Neostigmine

Leaving group
FIGURE A12-1 (**A**) General formula for carbamate inhibitors. (**B**) Structure of physostigmine. (**C**) Structure of neostigmine.

PHARMACOKINETICS

Physostigmine is poorly absorbed orally, with a bioavailability of less than 5% to 12%.[1,31] Cholinesterases cleave the ester linkage, and very little physostigmine is eliminated unchanged in the urine. Pharmacokinetic parameters following IV administration of 1.5 mg over 60 minutes in nine patients with Alzheimer disease demonstrated the following: Vd 2.4 ± 0.6 L/kg; $t_{1/2}$ 16.4 ± 3.2 minutes; peak serum concentration 3 ± 0.5 ng/mL; clearance 0.1 L/min/kg (7.7 L/min). There was a three-fold interindividual variability in plasma physostigmine concentrations. Plasma cholinesterase concentrations demonstrated inhibition within 2 minutes of initiating the physostigmine infusion. The half-life of plasma cholinesterase inhibition was 83.7 ± 5.2 minutes, with full recovery within 3 hours of termination of physostigmine infusion. The effects on plasma cholinesterase inhibition lasted approximately five times longer than the half-life of physostigmine.[25] All patients experienced varying degrees of diaphoresis, nausea, vomiting, headache, and generalized fatigue despite pretreatment with 2.5 mg methscopolamine.[2,25]

CLINICAL USE

Physostigmine was first used as an antidote in 1864 to counteract severe atropine poisoning.[33] Today its role is primarily in the treatment of antimuscarinic poisoning. More than 600 xenobiotics respond to physostigmine.[12] Anticholinergics fall into the categories of antimuscarinic (atropine, scopolamine, propantheline, benztropine, trihexyphenidyl), neuromuscular blockers (exemplified by curare), and ganglionic blockers (eg, trimethaphan). Other xenobiotics (eg, antihistamines, antipsychotics, and antidepressants) have anticholinergic properties that are not their primary therapeutic actions and are often considered adverse drug effects.

The clinical use of physostigmine has varied over time.[41] Owing to its ability to cause CNS arousal physostigmine was used in the 1970s to reverse the CNS effects of a large number of anticholinergics. It also was used inappropriately to treat toxicity from nonanticholinergics.[18,30,32,34,37] The success with regard to anticholinergics is directly antidotal by virtue of its inhibition of cholinesterase. Effects of physostigmine on xenobiotics such as the benzodiazepines, opioids,[27,38,50] and GHB[4,47] result from either acetylcholine's direct action on the reticular activating system or interdependence of central neurotransmitters.[34] Few serious adverse effects are reported.[49] However, asystole followed administration of physostigmine in two patients with tricyclic antidepressant overdose.[35] This occurrence led to the realization that toxicity from tricyclic antidepressants is complex and consists of more than just anticholinergic effects.[35] Cyclic-antidepressant-induced sodium channel blockade causes myocardial depression, QRS interval prolongation, and ventricular dysrhythmias. Physostigmine probably augments vagal effects, thus contributing to decreased cardiac output and cardiac conduction defects. A reevaluation must conclude that the risks of physostigmine use for xenobiotics that are not primarily antimuscarinic often outweigh any benefit.

This analysis appears to hold true for reversing the effects of GHB (Chap. 80) as well.[47] GHB is rarely used alone, and its effects are highly variable.[54] Recovery from GHB typically occurs spontaneously in approximately 2 hours (16 min-6 h).[7,8,14,28,47,48] Three patients in whom a presumptive diagnosis of GHB toxicity was made were treated with physostigmine.[7] The three patients had an improved mental status within 5 to 15 minutes. One of these patients relapsed and then fully awakened 40 minutes later. This patient was incontinent of feces, an adverse effect likely caused by the physostigmine.[7] A closer look at the patient descriptions reveals that all three improved with stimulation prior to physostigmine. Furthermore, justification for use based upon a study performed in the 1970s in the operating room at a time when GHB was first being evaluated as an anesthetic appears illogical when caring for those who illicitly use GHB.[19]

However, in cases of anticholinergic overdose, physostigmine use clearly is beneficial. A study of 52 patients showed that physostigmine controlled agitation and reversed delirium in 96% and 87% of patients, respectively,[6] whereas benzodiazepines controlled agitation in 24% of patients but were ineffective in reversing delirium. A shorter time to recovery following agitation was observed in those treated with physostigmine. No significant differences between these groups with regard to side effects and length of stay were noted.[6]

INDICATIONS

Indications for physostigmine use include the presence of peripheral or central anticholinergic manifestations without evidence of significant QRS or QT prolongation. Peripheral manifestations include dry mucosa, dry skin, flushed face, mydriasis, hyperthermia, decreased bowel sounds, urinary retention, and tachycardia. Central manifestations include agitation, delirium, hallucinations, seizures, and coma.[16,29] The peripheral and central findings usually occur simultaneously. In the early phases of overdose, finding only central manifestations is uncommon, although they often are more remarkable.[1,5,9,13,15,21,40,43] The central findings may persist longer than the peripheral findings, particularly when a patient is recovering from an overdose of an antimuscarinic xenobiotic.

ADVERSE EFFECTS

An excess of physostigmine results in accumulation of acetylcholine at peripheral muscarinic receptors, nicotinic receptors (skeletal muscle, autonomic ganglia, adrenal glands), and CNS sites.[24] Muscarinic effects

produce stimulation of smooth muscle and glandular secretions in the respiratory, gastrointestinal, and genitourinary tracts and inhibition of contraction of most vascular smooth musculature. Nicotinic effects are stimulatory at low doses and depressant at high doses. For example, acetylcholine excess at the neuromuscular junction produces fascicula-tions followed by weakness and paralysis. Its effect on the CNS results in anxiety, dizziness, tremors, confusion, ataxia, coma, and seizures.[24] Electroencephalograms (EEGs) demonstrate desynchronous discharges followed by higher-voltage discharges and a pattern similar to tonic clonic seizures.[24] The cardiovascular effects are dose dependent and directly related to the presence of the diverse muscarinic and nicotinic effects.[24] In addition to its inhibition of cholinesterase, physostigmine has a direct action on the nicotinic acetylcholine receptor ionic channel.[42]

Physostigmine toxicity results when physostigmine is used in the absence of antimuscarinic toxicity or when excess is administered with regard to the antimuscarinic xenobiotic. Patients overdosed with physostigmine should be managed with intensive supportive care, including mechanical ventilation if needed, intravenous atropine[51] titrated to reverse bronchial secretions, and, rarely, pralidoxime to reverse skeletal muscle effects.[10]

Relative contraindications to physostigmine use include reversible air-way disease, peripheral vascular disease, intestinal or bladder obstruction, intraventricular conduction defects, and atrioventricular block. Little infor-mation is available regarding the effects of physostigmine in pregnancy. Transient muscular weakness occurred in 10% to 20% of neonates whose mothers received anticholinesterase treatment for myasthenia gravis.[31]

Drug interactions with cholinergic agonists (eg, ophthalmic pilocarpine), depolarizing neuromuscular blockers, or other anticho-linesterases such as carbamates, organic phosphorous compounds, and pyridostigmine are expected to be at least additive when taken con-comitantly with physostigmine. The actions of xenobiotics metabolized by plasma cholinesterases such as cocaine, succinylcholine, or mivacu-rium are expected to be prolonged.

DOSING

The dose of physostigmine is 1 to 2 mg in adults and 0.02 mg/kg (maxi-mum 0.5 mg) in children intravenously infused over at least 5 minutes. The onset of action usually is within minutes.[21] The dose can be repeated after 10 to 15 minutes if an adequate response is not achieved and musca-rinic effects are not noted. Rapid administration may cause bradycardia, hypersalivation leading to respiratory difficulty, and seizures. Although the half-life of physostigmine is approximately 16 minutes, its duration of action usually is much longer (often >1 hour) and is directly related to the duration of cholinesterase inhibition.[2] After reversal of anticholin-ergic symptoms is achieved, additional doses may be required if clinical relapse occurs. The effective dose depends upon the ingested dose and duration of action of the antimuscarinic xenobiotic. Although a total of 4 mg in divided doses usually is sufficient in most clinical situations,[16] significant interindividual variability exists. Atropine should be available at the bedside and titrated to effect should excessive cholinergic toxicity develop. A dose of atropine administered at half the physostigmine dose is often recommended.

Physostigmine is available as an ophthalmic ointment that can be applied topically to the conjunctival sac to produce miosis as treatment of acute angle-closure glaucoma. Miosis occurs within 10 to 30 minutes and persists for 12 to 48 hours.[31]

AVAILABILITY

Physostigmine is available in 2-mL ampules, with 1 mL containing 1 mg physostigmine salicylate. The vehicle contains sodium meta-bisulfite and benzyl alcohol.[36]

SUMMARY

Physostigmine has been used extensively in the fields of anesthesiology, emergency medicine, and medical toxicology. The only evidence-based use of physostigmine is for the management of patients with an anti-cholinergic syndrome, particularly those without cardiovascular com-promise who have an agitated delirium and a normal QRS duration. In this population, physostigmine has an excellent risk-to-benefit profile.

CHAPTER 51

ANTIMIGRAINE MEDICATIONS

Jason Chu

A migraine headache is a neurovascular disorder often initiated by a trigger and characterized by a headache, which 20% of the time is preceded by a visual aura. The headache may be accompanied by a variety of multiple organ system symptoms, such as allodynia, nausea, vomiting and urinary frequency. There are various types of migraine, the diagnostic criteria for which have been established by the International Headache Society.[77] The types of migraine are divided into two groups: migraine without aura ("common migraine") and migraine with aura ("classic migraine"). Further subdivisions include migraine with typical aura with or without headache, familial hemiplegic migraine, sporadic hemiplegic migraine, basilar type migraine, and retinal migraine.[77] Treatment of migraines encompasses a wide variety of xenobiotics and can be broadly classified as prophylactic or abortive therapies (Table 51–1).

PATHOPHYSIOLOGY OF MIGRAINE HEADACHES

The initiation of migraines is not fully understood, but likely involves genetic abnormalities in central nervous system (CNS) ion channels that predispose sufferers to specific triggers. Patients with familial hemiplegic migraine, an autosomal dominant disorder, have missense mutations in the α1 subunit of brain specific P/Q voltage gated calcium channels resulting in altered function of these channels. During migraines, the upper brainstem has increased blood flow and is implicated as a "migraine generator." After activation, a wave of cortical depression spreads across the cortex from a caudal to rostral fashion followed by a spreading wave of oligemia, which can produce the auras that occur in 20% of migraineurs.[23,34,83] Current theories suggest that this spreading wave occurs in patients who do not experience visual auras and spares the visual cortex.

Cephalagia begins during vasoconstriction prior to vasodilation unlike previous vascular theory suggested prior to cerebral blood flow studies. Antidromic activation of the afferent neurons of the ophthalmic division of the trigeminal nerve and branches of the C1 and C2 nerves (first order neurons) located on dural arteries at the base of the brain releases inflammatory neuropeptides such as calcitonin gene related polypeptide, VIP and neurokinase A. Vasoactive neuropeptides, including serotonin, vasoactive intestinal peptide, nitric oxide, substance P, neurokinin A, and calcitonin gene-related peptide (CGRP), are released during this process, which exacerbates the vasodilation and irritates the meninges at the base of the brain, causing further pain. CGRP from trigeminal Aδ-fibers produces dural vasodilation, while substance P and neurokinin A from trigeminal C-fibers increase dural vessel permeability.[23,33] Pain impulses are relayed orthodromically to the trigeminal nucleus caudalis (second order neurons) in the lower medulla and upper cervical spinal cord, then to the thalamus (third order neurons) via the quintothalamic tract, and finally to higher cortical areas (fourth order neurons probably located in the limbi cortex).[23,31] The trigeminocervical complex also produces retrograde parasympathetic impulses from sphenopalatine ganglion and the superior salivatory nucleus in the pons through the pterygopalatine, otic, and carotid ganglia to the cerebral vessels.[31] abort migraines when administered intravenously, but it is too dangerous to utilize clinically. Migraineurs have increased serotonin release during migraine attacks.[23,83] Abortive and prophylactic therapy ideally target these processes (see Table 51–1). Current abortive therapies include analgesics (nonsteroidal anti-inflammatory drugs [NSAIDs], acetaminophen, opioids), antiemetics, ergots alkaloids, triptans, oxygen, magnesium sulfate and intranasal lidocaine. Triptans are considered the drugs of choice for migraine therapy. Newer therapies such as CGRP antagonists are currently in phase 2 and 3 trials.

Toxicity of many of these xenobiotics is discussed in depth elsewhere in the text (see Table 51–1).

ERGOT ALKALOIDS

◼ HISTORY AND EPIDEMIOLOGY

Ergot is the product of *Claviceps purpurea*, a fungus that contaminates rye and other grains. The spores of the fungus are both wind borne and transported by insects to young rye, where they germinate into hyphal filaments. When a spore germinates, it destroys the grain and hardens into a curved body called the sclerotium, which remains the major commercial source of ergot alkaloids.[68] The *C. purpurea* fungus can elaborate diverse substances, including ergotamine, histamine, lysergic acid, tyramine, isomylamine, acetylcholine, and acetaldehyde.

In 600 BC, an Assyrian tablet mentioned grain contamination believed to be by *C. purpurea*. In the Middle Ages, epidemics causing gangrene of the extremities, with mummification of limbs, were depicted in the literature as blackened limbs resembling the charring from fire and caused a burning sensation expressed by its victims. The disease was called holy fire or St. Anthony's fire, but the improvement that reportedly occurred when victims went to visit the shrine of St. Anthony were probably the result of a diet free of contaminated grain on the journey.[35] Abortion and seizures were also reported to result from this poisoning. On the other hand, as early as 1582, midwives used ergot to assist in the childbirth process. In 1818, Desgranges was the first physician to use ergot for obstetric care, and in 1822 Hosack reported that ergot could be used for the control of postpartum hemorrhage.[81] Since 1950, the clinical use of ergot derivatives is almost entirely limited to the treatment of vascular headaches. Ergonovine, another ergot derivative, is used in obstetric care for its stimulant effect on uterine smooth muscle and was used in cardiac stress tests. Methylergonovine is used for postpartum uterine atony and hemorrhage. Ergot derivatives have also been used as "cognition enhancers,"[84] to help manage orthostatic hypotension,[74] and to prevent the secretion of prolactin.[68]

Currently in the United States, ergot grain infections are prevented by government inspections of grain fields. If a grain field contains more than 0.3% infected grain, it is rejected for commercial sale; in some years as much as 36% of the grain was rejected.[68] However, elsewhere in the world ergot toxicity remains a problem predominantly in animals.[7,45]

◼ PHARMACOLOGY AND PHARMACOKINETICS

All ergot alkaloids are derivatives of the tetracyclic compound 6-methylergoline. They can be divided into three groups: amino acid alkaloids (ergotamine, ergotoxine), dihydrogenated amino acid alkaloids, and amine alkaloids (Fig. 51–1).

The pharmacokinetics of the ergot alkaloids are well defined by controlled human volunteer studies, whereas the toxicokinetics are essentially unknown (Table 51–2). Almost all of the ergots are poorly absorbed orally and there is considerable first-pass hepatic

TABLE 51–1. Xenobiotics Used in Migraine Treatment*

Prophylactic	Abortive
β adrenergic antagonists	Acetaminophen
Butterbur root	Antiemetics: metoclopramide, ondansetron, prochlorperazine
Calcium channel blockers	
Candesartan	Aspirin
Coenzyme Q10	Butalbital
Cyclic antidepressants	Caffeine
Enalapril	Corticosteroids
Feverfew	Ergots
Flunarizine	Lidocaine (intranasal)
Gabapentin	Magnesium (IV)
Isometheptene/dichloraphenazone/ acetaminophen (midrin)	Metoclopramide
	NSAIDs
Lamotrigine	Opioids
Levetiracetam	Oxygen
Lisinopril	Sedative-hypnotics
Magnesium (oral)	Triptans
MAO inhibitors	Valproic acid
Memantine	
Nefazadone	
Onabotulinumtoxin/A (Botox A)	
Pizotifen	
Riboflavin	
Selective serotonin reuptake inhibitors	
Topiramate	
Valproic acid	

MAO, monoamine oxidase; NSAIDs, nonsteroidal anti-inflammatory drugs.

* Prophylatic xenobiotics are usually taken to prevent triggering of migraines, and abortive xenobiotics are usually taken to stop the clinical manifestations of migraines once they are triggered. However, the separation between the two groups of xenobiotics is not strict, and some xenobiotics may be used in both roles. Triptans are currently considered the drug class of choice for migraine treatment.

metabolism, resulting in highly variable bioavailability. Intramuscular absorption is unpredictable and actions are often delayed.[60] Peak plasma concentrations with oral ergotamine occur within 45 to 60 minutes.[60] The volume of distribution of ergotamine is approximately 2 L/kg and the half-life varies from 1.4 to 6.2 hours. Ergot alkaloids are metabolized in the liver, probably by CYP3A4, and the metabolites are excreted in the bile.[6,68]

The pharmacologic effects of the ergot alkaloids are complex and can be mutually antagonistic.[68] These actions can be subdivided into central and peripheral effects (Table 51–3). In the CNS, ergotamine stimulates serotonergic (tryptaminergic) receptors, potentiates serotonergic effects, blocks neuronal serotonin reuptake, and has central sympatholytic actions.[35,68] The ergot alkaloids interact with all known 5-HT$_1$ and 5-HT$_2$ receptor subtypes.[68] The result is increased intrasynaptic serotonin activity in the median raphe neurons of the brainstem.[65] Ergotamine and dihydroergotamine are thought to decrease the neuronal firing rate and stabilize the cerebrovascular smooth musculature, which make them useful drugs for both acute and prophylactic treatment of migraine headaches.

Amine alkaloids
Methylergonovine

Amino acid alkaloids
Ergotamine

FIGURE 51–1. Chemical structures of 2 ergot derivatives representative of the amine and amino acid alkaloids.

Peripherally, ergotamine acts as a partial α-adrenergic agonist or as an antagonist at adrenergic, dopaminergic, and serotonergic (tryptaminergic) receptors.[68] The amino acid ergot alkaloids (ergotamine, ergotoxine) exhibit α-adrenergic agonism, and dehydrogenation (dihydroergotamine) of the lysergic acid nucleus increases the potency of this effect.[68] However, the peripheral vasoconstrictive effects predominate over the α-adrenergic antagonist effects, and there may be an additional vasoconstrictive effect caused by the direct action of ergotamine on the media of the arterioles.[68] Table 51–3 summarizes the pharmacologic actions of selected ergot alkaloids currently used in clinical medicine. The spectrum of effects depends on dosage, host response, and physiologic conditions.

The clinical effects following overdose are an extension of the therapeutic effects. At toxic doses, extreme vasoconstriction produces the characteristic ischemic changes that occur in ergotism.

The cerebrovascular effects of ergot alkaloids are not as clearly understood. In migraine treatment, for example, therapeutic doses of ergotamine produce mild vasoconstriction via α-adrenergic agonism. This may be more pronounced in intracranial vessels that are already dilated during a migraine. In toxic doses cephalic vasodilation may occur, but the mechanism for this effect is unknown. One hypothesis is that toxic doses of the drug initially produce cerebral vasoconstriction and ischemia, just as it does in the periphery, but since the cerebral vasculature cannot tolerate hypoxia and hypercapnia, rapid vasodilation then ensues to improve local perfusion. Also α-adrenergic receptors in the CNS function differently from those in the periphery, and it may be that CNS vascular tone cannot be maintained in the setting of local tissue hypoxia.

■ CLINICAL MANIFESTATIONS

Ergotism, a toxicologic syndrome resulting from excessive use of ergot alkaloids, is characterized by intense burning of the extremities, hemorrhagic vesiculations, pruritus, formications, nausea, vomiting,

TABLE 51–2. Pharmacokinetics of Ergots

Ergot Derivative	Clinical Use	t ½ (hours)	Duration of Action (hours)	Bioavailability (%)	Metabolism/ Elimination

and gangrene (Table 51–4). Headache, fixed miosis, hallucinations, delirium, cerebrovascular ischemia, and convulsions are also associated with this condition, which has been called "convulsive" ergotism.[35] Chronic ergotism usually presents with peripheral ischemia of the lower extremities, although ischemia of cerebral, mesenteric, coronary, and renal vascular beds are well documented.[3,24,25,66,67] Ergotism can also result from interactions of ergot derivatives with P450 CYP3A4 inhibitors such as macrolide antibiotics and protease inhibitors, which increase the area under the curve (AUC) of ergots.[5,6]

The vascular effects ascribed to ergot alkaloids are complex and sometimes conflicting (see Table 51–3). Subintimal and medial fibrosis, vasospasm, and arteriolar and venous thrombi (stasis related) are all reported.[52] Angiography can demonstrate distal, segmental vessel spasm with increased collateralization in patients with chronic

TABLE 51–3. Pharmacology of Ergot Derivatives

Ergot Derivative	Interactions With Tryptaminergic (Serotonergic) Receptors	Interactions with Dopaminergic Receptors	Interactions With α-Adrenergic Receptors
Bromocriptine (amino acid alkaloid)	Weak antagonist	CNS: Partial agonist/antagonist; inhibits prolactin secretion; emetic (high)	Vasculature: Antagonist
Dihydroergotamine (dihydrogenated group)	Smooth muscles: Partial agonist/ antagonist CNS: Agonist lateral geniculate nucleus	CNS: Emetic (mild) Sympathetic ganglia: Antagonism	Vasculature: Partial agonist (veins); antagonist (arteries) Smooth muscles: Antagonism CNS/PNS: Antagonism
Ergonovine and methyl ergonovine (amine alkaloid)	Smooth muscles: Potent antagonist Vasculature: Agonist in umbilical and placental vessels CNS: Partial antagonist/agonist	CNS: Emetic (mild); inhibits prolactin (weak); partial agonist/antagonist Vasculature: Weak antagonist	Vasculature: Partial agonist

Twitching (facial)	
Vomiting	

ergotism. The coronary, renal, cerebral, ophthalmic, and mesenteric vasculature,[67] as well as the vessels of the extremities, may also be affected.[71] Neuropathic changes may be secondary to ischemia of the vasa nervorum.

Bradycardia is a characteristic effect of the ergot alkaloids, and is believed to be a reflex baroreceptor-mediated phenomenon associated with vasoconstriction, but a reduction in sympathetic tone, direct myocardial depression, and increased vagal activity may also be factors.[68]

Myocardial valvular abnormalities are reported with ergot alkaloids. Ergotamine and methysergide both cause mitral and aortic valve leaflet thickening and immobility resulting in valvular regurgitation.[26,66] This finding is particularly striking considering that a similar phenomenon from a class of weight loss agents recently resulted in their withdrawal.

■ TREATMENT

The treatment for a patient with ergot alkaloid toxicity depends on the nature of the clinical findings. Gastric emptying should rarely be used, if at all, because vomiting is a common early occurrence, and the ingestion may be complicated by seizures. If the patient is not vomiting shortly after an acute oral overdose, activated charcoal should be administered. If emesis is present, metoclopramide a promotility dopamine antagonist or a 5-HT$_3$ antagonist can be used as an antiemetic to facilitate the administration of activated charcoal. In mild cases, characterized by minimal pain of the extremities, nausea, or headache, supportive measures such as hydration and analgesia are all that are needed. With more serious cases, severe peripheral vasoconstriction may produce ischemic changes that include angina, myocardial infarction, cerebral ischemia, intermittent claudication, and internal organ/mesenteric ischemia. Intravenous vasodilators, such as sodium nitroprusside,[3,10,58] nitroglycerin,[40] and phentolamine, are indicated to reverse the ischemia. Methylprednisolone was reported to reverse ergotamine-induced lower extremity arterial vasospasm.[63] Prazosin,[12] captopril,[86] and nifedipine[14] have also been used to achieve peripheral vasodilation in cases with mild signs and symptoms of vasospasm, such as dysesthesias and minimal ischemic pain of the digits.

Although sympathetic block, epidural block, or sympathectomy—all of which have been used in the past—may relieve vasoconstriction mediated via the CNS, these modalities are not expected to antagonize the direct action of the ergot alkaloids on arteriolar smooth muscle.[3] Heparin, corticosteroids, or low-molecular-weight dextran[70] may be used to prevent sludging and subsequent clot formation. The use of thrombolytic agents in this setting has not been evaluated, but has theoretical utility. Arteriotomy may be necessary to remove large clots. Hyperbaric oxygen may correct local tissue hypoxia, but is not generally indicated.[22] Benzodiazepines should be used to treat seizures or hallucinations.

TRIPTANS

In 1974 investigations began on a new class of compounds that produced vasoconstrictive effects via 5-HT receptors. The first compound successfully use in this way was 5-carboxamidotryptamine (5-CT). When applied to an isolated dog saphenous vein, 5-CT caused potent venoconstriction and induced significant hypotension in vivo. The next compound developed, AH25086 [(3–2-aminoethyl)-N-methyl-1-H-indole-5-acetamide], also constricted saphenous veins in dogs but had more 5-HT receptor selectivity. AH25086 was effective against acute migraine in human volunteers, but further research was stopped because it was deemed less suitable for development in humans, possibly owing to the fact that it was highly lipophilic and unsuitable for oral use.[38,69] In 1984, sumatriptan was synthesized and its clinical success led to the rapid development of six other triptans currently including naratriptan, zolmitriptan, rizatriptan, eletriptan, almotriptan, and frovatriptan (Fig. 51–2 and Table 51–5).

■ PHARMACOLOGY

The triptans are all primarily 5-HT$_{1B}$ and 5-HT$_{1D}$ receptor agonists and have less activity at 5-HT$_{1A}$ and 5-HT$_{1F}$ receptors[27] (Chap. 13). In the CNS, 5-HT$_{1B}$ receptors are located on cerebral vessels.[32] Stimulation of these receptors results in cerebral vasoconstriction,[15] reversing abnormal cerebral vasodilation. In contrast, the 5-HT$_{1D}$ receptors are located presynaptically on trigeminal neurons, and act as "autoreceptors" to decrease neurotransmitter release from central trigeminal nerve terminals.[43] The triptans also inhibit dural neurogenic inflammation by preventing the release of vasodilating neuropeptides from peripheral trigeminal nerves.[54,72] Peripherally, triptans cause vasoconstriction systemically through the 5-HT$_{1B}$ receptor.[17,49]

Sumatriptan has poor oral bioavailability but good subcutaneous bioavailability (96%), and is therefore preferentially given by this route. The newer triptans differ substantially from sumatriptan with regard to oral bioavailability, plasma half-life, time to maximum effect, and recurrence rate of headaches. All triptans are pharmacodynamically the same but pharmacokinetically different (see Table 51–5).

■ CLINICAL MANIFESTATIONS

With appropriate therapeutic use, the common adverse effects associated with the triptans are minor and include nausea, vomiting, dyspepsia, flushing, and paresthesias.[16,68] However, the most consequential adverse effects are chest pressure and vasoconstriction. Chest pressure symptoms are reported in up to 15% of sumatriptan users.[9,62] Although triptans reduce coronary artery diameter by 10% to 15%, chest pressure symptoms are not believed to be secondary to cardiac ischemia. Alternate hypotheses for the chest pressure sensations include a

Sumatriptan

TABLE 51–5. Pharmacokinetics of Triptans

Triptan	t ½ (hours)	Duration of Action (hours)	Lipophilicity	Bioavailability (%)	Metabolism/ Elimination
Almotriptan	3.0–3.7	24	Unknown	70–80	CYP3A4, CYP2D6 MAO-A (minor)
Eletriptan	3.6–6.9	14–16	High	50	CYP3A4
Frovatriptan	25	24	Low	24–30	CYP1A2 Renal elimination
Naratriptan	4.5–6.6	Unknown	High	63–74	Renal (major) P450
Rizatriptan	1.8–3.0	25	Moderate	40–45	MAO-A
Sumatriptan	2.0–2.5	4	Low	14 (PO); 96 (SQ)	MAO-A
Zolmitriptan	1.5–3.6	18	Moderate	40–49	CYP1A2 MAO-A (minor)

MAO, monoamine oxidase.

generalized vasospastic disorder in migraineurs, esophageal spasm, bronchospasm, alterations of skeletal muscle energy metabolism, and central sensitization of pain pathways.[18] Although the triptans show some degree of coronary artery constriction in vitro, recent studies demonstrate, and hence recommendations state, that there is no need for routine stress tests in low-risk patients prior to therapy with triptans.[19,48,80]

However, triptans can cause ischemia due to vasoconstriction. Therapeutic sumatriptan use is also associated with myocardial ischemia and or infarction, dysrhythmias, renal infarction, splenic infarction, and ischemic colitis.[1,4,13,44,50,55,57,61] Cephalic vasoconstriction is the desired effect of sumatriptan, but there are reports of adverse neurologic events ranging from transient ischemic attacks to cerebral vascular events, hemorrhages, or infarctions.[11,42,47,53] Extrapyramidal symptoms such as akathisia and dystonia may also occur.[46] Spinal cord infarction is reported after therapeutic zolmitriptan use,[82] and renal infarction is reported after therapeutic rizatriptan use.[29] These complications have not been reported to date with the other triptans but are possible given their similar mechanisms of action.

Animal studies showed a wide margin of safety with oral sumatriptan. Subcutaneous administration of 2 g/kg of sumatriptan to rats was lethal. Death was preceded by erythema, inactivity, and tremor.[39] Dogs survived 20 mg/kg and 100 mg/kg subcutaneous doses, but developed hind limb paralysis, erythema, tremor, salivation, and loss of vocalization.[38] Reactions in other animals include seizures, inactivity, reduced respiratory rate, cyanosis, ptosis, ataxia, mydriasis, salivation, and lacrimation.[39,75]

Excessive triptan usage is associated with vasoconstrictive symptoms. A 43-year-old man who used 23 (25 mg) tablets of sumatriptan and 32 tablets of Midrin (a combination xenobiotic with isometheptene 65 mg, dichloraphenazone 100 mg, and acetaminophen 325 mg) over 7 days for headaches developed a left occipital infarction with a right hemianopsia. Digital subtraction angiography revealed segmental narrowing in multiple cerebral vessels. The hemianopsia and vessel findings resolved after cessation of the sumatriptan and Midrin and treatment with nicardipine.[53] Two patients who received four times and 10 times the recommended dose of naratriptan developed severe hypertension.[56] However, not all triptan overdosages result in toxicity. One 36-year-old man reportedly used 66 (6 mg) doses of sumatriptan

subcutaneously over 4 weeks for his cluster headaches and had no adverse effects.[78] The maximum recommended dosage of sumatriptan is 12 mg subcutaneously in a 24-hour period. Patients who took single doses of 100 to 150 mg of almotriptan did not have any adverse effects.[2]

In 2006, the FDA issued an alert, warning of an increased risk of serotonin syndrome with triptans used in combination with selective serotonin reuptake inhibitors (SSRIs) or selective serotonin-norepinephrine reuptake inhibitors. The alert was based on 27 cases reported to the FDA Adverse Events Reporting System between 1998 and 2002. The cases involved triptan use in conjunction with SSRIs that were coded as serotonin syndrome or symptoms indicative of serotonin syndrome.[73] A case series of serotonin syndrome from migraine medications described three cases of serotonin syndrome with sumatriptan use alone, sumatriptan with sertraline, and sumatriptan with methysergide, lithium, and sertraline.[51] Other medications that might precipitate serotonin syndrome when used in conjunction with triptans include monoamine oxidase (MAO) inhibitors (see Chaps. 71 and 72).

■ TREATMENT

Treatment of triptan-induced vasoconstriction is dependent on the route of exposure and the organ system affected. Decontamination is not feasible after subcutaneous exposures, but can be effective following overdose of oral preparations. Gastrointestinal (GI) decontamination should be performed with activated charcoal. Since vomiting is not as prominent with triptan exposure as with exposure to the ergot alkaloids, gastric emptying procedures such as orogastric lavage may be considered early, but only following massive ingestion. The oral forms of rizatriptan and zolmitriptan are formulated to dissolve on the tongue, limiting the effectiveness of gastrointestinal decontamination.

Triptan-induced vasoconstriction and ischemia should be reversed with a calcium channel blocker or intravenous vasodilators, such as sodium nitroprusside, nitroglycerin, or phentolamine.[53] Cases of sumatriptan-associated myocardial ischemia were effectively treated with aspirin, heparin, and intravenous nitroglycerin.[61] Thrombolytic therapy has not been investigated in this setting but should be instituted if clinically warranted.

ISOMETHEPTENE

Isometheptene is a mild vasoconstrictor marketed as a combination preparation (Midrin) that includes dichloraphenazone, a muscle relaxant, and acetaminophen. It has indirect α- and β-adrenergic agonist effects as well as minor direct α-adrenergic agonist effects on the peripheral vasculature.[79] When administered early during a migraine exacerbation, it is as effective as sumatriptan in relieving migraine headache.[28] Cerebral vasoconstriction is reported after therapeutic and excessive isometheptene use.[55,64] Autonomic dysreflexia, which presented with hypertension, headache, diaphoresis, and flushing, was also reported in a man with spinal cord injury who used isometheptene for treatment of a migraine headache.[85] Treatment of isometheptene-induced vasoconstriction should include discontinuation of the medication and reversal of the vasoconstriction with calcium channel blockers or vasodilators, such as sodium nitroprusside, nitroglycerin, or phentolamine.

CGRP ANTAGONISTS

During migraines, calcitonin gene-related peptide is among the many vasoactive peptides released from activated trigeminal nerves.[30] Treatment of active migraine with sumatriptan decreased CGRP levels to normal.[30] CGRP is a potent vasodilator[8] and is involved in the transmission of nociceptive signals from cerebral vessels to the central nervous system.[20] CGRP receptors are found in nerve fibers in cerebral and dural vessels and in multiple areas of the central nervous system postulated in migraine genesis—the cerebral cortex, periaqueductal gray, locus coeruleus, dorsal raphe nuclei, solitary tractus nucleus, spinal dorsal horn, dorsal root ganglia, and trigeminal ganglia.[76]

Two CGRP antagonists for migraine therapy were recently developed—olcegepant and telcagepant. Olcegepant is available in parenteral form while telcagepant is available as an oral preparation. Based on two high dosing administrations, olcegepant has a volume of distribution of 20 L with a terminal half-life of 2.5 hours and minor renal excretion.[41] Adverse events reported with olcegepant included paresthesia, flushing, fatigue, headache, abdominal pain, diarrhea, flatulence, rhinitis, dry mouth, and abnormal vision.[21,41] Adverse effects reported with telcagepant included nausea, dizziness, somnolence, dry mouth, fatigue, paresthesia, and asthenia.[36,37] Systemic vasoconstrictive adverse effects did not occur in the phase 2 and 3 trials with either olcegepant or telcagepant.

SUMMARY

Although epidemic ergotism is no longer a common concern because of widespread systemic inspection of grain in the United States, ergot poisoning by both unintentional and intentional ingestions continues to be reported. Knowledge of the complex pharmacologic and physiologic actions of these agents and the use of appropriate pharmacologic antidotes enable the clinician to minimize the morbidity and mortality previously associated with ergot alkaloids. The introduction of the triptans for the treatment of migraine has decreased the use and subsequently the toxicity of ergot alkaloids. Ergots, triptans, and isometheptene all share toxicities related to vasoconstriction. CGRP antagonists do not cause vasoconstriction but are currently too new for its toxicities to be characterized.

CHAPTER 52
ANTINEOPLASTICS OVERVIEW

Richard Y. Wang

Although overdoses of antineoplastics are infrequent, these events are of greater consequence than overdoses of many other xenobiotics because of their narrow therapeutic index. This is evident from survey data from poison centers in the United States. From 1988 to 2007, the median annual number of people exposed to antineoplastics reported to US poison centers was about 1000. In the last 5 years, the number of annual exposures to these agents has steadily increased to slightly over 1500 (see Chap. 135). These exposures represent about one per 1000 cases of exposures to pharmaceutical agents, or one per 2000 cases of all exposures annually reported to US poison centers. Approximately two-thirds of the people exposed to antineoplastic agents in these reports were adults, one-fourth of the group was young children, and the remainder was adolescents. The annual trend for the proportion of exposures among adults and children appears to have remained at 70% and 20%, respectively, from 2001 to 2007. Children and adolescents between the ages of 6 and 19 years accounted for approximately 7% of the population annually exposed, and this frequency did not change between these years. Although these differences among age groups can represent the incidence of cancer in these populations, further analysis is warranted to better define the reasons for these observations because they are not apparent.

From 2001 to 2007, the annual prevalence of exposures to antineoplastics reported to US poison centers that resulted in toxicity that was defined as moderate or major in severity has declined from approximately 10% to 5% in the last 2 years. The mortality was about two per 1000 exposures in this same period. This frequency of significant morbidities was higher than expected because unintentional exposures to antineoplastics occurred eight times more frequently than intentional exposures. This observation is consistent with a hospital-based survey and is attributed to the increased toxicity of these agents.[21] The prevalence of the exposure to antineoplastic agents is expected to increase over the next few years because of the increased availability of oral formulations, such as capecitabine, etoposide, vinorelbine, erlotinib and sorafenib, and their expanding therapeutic indications.

MEDICATION ERRORS WITH ANTINEOPLASTICS

The importance of understanding the occurrence of medication errors is to prevent future events of a similar nature. Fortunately, medical errors related to the use of antineoplastics occur infrequently. The reported medical error rate for the antineoplastics ranges from 0.06% to 5.5% based on data from US centers,[12,21,59] although the true prevalence of this event remains unknown. The rates reported by international centers are similar.[35,36,54] These reported estimates vary by the clinical setting, hospital versus outpatient, and the patient population, adults versus children. The outpatient setting and the treatment of children present several unique challenges to the healthcare system: increased volumes, decreased control measures, increased workload, and unique

dosing schemes such as dose based on body surface area.[21,59] In a satellite pharmacy setting, two of the potentially lethal overdoses of cisplatin were a result of errors in duration of administration (100 mg/m² for 3–4 consecutive days instead of for 1 day).[18] Lack of healthcare provider familiarity with the antineoplastics and its dosing was a major cause of these events.

The factors contributing to the occurrence of medication errors with antineoplastics and the measures identified to prevent these events, such as centralization of services (medical oncology, pharmaceutical) and the use of standardized protocols, are similar to those for other pharmaceutical agents and they are discussed elsewhere (see Chap. 139).[5,7,54] The centralization of services and the institution of information technology, such as electronic prescribing protocols, production, and bedside scanning, can reduce medication error rates with antineoplastics by approximately 25% and 10%, respectively,[7] although drug labeling errors can continue to occur.[35,36] Additional strategies to reduce these errors include tracking and following up on errors, and increased patient education and participation. Many of these features to prevent errors can also improve worker safety by reducing occupational exposures. As more antineoplastics become available and their indications broaden, unintentional exposures and unintended dosing regimens (see Chap. 139) will increase in number and frequency.

Aside from unintentional exposures, additional factors leading to increased toxicity associated with antineoplastics include age, gender, comorbidities, compromised host state, and diminished renal and hepatic function. Diminished hepatic clearance caused by altered enzyme expression can be accounted for by age, gender, smoking status, and the concurrent use of other xenobiotics. Differences in gender can contribute to varying pharmacokinetic parameters, including bioavailability, distribution, metabolism, and elimination. In a study, women treated with 5-fluorouracil (5-FU) for colon cancer were found to have a twofold higher frequency of drug-related toxicity than men.[61] The manifestations included leukopenia, diarrhea, and stomatitis, which also were observed in other reports.[42,56] Although the basis for this difference in toxicity between genders is not known, it may be because of decreased 5-FU clearance from diminished dihydropyrimidine dehydrogenase activity in women.[37,42] Dihydropyrimidine dehydrogenase inactivates more than 80% of fluorouracil by metabolizing it to 5-fluorodihydrouracil, and low activity of this enzyme can result in hematologic and gastrointestinal (GI) toxicity.

At an individual level, genetic polymorphisms can contribute to differences in xenobiotic response with resultant toxicity by altering targets, transporters, and enzyme complexes. Such variations have been characterized for several enzymes that are involved in the metabolism of antineoplastics. Irinotecan and amonafide are two examples that are associated with toxicity. Irinotecan is a topoisomerase I inhibitor that works through its active metabolite, SN-38, which can cause diarrhea and neutropenia at elevated concentrations.[63] A genetic variant of uridine diphosphate glucuronosyltransferase (UGT1A1) containing the T7 allele glucuronidates SN-38 at a slower rate than other variants, which results in increased SN-38 concentrations and increased toxicity.[3,25] Another example is amonafide, which is a topoisomerase II inhibitor, and its active metabolite, N-acetyl amonafide is formed by N-acetyltransferase 2 (NAT2). Patients capable of "rapid acetylation" have a genetic variation of NAT2 and are more likely to develop myelotoxicity than are slow acetylators.[43] There are additional polymorphisms in metabolism associated with antineoplastics; however, further work is necessary to define their clinical significance. Because of the narrow therapeutic index of the antineoplastics, the significance of such findings demonstrates the benefit of individual drug monitoring and genetic screening for use to maximize the therapeutic efficacy of these agents while limiting host toxicity.

CLASSES OF ANTINEOPLASTICS

Most antineoplastics can be grouped into one of four categories: alkylating agents, antimetabolites, antimitotics, and antibiotics (Table 52–1). There are new antineoplastics that target specific proteins located on the cell membrane, such as growth factor receptors, to inhibit the proliferation of tumor cells.[30,44] These antineoplastics can be categorized as monoclonal antibodies and protein kinase inhibitors based on their therapeutic approach. The antimetabolites are grouped by the substrates with which they interfere. Methotrexate is a folate antagonist; other pharmaceuticals with similar but lesser toxicity include trimethoprim and pyrimethamine. The antimitotics are plant alkaloids and they exert toxic effects by interrupting microtubule assembly. Others are naturally derived and include the antibiotics and the enzyme L-asparaginase, which can be isolated from bacteria. The alkylating agents are more commonly used than other antineoplastics and cause covalent binding to nucleic acids, which inhibits DNA activity (replication and transcription). The more notable antineoplastics in this class, including

TABLE 52–1. Classification of Antineoplastics, Their Adverse Effects and Antidotal Therapy

Class	Antineoplastic	Adverse Effects	Overdose	Antidotes
Alkylating, alkylating like	Busulphan	Hyperpigmentation, pulmonary fibrosis, hyperuricemia	Myelosuppression	
	Dacarbazine	Hypotension, hepatocellular toxicity, influenza-like syndrome		
	Nitrogen mustards			
	Chlorambucil, cyclophosphamide, ifosfamide, mechlorethamine, melphalan	Hemorrhagic cystitis, encephalopathy, pulmonary fibrosis	Seizures, encephalopathy, myocardial necrosis, renal failure, hyponatremia	MESNA; methylene blue
	Nitrosoureas			
	Carmustine, lomustine, semustine	Pulmonary fibrosis, hepatocellular toxicity, renal insufficiency	Myelosuppression (delayed onset and prolonged duration)	
	Platinoids			
	Cisplatin, carboplatin, iproplatin	Renal failure, peripheral neuropathy, hypomagnesemia, hypocalcemia, hyponatremia, ototoxicity, myelosuppression	Seizures, encephalopathy, ototoxicity, retinal toxicity, myelosuppression	Amifostine; thiosulfate
	Procarbazine	MAOI activity		
	Temozolomide		Myelosuppression	
Antimetabolites	Methotrexate	Mucositis, nausea, diarrhea, hepatocellular toxicity	Mucositis, myelosuppression, renal failure	Leucovorin (folinic acid); Glucarpidase (carboxypeptidase G2)
	Purine analogs			
	Fludarabine	Encephalopathy, muscle weakness		
	Mercaptopurine	Hyperuricemia, pancreatitis, cholestasis		
	Pentostatin	Hepatocellular toxicity		
	Thioguanine	Hyperuricemia		
	Pyrimidine analogs			
	Cytarabine	Acute lung injury, neuropathy, cerebellar ataxia		
	Fluorouracil	Cardiogenic shock, cardiomyopathy, neuropathy, cerebellar ataxia		
Antimitotics	Taxenes			
	Docetaxel, paclitaxel	GI perforation, peripheral neuropathy, dysrhythmias		
	Vinca alkaloids			
	Vinblastine, vincristine, vindesine	Peripheral neuropathy, hyponatremia SIADH	Encephalopathy, seizures, autonomic instability, paralytic ileus, myelosuppression	

(Continued)

TABLE 52–1. Classification of Antineoplastics and Their Effects (*Continued*)

Class	Antineoplastic	Adverse Effects	Overdose	Antidotes
Antibiotics	Anthracycline			
	Daunorubicin, doxorubicin, epirubicin, idarubicin	Dilated congestive cardiomyopathy	Dysrhythmias, cardiomyopathy, CHF	Dexrazoxane
	Bleomycin	Pulmonary fibrosis		
	Dactinomycin	Hepatocellular toxicity		
	Mitomycin C	Hemolytic uremic syndrome		
	Mitoxantrone	Congestive dilated cardiomyopathy	Cardiomyopathy, CHF	None
Enzyme	L-asparaginase	Hypersensitivity, pancreatitis	No reports	None
Monoclonal antibodies	Alemtuzumab (CD52)			
	Bevacizumab (VGFR)			
	Cetuximab (EGFR)			
	Gemtuzumab ozogamicin (CD33, conjugated to calicheamicin)			
	Ibritumomab tiuxetan (CD20, conjugated to yttrium-90)	Hypersensitivity, and specific to the site of action	No reports	None
	Panitumumab (EGFR)			
	Rituximab (CD20)			
	Tositumomab (CD20, conjugated to iodine-131)			
	Trastuzumab (HER2)			
Protein kinase inhibitors	Dasatinib (bcr-Abl, c-KIT, PDGFR) Erlotinib (EGFR) Gefitinib (EGFR) Imatinib (bcr-Abl, PDGFR, c-KIT) Lapatinib (EGFR, HER2) Sorafenib (VEGFR, PDGFR, Raf-1, c-KIT, FLT3, BRAF) Sunitinib (VEGFR, PDGFR, RET, CSF1R, FLT3)	Gastrointestinal (nausea, diarrhea), acneiform rash (folliculitis), nail fragility, and xerosis (EGFR inhibitor), interstitial lung disease (erlotinib, gefitinib), hypertension (inhibitors of VEGF and PDGF), and hypothyroidism (sunitinib)	Nausea, vomiting, facial rash	None
Topoisomerase inhibitor	Camptothecins Irinotecan Topotecan Epipodophyllotoxins Etoposide, teniposide	Neutropenia, mucositis, diarrhea, early onset cholinergic syndrome (irinotecan) CHF, hypotension	Myelosuppression	None

bcr-Abl, breakpoint cluster region-Abelson, fusion oncogene; B-RAF; B-RAF murine sarcoma viral oncogene homolog B1; c-KIT, murine leukemia viral oncogene homolog 1; CSF1R, colony-stimulating factor 1 receptor; EGFR, epidermal growth factor receptor; FLT3, FMS-related tyrosine kinase 3; HER2, human epidermal growth factor receptor 2; MESNA, mercaptoethane sulfonate; MOAI, monoamine oxidase inhibitor; PDGFR, platelet-derived growth factor receptor; Raf-1, murine leukemia viral oncogene homolog 1; RET, rearranged during transfection; VEGFR, vascular endothelial growth factor.

those with similar activity, are the nitrogen mustards, platinoids, and nitrosoureas. The antimetabolites and the alkylating agents are cell-cycle active, meaning that they only affect cells undergoing cell division. Some xenobiotics are phase specific; that is, they affect the cell only at a period during cell division. The cell cycle consists of the S phase (DNA replication) and the M phase (mitosis). DNA regulation and chromosomal separation occur during mitosis. Vincristine is M-phase specific and cytarabine is S-phase specific, in their sites of action. Other antineoplastics inhibit topoisomerase, which is necessary for DNA replication because it allows for reversible DNA strand breaks.

Because the majority of the cases of antineoplastic overdoses involve methotrexate, vincristine, mitoxantrone (related to the anthracyclines),[53]

nitrogen mustards, and cisplatin, the discussion in this section focuses on these xenobiotics (see Chap. 37 for Vinca alkaloids).

MECHANISMS OF ACTION

The mechanisms responsible for the cytotoxic effects of the antineoplastics are the disruption of cellular replication and proliferation. The former category impairs DNA function by causing strand breaks, inhibiting strand relaxation, and serving as inhibitory analogs of essential cofactors and nitrogenous bases of nucleic acids. For example, alkylating agents form reactive intermediates that covalently

bind to nitrogenous bases on the DNA structure, which leads to the formation of strand breaks and mispairings. Cross-linkages between strands can occur with the nitrogen mustards because they contain two reactive chloroethyl side chains. The planar anthracycline antibiotics can intercalate with DNA to alter replication and cause strand breaks through oxidative damage induced by a reactive semiquinone intermediate. DNA strand relaxation can be impaired by topoisomerase inhibitors, such as topotecan. Topotecan is derived from camptothecin, which is isolated from the tree *Camptotheca acuminata*. Single methyl transfer reactions and base pairings are essential activities during DNA synthesis that are affected by the antimetabolites, which include structural analogs to folate, pyrimidines, and purines.

Recent cancer therapy includes antineoplastics that limit cellular proliferation by inhibiting growth factor receptor activation and enhancing cell lysis by antibody-dependent cell-mediated cytotoxicity and complement-dependent cytotoxicity. Monoclonal antibodies to tumor cell surface antigens, such as CD20, CD52, and CD33, and the C1q complement are used to direct host defense mechanisms or deliver antineoplastics to these sites. For example, gemtuzumab ozogamicin is an antibody conjugated to the antibiotic, calicheamicin, and it is directed at CD33-positive leukemic blast cells. Other conjugates under investigation include radio-labeled isotopes (131-iodine, 225-actinium, 177-lutetium) and toxins, such as diphtheria, pseudomonal, ricin-A, saporin, staphylococcal, and enterotoxin A. In addition to the above, monoclonal antibodies against tumor growth factor receptors are available.

Tumor growth factors promote cell progression, proliferation, and differentiation (by angiogenesis). Their receptors located at the cell membrane are characterized for certain tumors, such as epidermal growth factor receptor (EGFR) (lung, renal, and gastrointestinal tumors) and human epidermal growth factor receptor 2 (HER2) (breast). Vascular endothelial growth factor receptor (VEGFR) and platelet derived growth factor receptor (PDGFR) are active in angiogenesis. Inactivation of these receptors can be accomplished with therapeutic monoclonal antibodies (MAB) and protein kinase inhibitors. Monoclonal antibodies prevent the activation of these receptors by inhibiting substrate binding to the receptor located at the extracellular surface. Kinase inhibitors are considered to be small molecule therapeutics that impair the ATP activation of growth factor receptors, tyrosine kinase inhibitors and certain signal transduction proteins responsible for tumor cell division serine/threonine kinase inhibitors. The disruption of the proliferation of keratinocytes, and GI mucosa and epithelial cells at these tissue sites can account for the anticipated toxic effects from the use of MABs and kinase inhibitors directed at EFGR. The therapeutic use of the protein kinase inhibitors of VEGFR and PDGFR, such as sunitib and sorafenib, is associated with hypertension, which can be due to endotheilial dysfunction and diminished microvascular regrowth.

The monoclonal antibodies are derivitized from human and chimeric (human and murine) sources, which contributes to the toxicity. Immunogenic effects from the presence of foreign proteins include rigors, nausea, vomiting, and rashes. Some organ-specific effects include bone marrow, skin (via EGFR), kidney (hypomagnesemia via EGFR), gastrointestinal (via EFGR), and cardiac (via HER2, trastuzumab).

MANIFESTATIONS OF TOXICITY

The antineoplastics are known for their toxicity to cells with a high level of mitotic activity, such as malignant cells. This characteristic feature accounts for their common clinical manifestations of toxicity, including mucositis, alopecia, and bone marrow suppression. They can also cause protracted vomiting because of their ability to stimulate the chemoreceptor trigger zone in the medulla by vagal and sympathetic pathways either directly or indirectly through the GI tract. The likelihood for vomiting depends on the dose, the route of administration,

and the type of antineoplastic. Although the onset of emesis typically occurs within 6 hours and lasts for 24 hours, emesis developing beyond this period can occur (ie, cisplatin cyclophosphamide, carboplatin, and doxorubicin). The time of onset for the other manifestations is typically in the first week following treatment, with mucositis preceding leukopenia, which varies depending on the agent and dose. For example, the nadir and recovery for neutropenia is about 7 to 13 days and 21 to 24 days, respectively, but it can be more delayed for busulfan and carmustine, and when high doses are used. Antineoplastics likely to cause severe neutropenia include anthracyclines and platinum-based antineoplastics, and those likely to cause mucositis include methotrexate, 5-fluorouracil, bleomycin, and doxorubicin. Because of the amount of GI fluid loss associated with diarrhea and vomiting, patients can develop dehydration. Death is usually from overwhelming sepsis due to enteric organisms that enter the blood stream through compromised GI epithelium and attack a host with neutropenia from bone marrow suppression. For example, an overdose with topotecan has resulted in bone marrow suppression with overwhelming sepsis and death.[47] Some of the unique manifestations for certain antineoplastics involve the skin, heart, central and peripheral nervous systems, and kidneys.

Dermatologic manifestations caused by antineoplastics can be due to hypersensitivity reactions, extravasations (see Special Considerations SC3: Extravasation of Xenobiotics), or cytotoxicity from the use of tyrosine kinase inhibitors for the EGFR (eg, gefitinib, erlotinib).[67] Patients commonly develop pruritus, xerosis, erythema, and folliculitis or an acneiform rash that can desquamate during therapy. The time of onset is within the first week of treatment and it intensifies at about 2 to 3 weeks. The folliculitis is a dose-dependent response and typically resolves within weeks after treatment. The dermal response appears to be more intense with monoclonal antibodies than the kinase inhibitors for the EFGR. The other kinase inihibitors (ie, sunitinib, sorafenib) involved with growth factor receptors for angiogenesis (ie, VEGFR, PDGFR) are associated with a "hand-foot" skin reaction, which is a painful erythema and edema of the palm and sole that leads to desquamation.

The cardiovascular manifestations of toxicity depend on the antineoplastic, and the common ones include congestive heart failure (CHF), dysrhythmias, and hypertension. The anthracyclines, cyclophosphamide, and 5-fluorouracil can cause cardiac toxicity (Table 52–2). Although

TABLE 52–2. Cardiovascular Manifestations of Toxicity of Selected Antineoplastics

Antineoplastic	Time of Onset Since Treatment	Manifestation
Anthracycline	<24 hours	Dysrhythmias, ST segment and T wave changes on ECG; diminished left ventricular ejection fraction leading to congestive heart failure (CHF), pericarditis, myocarditis, and sudden death
	Months to years, typically at 1–4 months	Dilated congestive cardiomyopathy
Cyclophosphamide	Days	CHF, hemorrhagic pericarditis, tamponade, and death
5-Fluorouracil	Hours to days	Myocardial ischemia and cardiogenic shock

the anthracyclines are known for their late-onset cardiomyopathy, they can also cause acute cardiac manifestations. Those occurring within 24 hours of therapy include dysrhythmias, ST segment and T wave changes on electrocardiogram (ECG), diminished left ventricular ejection fraction leading to congestive heart failure, pericarditis, myocarditis, and sudden death.[8,50,51,58,66] Myocardial ischemia leading to cardiogenic shock can occur from the high dose infusion of 5-fluorouracil.[62] The metabolite fluoroacetate[4] is purported to cause endothelial damage and result in vasospasm.[23] Normalization of ECG findings, including diminished QRS voltage and abnormal ventricular wall motion, are expected by 48 hours after the discontinuation of infusion therapy.[14] Within a few days of exposure, cyclophosphamide can cause CHF, hemorrhagic pericarditis, tamponade, and death at high doses from therapy during bone marrow transplant or the overdose setting. The cardiomyopathy from anthracyclines involves biventricular failure and its onset is variable, from months to years, depending on the agent. Although this period is usually 1 to 4 months, it tends be longer for the less toxic anthracycline analogs.[22,26,54] Trastuzumab is associated with a slight increase in cardiac dysfunction among patients previously treated with anthracyclines or with underlying heart disease. A potential mechanism for the enhanced cardiac toxicity from the drug interaction is that trastuzumab disrupts the HER2-neuregulin compensatory response by the heart to the exposure to anthracyclines.[15]

The neurologic toxicities of antineoplastics include central and peripheral manifestations. The acute manifestations of toxicity include altered mental status and seizures, which occur from the systemic administration of high doses of nitrogen mustards (cyclophosphamide, ifosfamide, and chlorambucil), nitrosureas (lomustine), methotrexate, and vincristine (see Special Considerations SC–2: Intrathecal Administration of Xenobiotics). Also, the inappropriate intrathecal administration of vincristine and methotrexate can cause central nervous system toxicity (see Special Considerations SC–2: Intrathecal Administration of Xenobiotics). Patients with prior seizure disorders, delayed drug clearance, and altered drug pharmacokinetics (eg, nephrotic syndrome)[48] are at increased risk for seizures. ʟ-asparaginase, 5-fluorouracil, and procarbazine are associated with altered mental status.[64] Cerebellar ataxia has been described in 5% of patients treated with 5FU,[41] and high frequency ototoxicity can occur with cisplatin toxicity. The late-onset manifestations of neurotoxicity from antineoplastics include leukoencephalopathy and peripheral neuropathies. Leukoencephalopathy from methotrexate typically presents as the late-onset of behavioral and progressive dementia and it is irreversible at this stage. Peripheral neuropathy involving both sensory and motor findings is seen with the Vinca alkaloids (vincristine), and only with sensory involvement with cisplatin and paclitaxel.[33]

Renal insufficiency due to tubulointerstitial pathology can occur from methotrexate, cisplatin, or nitrosureas in a dose-dependent manner. Also, the nitrosureas (semustine) can cause glomerular injury leading to sclerosis. Renal damage from these agents is attributed to the formation of insoluble intratubular precipitates of drug metabolites (ie, 7-OH MTX metabolite for MTX) or reactive intermediates (eg, cisplatin, nitrosureas) that lead to cell death. The nitrosureas can also form isocyanate, which can impair DNA repair enzymes and lead to irreversible renal damage.[32] The onset, severity, and reversibility of renal toxicity depend on the administered dose and the particular agent in the drug class. For example, streptozocin is more nephrotoxic than the other nitrosureas: semustine, lomustine, and carmustine. Patients at increased risk for worsening renal function from the therapeutic use of these agents include those with prior renal disease, increased age, salt and water depletion, hypotension, and concomitant use of nephrotoxic xenobiotics, such as aminoglycosides. Also, patients with third space fluid, such as ascites and pleural effusions, and aciduria are at increased

risk for MTX-induced renal toxicity because of the drug's prolonged half-life and the increased likelihood for the formation of insoluble precipitates in the renal tubules at a low urinary pH. The renal failure due to methotrexate, cisplatin, and streptozocin typically presents in an acute fashion within 1 to 2 weeks unlike that for semustine. Patients treated with semustine can present with elevated serum creatinine in a delayed fashion, months to years, following exposure.[65]

DIAGNOSTIC TESTING

The determination of the antineoplastic concentration in clinical specimens is not routinely available, except for methotrexate. At certain research centers,[9] the testing for specific xenobiotics can be available: busulfan,[57] cisplatin (platinum),[17] vincristine,[16] and topotecan. These concentrations can be used to assist in confirming exposure and monitoring drug clearance, but should not be relied upon to determine initial management because of the difficulty in obtaining these tests and ability to correlate the concentrations with clinical toxicity.

For certain antineoplastics, the presence of typical clinical manifestations can strongly suggest their toxicity. For example, cisplatin (renal insufficiency and ototoxicity), Vinca alkaloids (peripheral neuropathy, central autonomic instability, and syndrome of inappropriate antidiuretic hormone secretion), anthracyclines (CHF and dilated cardiomyopathy), ifosfamide (encephalopathy and seizures), and methotrexate (renal insufficiency, mucositis, and pancytopenia). The diagnosis of a patient with toxicity from these xenobiotics is based on a historical evidence for exposure, clinical manifestations, and laboratory findings that support toxicity or exposure. For patients presenting with delayed or late-onset symptoms, the association between toxicity and exposure requires an increased level of awareness to establish the causation.[22] Additional studies can be obtained to evaluate for specific disorders noted on the clinical examination, such as electromyography and nerve conduction studies for peripheral neuropathies, electroretinogram for retinopathies, and echocardiography for cardiac dysfunction.

GENERAL MANAGEMENT

The initial management of these patients includes stabilization of the hemodynamic status, decontamination, institution of antidotal therapy, and enhanced elimination. Maximal benefits from antidotes and enhanced elimination can be obtained through their timely institution. Hypotension can result from dehydration, cardiac dysfunction, or sepsis. Patients with myocardial ischemia from 5-FU can be treated with coronary vasodilators, such as nitrates and calcium channel blockers. Seizures are treated with benzodiazepines, barbiturates, and propofol. Encephalopathy from high-dose ifosfamide has been treated with methylene blue (adult: 50 mg intravenously [IV] as a 1% solution).[40] Patients with blood dyscrasias, including neutropenia and thrombocytopenia, should be evaluated for gastrointestinal bleeding and infections. Those at risk for overwhelming sepsis should be started on broad-spectrum antibiotics and granulocyte colony stimulating factor as indicated. Oral activated charcoal can be administered to patients soon after an oral exposure to limit the gut bioavailability of the agent. Repeat oral doses of activated charcoal can enhance the clearance of methotrexate in patients with renal insufficiency.[20]

Patients with vomiting are typically difficult to manage. Combination therapy involving multiple antiemetics are needed to treat patients exposed to antineoplastics with high emetogenic potential (eg, cisplatin, doxorubicin, cyclophosphamide, lomustine) or excessive doses of antineoplastics with low emetogenic potential (eg, Vinca alkaloids, fluorouracil). Therapy can include a serotonin receptor antagonist,

glucocorticoid, dopamine receptor antagonist, a neurokinin-1 receptor antagonist (eg, aprepitant), or a benzodiazepine.[34] Serotonin receptor antagonists are effective for acute onset vomiting (circa within 6 hours of exposure) and are used with dexamethasone and aprepitant in patients with protracted vomiting. Once the serotonin receptors are saturated, additional doses of these agents are no longer effective. Aprepitant, when used in combination with a glucocorticoid (eg, dexamethasone), is effective for managing delayed-onset vomiting, which can last for 5 days. Dopamine receptor antagonists, serotonin receptor antagonists, or dexamethasone at a higher dose can be used to treat breakthrough vomiting. Also, benzodiazepines can be used in this setting, but they are most effective for the treatment of anticipatory vomiting. A comprehensive serum chemistry panel, complete blood count (CBC), urinalysis, and electrocardiogram should be obtained for patients with a significant overdose to evaluate for extent of toxicity and for establishing baseline values and performance parameters. The patient's peripheral blood count should be followed for up to 2 weeks after antineoplastics administration because the onset of myelosuppression can be delayed.

Gastrointestinal fluid losses from vomiting, diarrhea, and mucosal ulcerations can lead to dehydration, which needs to be treated with intravenous fluids. Also, intravenous fluids are important for patients with cisplatin and methotrexate toxicity to promote the renal elimination of toxic metabolites. Patients with cisplatin toxicity should be treated with normal saline with an osmotic diuretic to maintain an adequate chloride gradient to promote the renal elimination of cisplatin. Urinary alkalinization is indicated for patients with MTX toxicity to limit the precipitation of drug metabolites in the renal tubules.

Antidotal therapy is available for only a few xenobiotics, including anthracyclines (dexrazoxane), methotrexate (leucovorin, glucarpidase), cisplatin (amifostine, thiosulfate), 5-FU (vistinuridine) and ifosfamide (methylene blue, mercaptoethane sulfonate). They are used in medical therapy to allow higher dose therapies of antineoplastics in cancer patients. However, patients with overdoses from antineoplastics can also benefit from these therapies, which should be initiated soon after the decision to treat has been made. Additional information regarding them can be found in chapters 53 and 54 and Antidotes A 13, A 14).

Information on the use of enhanced elimination to remove these agents is limited to case reports in the literature. The effectiveness of these procedures is based on principles similar to other xenobiotics, including molecular size, extent of protein binding, and volume of distribution. Patients with diminished endogenous clearance due to inherent disorders, such as renal failure, or third spacing of fluid, can benefit from these procedures as well. For example, cisplatin is highly protein bound and favored for removal by plasmapheresis, but patients with renal failure can also benefit from hemodialysis. Hemoperfusion has been used for doxorubicin and it appears to be more effective than hemodialysis. For the nitrogen mustards and the alkyl sulfonates, hemodialysis has been used. The early institution of these procedures can maximize the potential benefits to the patient.

The decision to use myeloid growth factors in patients with agranulocytosis depends on the severity and nature of the neutropenia, the anticipated speed of recovery, and the tumor type. Granulocyte-macrophage colony-stimulating factor (GM-CSF) has been used in several patients with antineoplastic overdoses that included cisplatin, melphalan, bleomycin, and methotrexate.[13,24,27-29,31,39,55] Typically, if promyelocytes and myelocytes are present in the bone marrow, neutrophil recovery will occur spontaneously in 4 to 7 days, following the withdrawal of the offending antineoplastic.[19] However, when granulopoiesis is completely absent, neutrophil recovery cannot be expected for at least 14 days. Using granulocyte colony-stimulating factor (G-CSF) or GM-CSF can accelerate neutrophil recovery during cytotoxic antineoplastic therapy. When myeloid precursors are present in the bone

marrow, G-CSF can accelerate neutrophil recovery in 1 to 4 days. If myeloid precursors are absent, neutrophil recovery with G-CSF may take longer, but can be expected to occur sooner than without G-CSF therapy. GM-CSF is indicated for use in neutropenic patients following induction antineoplastic therapy for acute myelogenous leukemia because this agent enhances the response of macrophages, neutrophils, and eosinophils. Serum concentrations of the antineoplastic should be below detection before institution of G-CSF to gain maximal response; typically, G-CSF is initiated 24 hours after the completion of the treatment cycle. The initial dose is 5 μg/kg/d IV or subcutaneously, and it is continued beyond the expected white blood cell (WBC) nadir. This is usually a 2-week course; however, it can be prolonged with lomustine overdoses.[1,60] The dose may be adjusted, depending on the patient's WBC response. Therapy can be discontinued when the post-nadir absolute neutrophil count is greater than 10×10^3 cells/mm³. Bone pain can be anticipated from the use of colony-stimulating factors, presumably because of the increase in cellularity in the marrow space. Additional side effects can be expected from GM-CSF therapy, including myalgia, fevers, and pericarditis.

GM-CSF might produce a transient beneficial response in the WBCs in patients with aplastic anemia.[11] However, when the anemia was severe, the GM-CSF therapy was not effective. Another hematopoietic growth factor is erythropoietin (epoetin alfa and darbepoetin alfa), which is approved for use in patients with anemia associated with cancer chemotherapy treatment.[6,46] Although the purpose of this therapy is to decrease the need for red blood cell transfusions, it does not replace the need for red blood cell transfusion when indicated.

ANTINEOPLASTICS IN THE WORKPLACE

A variety of workers are at risk for increased exposure to antineoplastics, including pharmacists, nurses, physicians, and others involved in the preparation and dispensing of these antineoplastics, and who may be exposed to the body fluids of patients treated with these agents. Several studies demonstrate that these agents can be detected in the work environment and measured in workers,[49] and there is concern about the possible genotoxic effects from these exposures.[52] The worker may absorb these xenobiotics by either the dermal, inhalational, or gastrointestinal route. The factors determining the amount of worker exposure include the nature of the work, the amount of drug used, the frequency and duration of exposure, the physical and chemical nature of the drug, and the use of ventilated cabinets and personal protection equipment during the handling of these agents. The workplace guidelines for antineoplastics fall under the broader category of hazardous xenobiotics. A sample list of drugs considered to be hazardous agents by the National Institute for Occupational Safety and Health (NIOSH) is available for further information.[10] The NIOSH defines a "drug" as a "hazardous agent" if it is carcinogenic, teratogenic, genotoxic, associated with developmental or reproductive toxicity, or toxic to organs at low dose.

Regulatory and workplace recommendations for exposure levels and the waste management of these xenobiotics are available from various agencies and organizations. These recommendations are limited in scope because only a small number of xenobiotics or adverse health effects have been adequately studied, and many xenobiotics do not meet the current definition for inclusion. US Environmental Protection Agency (Resource Conservation and Recovery Act, 40 CFR §§260–279)[45] regulates nine antineoplastics (arsenic trioxide, chlorambucil, cyclophosphamide, daunomycin, melphalan, mitomycin C, naphthylamine mustard, streptozocin, and uracil mustard) and the equipment and devices associated with their preparation or delivery, as well as their disposal, as hazardous

waste.[45] The current recommendations for worker safety with these xenobiotics in the workplace include the proper management of the work environment (eg, storage, handling, preparation, administration, use of personal protection equipment, decontamination, waste disposal) and the institution of a medical surveillance program with approved laboratory testing.[2,38,52]

SUMMARY

The antineoplastics are a unique therapeutic class because their cytotoxicity is a direct effect. Medicine is challenged to carefully balance this measure so that there is limited damage to native cells, and thus the patient. Over the years, the number of antineoplastic exposures reported to the American Association of Poison Control Centers National Poison Data System has remained small; however, the consequences of toxicity to the patients in these reports were great. The majority of these occurrences were iatrogenic, involving misreading of the product label, and errors in dosing and transcription of orders (see Chap. 139). A key element was the lack of familiarity of the healthcare provider with the use of these select xenobiotics. The number of antineoplastics and their indicated use has increased over the years and will continue in this fashion into the future, increasing the chance for medical error and patient toxicity. The clinical manifestations of toxicity can develop in various organ systems and are primarily determined by the mechanism of action, route of administration, and duration of exposure. The gut epithelium and bone marrow are extremely susceptible to toxicity because of their high mitotic activity. They are important because their failure will lead to overwhelming sepsis and death. Treatment remains primarily supportive in nature. The early institution of cytoprotectants, such as glucarpidase for methotrexate, amifostine for cisplatin, vistonuridine for 5-FU, and dexrazone for anthracyclines, as antidotal therapy in overdosed patients can limit further toxicity. However, further work is needed to better define their use in these situations. Although cytoprotectants will continue to be developed, they cannot be relied on to rescue patients from exposures, because their number will be few in comparison to the quantity of available antineoplastics and their effectiveness limited to pretreatment. Thus, prevention is the best treatment, which can be accomplished by maintaining a heightened awareness when working with these xenobiotics, educating the patient and healthcare provider regarding their use, and providing increased skilled care.

CHAPTER 53
ANTINEOPLASTICS: METHOTREXATE

Richard Y. Wang

Methotrexate (MTX) is commonly used for a substantial number of therapeutic cancerous and noncancerous indications. Its immunosuppressive activity allows it to also be used for rheumatoid arthritis, organ transplantation, psoriasis, trophoblastic diseases, and therapeutic abortion.[10,29]

Risk factors for MTX toxicity include impaired renal function (primary route of drug elimination); third compartment spacing: ascites and pleural effusions; use of nephrotoxins, such as nonsteroidal anti-inflammatory drugs (NSAIDs) and aminoglycosides[37] and certain intravenous radiologic contrast agents[16,24]; age; folate deficiency; and concurrent infection.[60] MTX toxicity depends more on the duration of exposure than the dose itself.

PHARMACOLOGY

The therapeutic and toxic effects of methotrexate are based on its ability to limit DNA and RNA synthesis by inhibiting dihydrofolate reductase (DHFR) and thymidylate synthetase (Fig. 53–1). Thymidylate synthesis is inhibited by polyglutamic derivatives of methotrexate. DHFR reduces folic acid to tetrahydrofolate (FH4), which serves as an essential cofactor in the synthesis of purine nucleotides. These reduced folates are also required by thymidylate synthetase to serve as methyl donors in the formation of thymidylate. Thymidylate is then used for DNA synthesis. MTX is a structural analog of folate and competitively inhibits DHFR by binding to this enzyme's site of action. This stops reduced folate production, which is necessary for nucleotide formation and DNA/RNA synthesis.

The bioavailability of methotrexate appears to be limited by a saturable intestinal absorption mechanism. At oral doses less than 30 mg/m², the absorption is 90%; at doses greater than 80 mg/m², the absorption is less than 10% to 20%.[8] The weekly adult dose used for the treatment of psoriasis and rheumatoid arthritis is low and can be administered orally. However, the dose used to induce abortion is higher (50 mg/m²) and must be administered parenterally to achieve effective drug concentrations. MTX dosing regimens for chemotherapy are variable, but can be generally classified as low (40 mg/m²), moderate, and high doses (1000 mg/m²). Conventional intravenous doses of up to 100 mg/m² can be administered without leucovorin rescue. Doses of 1000 mg/m² are considered potentially lethal. Much higher doses (2 to 3 g/m²) can be given when MTX is followed by leucovorin in order to prevent life-threatening toxicity. Mortality from high-dose MTX is approximately 6%, and occurs primarily when patients' MTX concentrations are not monitored.[60,63]

MTX has a triphasic plasma clearance. The initial plasma distribution half-life is short—0.75 hours. The second half-life is 2 to 3.4 hours and represents renal clearance of the drug. The third phase has a half-life of about 8 to 10.4 hours and represents tissue redistribution into the plasma. This third phase can be prolonged in the setting of renal failure and is associated with bone marrow and gastrointestinal (GI) toxicity. The volume of distribution is 0.6 to 0.9 L/kg and protein beveling is 50%. Healthy kidneys eliminate 50% to 80% of MTX unchanged within 48 hours of administration. When the creatinine clearance is less than 60 mL/min, MTX clearance is delayed.[53,65]

PATHOPHYSIOLOGY

At high doses, drug and insoluble drug metabolites 7-hydroxy methotrexate and 2,4-diamino-10-methyl pteroic acid accumulate and may precipitate in the renal tubules, causing reversible acute tubular necrosis. MTX is one-tenth as soluble at a pH of 5.5 as it is at a pH of 7.5.[8,54] Expressed another way, the serum concentration threshold for nephrotoxicity is 2.2 mmol/L when the urine pH is 5.5, and 22 mmol/L when the urine pH is 6.9. Thus, patients who are either inadequately hydrated or not alkalinized are at risk for acute renal failure from high-dose MTX treatment.[2,30] MTX is excreted unchanged in the urine by both glomerular filtration and active tubular secretion. Folic acid blocks MTX renal reabsorption and can enhance elimination during leucovorin rescue.[25] A small amount of MTX is metabolized intracellularly to polyglutamate derivatives, which inhibit DHFR and thymidylate synthetase and are believed to be responsible for the persistent cytotoxic effect of MTX because they do not easily diffuse outside of the cell.

CLINICAL MANIFESTATIONS

In the course of MTX therapy, a variety of disorders can occur, resulting from either increased patient susceptibility to toxicity or excessive administration. The clinical manifestations of MTX toxicity include stomatitis, esophagitis, renal failure, myelosuppression, hepatitis, and central neurologic system dysfunction. In a group of 23 patients who received 45 courses of high-dose MTX therapy with leucovorin rescue, the commonly observed signs included increased aspartate aminotransferase (AST)/alanine aminotransferase (ALT) (81%), nausea and vomiting (66%), mucositis (33%), dermatitis (18%), leukopenia (11%), thrombocytopenia (9%), and creatinine elevation (7%).[50]

Nausea and vomiting, considered rare after low-dose cancer therapy (40 mg/m²), typically begin 2 to 4 hours after high-dose therapy (1000 mg/m²) and last for about 6 to 12 hours. Mucositis, characterized by mouth soreness, stomatitis, or diarrhea, usually occurs 1 to 2 weeks after therapy and can last for 4 to 7 days. Other gastrointestinal symptoms resulting from MTX therapy include pharyngitis, anorexia, gastrointestinal hemorrhage, and toxic megacolon.[5] Hepatocellular toxicity, as described by increased AST (>1000 IU/L ALT >1000 IU/L), and hyperbilirubinemia, can be observed with both acute and chronic therapy.[42,44] It is usually associated with high-dosage regimens. Laboratory abnormalities improve within 1 to 2 weeks of discontinuation of MTX. The mechanism is incompletely understood, but toxicity is attributed to reduced liver folate stores.[6] Factors associated with hepatotoxicity are sustained high serum concentrations, increased cumulative dosages, chronic therapy, and host factors such as increase in age, obesity, diabetes, and alcoholism.[66]

Pancytopenia usually occurs within the first 2 weeks after an acute exposure. There are several reports demonstrating the occurrence of pancytopenia in individuals receiving chronic MTX therapy for rheumatoid arthritis and psoriasis.[14,36,42,52]

FIGURE 53–1. Mechanism of MTX toxicity. Methotrexate inhibits DHFR activity, which is necessary for DNA and RNA synthesis. Leucovorin bypasses blockade to allow for continued synthesis.

When used in low-dose intravenous (IV) doses of 40 to 60 mg/m^2, MTX is not associated with appreciable nephrotoxicity. However, at doses greater than 5000 mg/m^2 (approximately 130 mg/kg for an adult), several investigators report severe kidney damage, with oliguria, azotemia, and renal failure.[7] The renal function can normalize over time. Patients at risk for nephrotoxicity include the elderly, those with underlying renal disease defined as a glomerular filtration rate of less than 50 mL/min, and those who receive concurrent drug therapy that can delay MTX excretion, which includes agents that reduce renal blood flow such as NSAIDs, the nephrotoxins such as cisplatin, and the aminoglycosides, or weak organic acids such as salicylates and piperacillin which inhibit renal secretion.[28,60]

The neurologic complications associated with either high-dose systemic MTX therapy or intrathecal administration are the most consequential manifestations. The incidence of neurologic toxicity from high-dose MTX therapy is approximately 5% to 15%.[31] The manifestations usually occur from hours to days after the initiation of therapy and include hemiparesis, paraparesis, quadraparesis, seizures, and dysreflexia.[15,41,64,61] These events are reversible to varying degrees.[1] Clinical findings occurring within several hours (usually within 12 hours) of therapy are attributed to chemical arachnoiditis, and they include acute onset of fever, meningismus, pleocytosis, and increased cerebrospinal fluid (CSF) protein concentration.[26] Leukoencephalopathy is associated with the onset of behavioral disorders and progressive dementia from months to years after treatment and is irreversible, although manifestations presenting soon after treatment can be reversible depending on the extent of involvement.[4,69] Patients with increased age and prior cranial radiation are at risk for this disorder.[21] They have findings consistent with edema, and demyelination or necrosis of the white matter on computed tomography (CT) and magnetic resonance imaging (MRI) of the brain.[4]

DIAGNOSTIC TESTING

Serum methotrexate concentrations are monitored during therapy to help limit clinical toxicity. For example, patients with a serum concentration greater than 1.0 μmol/L at 48 hours posttreatment are considered at risk for bone marrow and gastrointestinal mucosal toxicity.[60] The measurement of methotrexate concentrations in the clinical setting is routinely conducted using an immunoassay

technique, such as enzyme immunoassay or fluorescence polarization immunoassay (FPIA). These measurements can be performed on serum, plasma, and cerebrospinal fluid. The presence of MTX metabolites, such as 7-OH-MTX and DAMPA (2,4-diamino-N10-methylpteroic acid), folic acid, and certain drugs, such as trimethoprim and aminopterin, can diminish the specificity of the method for MTX.[3,9,17,48,55] The amount by which these xenobiotics affect the MTX concentration depends on the assay. The advantages of the high performance liquid chromatography (HPLC) method over these other methods include improved sensitivity, specificity, and ability to detect metabolites; however, it takes longer to run than the routine clinical methods because it is not an automated procedure. When patients are treated with carboxypeptidase G2, (see Antidote in Depth A-14) it is preferable to use the HPLC method to measure MTX because of the presence of metabolites during therapy. The FPIA method with monoclonal antibodies is not recommended for use in patients who have developed antibodies to mouse monoclonal antibodies or elevated concentrations of DAMPA.

An elevated serum methotrexate concentration (greater than 100 μmol/L) is indicative of an excessive intrathecal dose or delayed cerebrospinal fluid outflow obstruction.[46] Radiological imaging of the brain, such as computed tomography and magnetic resonance imaging, can be obtained to evaluate for meningeal inflammation, demyelination and necrosis of the white matter, or other pathologies such as a cerebrovascular accident.

MANAGEMENT

In the event of an oral overdose of methotrexate, the initial concern should be gastrointestinal decontamination. Activated charcoal adsorbs methotrexate and should be administered as soon as possible to limit absorption.[22] The administration of multiple-dose activated charcoal and cholestyramine[15,57] can significantly decrease the elimination half-life of methotrexate by interrupting the enterohepatic circulation.[19,22] This approach can increase MTX clearance but is of most benefit to patients with diminished creatinine clearance.

Adequate hydration with 0.9% sodium chloride solution as well as urinary alkalinization with IV sodium bicarbonate (to urine pH 7 to 8) (see Antidotes in Depth A 5: Sodium Bicarbonate) is also important to prevent renal failure from the precipitation of drug and metabolites in patients who receive inadvertent high doses.[11] The complete blood count (CBC) should be monitored on days 7, 10, and 14 to assess the impact on the bone marrow.[38] Granulocyte-macrophage colony-stimulating factor (GM-CSF) was used in a patient with a chronic MTX overdose and pancytopenia.[59] The patient had a serum MTX concentration of 1.25 μmol/L on admission and was in renal failure. Bone marrow biopsy showed promyelocytes, but no mature white cells, and a marked reduction of megakaryocytes. Because of deteriorating conditions, GM-CSF (125 μg/m^2/d) was administered when the MTX concentration fell below the reference limit for toxicity. Seven days after the initiation of GM-CSF, the white blood cell (WBC) count rose and reached normal values within 10 days.

Patients presenting with meningismus or altered mental status following MTX therapy require an initial MRI of the brain and then CSF analysis for infection.[34] Although not considered standard, the CSF may be assayed for MTX if excessive exposure to this compartment is suspected. The CSF methotrexate concentration is about 0.1 mol/L (1 × 10^5 μmol/L) and lasts for 48 hours after an IV MTX dose of 1500 mg/m^2, and 100 mol/L (1 × 10^8 μmol/L) for the peak therapeutic concentration after a 12-mg intrathecal MTX dose.[45] MRI of the brain may demonstrate a high signal throughout the pachymeningeal (dura mater) region, which is consistent with a chemical meningitis,[18]

or a high signal of the white matter with a decreased diffusion coefficient in a diffusion weighted image to indicate the presence of edema, which is an early finding of leukoencephalopathy.

ANTIDOTES

The available rescue agents for methotrexate toxicity include folinic acid (leucovorin) (see Antidotes in Depth A–13: Leucovorin [Folinic Acid] and Folic Acid) and glucarpidase (carboxypeptidase G_2) (see Antidotes in Depth A–14: Glucarpidase [Carboxypeptidase G_2]). The effectiveness of these therapies depends on both the timing of administration and the dose, which warrants the monitoring of serum MTX concentrations during the use of these antidotes. Folinic acid rescue therapy limits methotrexate bone marrow and gastrointestinal toxicity by allowing for the continuation of essential biochemical processes that are dependent on reduced folates. The purpose of the initial dose of leucovorin is to achieve a serum concentration equal to the MTX and subsequent doses should be adjusted according to serum MTX concentrations at 12, 24, and 48 hours postexposure (see Fig. A13–1).[35,55] Leucovorin treatment is continued until the MTX concentration is less than 0.01 μmol/L.[10] In patients with marrow toxicity and no cancer, leucovorin therapy should be considered until marrow recovery occurs, even if serum MTX is no longer detectable,[40] because intracellular MTX activity may still be ongoing because of the presence of cytosolic MTX polyglutamates. Among 71 patients undergoing MTX therapy for rheumatoid arthritis (average 6.1 mg MTX per week), 75% of these patients had indirectly detectable MTX polyglutamates in red blood cells and nondetectable MTX in the serum (FPIA, monoclonal antibody).

Glucarpidase (carboxypeptidase G_2, Voraxaze™) is a recombinant bacterial enzyme that is used as a rescue therapy to inactivate MTX. Glucarpidase is available for use as an adjunctive therapy in patients receiving high dose MTX and experiencing MTX toxicity, or are at risk for MTX toxicity: diminished renal function or delayed MTX clearance based on serum MTX concentrations (Clinicaltrials.gov Identifier: NCT00481559; http://clinicaltrials.gov/ct2/show/NCT00481559). Following glucarpidase therapy, serum MTX concentrations need to be monitored because residual levels of MTX in the blood after initial enzymatic therapy can result from an inadequate dose of glucarpidase in patients with large MTX exposures or the redistribution of MTX from tissue stores to the blood compartment.[9,55,67] Glucarpidase has been successfully administered intrathecally to reduce elevated MTX concentrations in the cerebrospinal space (see SC Intrathecal Administration of Xenobiotics).[68]

EXTRACORPOREAL ELIMINATION

There are several reports of the use of hemodialysis and/or hemoperfusion for patients with MTX toxicity.[33,43,51,62,65] Although the volume of distribution (0.6 to 0.9 L/kg) and protein binding (50%) suggest that methotrexate is dialyzable, older clinical evidence suggests otherwise.[59] In one report, less than 10% of an initial 0.7 g dose of methotrexate was cleared in 12 sessions of hemodialysis.[62] The measured clearance was only 38 mL/min, which can be compared to 5 mL/min for peritoneal dialysis,[23] 0.28 to 24 mL/min for continuous venovenous hemodiafiltration,[32,35] and 180 mL/min for normal renal clearance.[39] Using plasma exchange transfusion to remove MTX is not recommended because of the drug's low degree of protein binding, which limits the efficacy of this procedure.[7,35,47,62]

Acute intermittent hemodialysis with a high-flux dialyzer membrane yielded an effective mean serum MTX clearance of 92 mL/min in six patients with renal failure that was a result of either chronic disease or high-dose MTX therapy.[65] These patients received high-dose MTX therapy and had predialysis plasma MTX concentrations ranging from 1.45 to 1813 μmol/L. The time of dialysis initiation after MTX treatment was from 1 hour to 6 days in this patient population. A serum MTX concentration of 0.3 μmol/L was used as an end point for dialysis. The reported serum MTX clearance by this technique closely approximates normal renal MTX clearance and is indicated to enhance the clearance of MTX in patients with diminished renal clearance and an elevated serum MTX concentration when it is available.[53]

Charcoal hemoperfusion removed more than 50% of methotrexate in four patients with impaired renal MTX clearance during high-dose MTX therapy.[13] This was thought to have prevented severe skin and mucosal toxicity. Sequential hemodialysis and hemoperfusion were used for a patient with substantial MTX toxicity.[22] These procedures decreased the half-life of elimination from 45 hours to 7.6 hours. In experimental animals, hemoperfusion significantly reduced the terminal half-life of methotrexate. In surgically anephric dogs, hemoperfusion decreased the half-life from more than 20 hours to 1.3 hours.[27] Consequently, hemoperfusion is recommended over hemodialysis when it is available; otherwise, high-flux hemodialysis is preferred.[51]

In vitro studies indicate that the toxic effects of 100 μmol/L of MTX cannot be reversed by 1000 μmol/L of folinic acid.[49] This suggests the need for extracorporeal elimination, such as high-flux hemodialysis, and enzymatic cleavage to lower persistent serum MTX concentrations of greater than 100 mol/L.[51] It is important to perform high-flux hemodialysis early, prior to distribution into tissues. Rebound of MTX concentrations from tissues may be expected after hemodialysis, which can begin at 2 hours postdialysis and plateau at 16 hours.[20,23,65] Patients who are at the greatest risk for developing MTX toxicity despite folinic acid treatment should be considered for glucarpidase therapy and extracorporeal elimination because they are most likely to benefit from this procedure. This includes patients with progressively diminishing renal clearance.[60] High-flux hemodialysis can offer the additional benefit of correcting fluid and electrolyte disorders resulting from renal failure. Other treatment options to limit additional organ toxicity, including leucovorin and urinary alkalinization, should be continued during extracorporeal MTX removal. Folic acid is water-soluble and can be removed by hemodialysis.[12,51,56,58] This is probably also applicable for folinic acid, and replacement doses of leucovorin postdialysis should be considered.

SUMMARY

The number of patients with methotrexate exposures and resultant toxicity is anticipated to increase due to the expanding therapeutic indications and available multiple formulations of this antineoplastic. Thus, clinicians need to understand the clinical presentations, acute and chronic, and management of methotrexate toxicity to improve the patient's outcome. Patients with associated chronic illnesses, diminished renal clearance, and chronic toxicity are at greatest risk for increased morbidity from overwhelming sepsis. Management includes supportive care, monitoring serum methotrexate concentrations, enhanced elimination (urinary alkalinization), and antidotal therapy with leucovorin and enzymatic cleavage. The early recognition of these patients and institution of these therapies can offer the patient the best outcome.

ANTIDOTES IN DEPTH (A13)

LEUCOVORIN (FOLINIC ACID) AND FOLIC ACID

Mary Ann Howland
Folic Acid
Folinic Acid

Leucovorin (folinic acid) is the primary antidote for a patient who receives an overdose of methotrexate. Methotrexate prevents the conversion of inactive folic acid to the biologically active reduced form of folic acid, known as leucovorin or folinic acid. Only leucovorin is an acceptable antidote for a patient with methotrexate toxicity. Following a methanol overdose, folic acid enhances the metabolism of formate. Since methanol does not interfere with the synthesis of folinic acid, either folic acid or leucovorin is acceptable for a patient poisoned by methanol.

PHARMACOLOGY

Folic acid, an essential water-soluble vitamin, consists of a pteridine ring joined to PABA (*para*-aminobenzoic acid) and glutamic acid.[7] Folic acid is the most common pharmaceutical preparation of the many folate congeners that exist in nature and perform essential cellular metabolic functions. After absorption, folic acid is reduced by dihydrofolic acid reductase (DHFR) to tetrahydrofolic acid, which accepts one-carbon groups. Tetrahydrofolic acid serves as the precursor for several biologically active forms of folic acid, including 5-formyltetrahydrofolic acid, which is best known as folinic acid, leucovorin, and citrovorum factor. These biologically active forms of folate are enzymatically interconvertible and function as cofactors, providing the one-carbon groups necessary for many intracellular metabolic reactions, including the synthesis of thymidylate and purine nucleotides, which are essential precursors of DNA.[23,25,29,31,36] The minimum daily requirement of folate is normally 50 μg, but in pregnant women and nutritionally deprived, acutely ill patients, 100 to 200 μg may be required.[7,8]

ROLE IN METHOTREXATE TOXICITY

Methotrexate, an antimetabolite, is a structural analog of folic acid, differing only in the substitution of an amino group for a hydroxyl group at the number 4 position of the pteridine ring (see Chap. 53). Methotrexate binds to the active site of DHFR, rendering it incapable of reducing folic acid to its biologically active forms, and incapable of regenerating the necessary active forms required for the synthesis of purine nucleotides and thymidylate.[30] At physiologic pH the binding between methotrexate and DHFR is competitive, with an inhibition constant of about 1 μmol/L.[27] Leucovorin is a reduced, active form of folate. As such, it does not require DHFR for enzymatic interconversion to the form required for purine nucleotide and thymidylate formation. Folic acid is unable to counteract methotrexate toxicity because following methotrexate therapy, DHFR is unavailable to convert folic acid to the active reduced forms. *Leucovorin rescue* is the term used to describe the practice of limiting the toxic effects of high-dose methotrexate therapy.

ROLE IN METHANOL TOXICITY

Monkeys experimentally made folate deficient develop methanol toxicity at lower methanol concentrations.[19] Administering folic acid to normal monkeys accelerates formate metabolism.[19] Pretreatment with folic acid or leucovorin decreased both formate concentrations and the accompanying metabolic acidosis, without affecting the rate of methanol elimination.[19] Leucovorin remained effective in hastening the metabolism of formate when given 10 hours after methanol administration.[21]

The hepatic concentrations of total folate, leucovorin, and folate dehydrogenase (which increases leucovorin concentrations) are all diminished in methanol-poisoned humans.[12] In an analysis of a single methanol-poisoned patient who was given folate and ethanol and hemodialyzed, the half-life of formate was 1.1 hours.[22] In another methanol-poisoned patient treated without folate, the formate half-life was 2.8 hours.[9] These comparative data are inadequate to draw definitive conclusions, but may support the therapeutic role of folate, in addition to that of fomepizole and hemodialysis.

LEUCOVORIN PHARMACOKINETICS

Leucovorin is naturally formed in the body as the active (*l* or −) isomer, whereas the commercial preparation is the racemic mixture, which means it consists of equal amounts of the inactive (*d* or +) and active (*l* or −) isomers. The pharmacokinetics of the racemic mixture of leucovorin and its active metabolite were studied after intravenous (IV) infusion, and as a constant infusion in normal human volunteers.[32,33] During constant infusion of 500 mg/m²/d, the steady-state concentration for the active isomer was 2.33 μM, the half-life was 35 minutes, and the volume of distribution was 13.6 L. The active isomer is metabolized to an active metabolite (L-5-CH3-THF) that achieved a steady-state concentration of 4.85 μM and a half-life of 227 minutes. Similar values were achieved for half-life and volume of distribution after single IV doses ranging from 25 to 100 mg. The inactive d isomer achieved higher concentrations and had a much longer half-life with oral administration which is saturable and stereoselective, resulting in absorption of the active isomer that is four to five times greater than that of the inactive isomer. Studies of stereospecific oral absorption demonstrate that 100% of the l-leucovorin is absorbed whereas only 20% of the d-leucovorin is absorbed at this dose.[15] One study detected no adverse effects of the inactive isomer on the intracellular uptake of the active isomer and concluded that giving the active isomer provided no pharmacokinetic advantage over the racemic mixture.[28]

The pharmacokinetics of IV leucovorin was compared to intramuscular (IM) and oral administration in male volunteers given 25 mg. The mean peak of the active L-5-CH3-THF concentration was 258 ng/mL at 1.3 hours after IV administration compared with 226 ng/mL at 2.8 hours for IM and 367 ng/mL at 2.4 hours for oral administration.

The pharmacokinetics of orally administered leucovorin was studied in healthy, fasted, male volunteers in single doses ranging from 20 to 100 mg, and 200 mg IV over 5 minutes as compared with 200 mg orally.[18,24] Bioavailability decreased from 100% for the 20-mg dose to 78% for the 40-mg dose, and ultimately to 31% for the 200-mg dose. A microbiologic assay was used to measure total tetrahydrofolates (reduced and active folates). Normal serum folate concentrations are approximately 0.05 μmol/L.[10] The 200-mg oral dose produced a peak serum concentration of 1.82 μmol/L, compared to 0.66 μmol/L for the 20-mg oral dose and 27.1 μmol/L for the 200-mg IV dose.[18,24]

LEUCOVORIN DOSING FOR METHOTREXATE OVERDOSES

When a patient overdoses on methotrexate, a dose of leucovorin estimated to produce the same plasma concentration as the methotrexate dose should be given as soon as possible and, preferably, within 1 hour. One mole of methotrexate weighs 455 D and 1 mol of leucovorin calcium weighs 511 D, with the molecular weight of the leucovorin portion equal to 471 D. Because of the safety of leucovorin and because of the toxicity of methotrexate, underdosing leucovorin should be avoided. Although serum methotrexate concentrations are often closely followed in patients on diverse oncologic regimens,[2,3] in the overdose setting, or in the treatment of methotrexate toxicity related to treatment for tubal pregnancies, it is inappropriate to wait for a serum methotrexate concentration before initiating treatment with leucovorin.[1] The toxic threshold for methotrexate is reported to be 1×10^{-8} mol/L (0.01 μmol/L or 10 nmol/L).[4] Normal serum folate concentrations are in the range of 13 to 43 nmol/L. In a patient who is not receiving methotrexate therapeutically, there is no need to permit any methotrexate to remain unantagonized by leucovorin.

For example, if a child unintentionally ingests one hundred 2.5-mg methotrexate tablets for a total dose of 250 mg, only part of this dose is absorbed because methotrexate absorption is saturable.[6] The bioavailability of methotrexate decreases from 100% with doses less than 30 mg/m² to approximately 10% to 20% with doses greater than 80 mg/m². In this case, it is safe to assume that a bioavailability of 50% would result in an absorbed dose of methotrexate of less than 125 mg. For this substantial exposure an IV dose of 125 mg of leucovorin could be given over 15 to 30 minutes. This dose of IV leucovorin would be expected to produce serum concentrations in excess of that of the methotrexate, given that the volume of distribution of leucovorin is about 25% less than methotrexate and the molecular weights are similar. This dose of IV leucovorin should be repeated every 3 to 6 hours until the serum methotrexate concentration is less than 1×10^{-8} mol/L, and preferably zero. The methotrexate half-life may vary from 5 to 45 hours, depending on the dose and the patient's renal function. For this reason, leucovorin therapy should be continued for 12 to 24 doses (3 days) or longer if methotrexate concentrations are unavailable. Patients who may develop third-space storage in ascites or pleural effusions may also require leucovorin dosing for an extended period of time. Patients with bone marrow toxicity require more prolonged dosing because plasma half-lives of methotrexate do not reflect persistent intracellular concentrations.

Unintentional overdose with intrathecal methotrexate is potentially quite serious and is dose dependent.[11,16] In these cases, IV leucovorin should be administered. Intrathecal leucovorin was considered a major factor in the death of a child given a slightly higher dose of intrathecal methotrexate than was prescribed.[14] Not all intrathecal methotrexate overdoses require aggressive intervention, but consultation with experienced hematologists/oncologists and medical toxicologists is warranted (see Special Considerations SC2: Intrathecal Administration of xenobiotics).[13]

An IV leucovorin dose of 100 mg/m² every 3 to 6 hours should be effective, in all but the most severe overdoses. A constant intravenous infusion of 21 mg/m²/h has been safely administered for 5 days. See Figure A13-1, which offers a nomogram for pharmacokinetically guided rescue after high-dose methotrexate.[2] A transition to the oral administration of leucovorin depends on the serum concentration of the methotrexate and whether adequate serum concentrations of leucovorin can be achieved by that route. In adults, a 200-mg oral dose of leucovorin produces a peak serum concentration of 1.82 μmol/L as compared with 27.1 μmol/L with a 200-mg IV dose.

Levoleucovorin, the active *l* isomer of folinic acid, is available and should be dosed at half the dose of the racemate leucovorin.[5]

Administration of activated charcoal precludes the subsequent administration of oral leucovorin. In addition to leucovorin, other
FIGURE A13–1. Example of a nomogram developed by Bleyer[2] for pharmacokinetically guided leucovorin rescue after high-dose methotrexate (MTX) administration.

modalities to treat patients with methotrexate overdoses include activated charcoal and urinary alkalinization, and glucarpidase (carboxypeptidase G) and extracorporeal removal should be considered (see Chap. 53).

ADVERSE EFFECTS AND SAFETY ISSUES

Reports of adverse reactions to parenteral injections of folic acid or leucovorin are uncommon; however, adverse reactions may include allergic or anaphylactoid reactions.[7] Seizures are rarely associated with leucovorin administration.[20] The calcium content of leucovorin warrants a slow intravenous infusion at a rate not faster than 160 mg/min in adults. Leucovorin should never be administered intrathecally.[11,14,26,35]

Leucovorin is not an antidote to 5-fluorouracil (5-FU) and can enhance the therapeutic and toxic effects of fluoropyrimidines such as 5-FU.[15,17]

Many protocols recommended separating leucovorin from glucarpidase by 2 hours (see Antidotes in Depth A14: Glucarpidase [Carboxypeptidase G_2]).

DOSING

The routine dose of leucovorin for "leucovorin rescue" ranges from 10 to 25 mg/m² IM or IV every 6 hours for 72 hours to 100 mg/m² every 3 hours in patients with renal compromise. If administration to neonates is necessary, a benzyl-alcohol-free preparation must be used because of the toxicity of benzyl alcohol in neonates (see Chap. 55).[34] For methotrexate overdoses, equimolar serum leucovorin concentrations should provide adequate protection, but precise determinations are invariably delayed, and the administration of leucovorin should not be delayed until a serum methotrexate concentration is determined.

As a rough guide, a single dose of IV 25 mg leucovorin in an adult produces a peak concentration of the active L-5-CH3-THF metabolite of approximately 258 ng/mL which is 5.5×10^{-7} M.[15] A dose of about 150 mg every 4 hours in an adult achieves a steady-state concentration of about 4.85×10^{-6} M.[32] And although the dose of leucovorin can be as high as 1000 mg/m² every 6 hours, this is rarely warranted and cannot adequately compete with serum concentrations of methotrexate above 10^{-4} M; under these circumstances glucarpidase should be strongly considered. An IV leucovorin dose of 100 mg/m² every 3 to 6 hours should be effective in all but the most severe overdoses and should be administered IV as soon as possible over 15 to 30 minutes, but not faster than 160 mg/min in adults due to the calcium content. This dose should be continued for at least several days, or until the serum methotrexate concentration falls below 1×10^{-8} mol/L in the absence of bone marrow toxicity.

Either folic acid or leucovorin (folinic acid) should be administered parenterally at the first suspicion of methanol poisoning. No complications are reported with the use of 50 to 70 mg of IV folic acid every 4 hours for the first 24 hours in the treatment of methanol-poisoned patients.[22] The precise dose necessary is unknown, but 1 to 2 mg/kg every 4 to 6 hours is probably sufficient. The folic acid should be continued until the methanol and formate are eliminated. As the first dose is usually administered prior to hemodialysis, a second dose should be administered at the completion of hemodialysis, because hemodialysis will remove this highly water-soluble vitamin.

AVAILABILITY

Leucovorin (folinic acid) powder for injection is available in 50-, 100-, 200-, and 350-mg vials. Each mg of leucovorin contains 0.004 mEq of calcium. Reconstitution with sterile water for injection—5 mL to the

TABLE A13–1. Rapid Calculations

1 mole = 1 gram molecular weight

1 Molar = 1 mole/L = 1 gram molecular weight/L

1×10^{-3} moles = 1 millimole = 1 mmole

1×10^{-6} moles = 1 micromole = 1 μmole

1×10^{-9} moles = 1 nanomole = 1 nmole

1 mole of methotrexate weighs 455 daltons; 1 mole methotrexate = 455 grams

1 Molar methotrexate = 455 grams/L = 455 mg/mL

1×10^{-8} Molar methotrexate = 455×10^{-8} g/L = 455×10^{-8} mg/mL = 455×10^{-5} μg/mL = 455×10^{-2} ng/mL = 4.55 ng/mL

50-mg vial, 10 mL to the 100-mg vial, or 20 mL to the 200-mg vial—results in a final concentration of 10 mg/mL. Adding 17.5 mL of sterile water for injection to the 350-mg vial results in a final concentration of 20 mg/mL. Leucovorin is also available in a single-use vial as a solution for injection at a concentration of 10 mg/mL in a 50-mL vial. Because of the calcium content, the rate of intravenous administration should not be faster than 160 mg/min in adults.[15] Leucovorin is also available orally in a variety of strengths, including 5-, 10-, 15-, and 25-mg tablets.

Levoleucovorin (Fusilev) lyophilized powder for injection is available in a single-use 50-mg vial containing the equivalent of 50 mg of levoleucovorin as the calcium pentahydrate salt and 50 mg mannitol. Reconstitution with 5.3 mL of 0.9% sodium chloride injection, USP, yields a concentration of 10 mg/mL. Because of the calcium content, the rate of IV administration should not be faster than 160 mg/min (16 mL of reconstituted solution/min).[5]

Folic acid is available parenterally in 10-mL multidose vials with 1.5% benzyl alcohol in concentrations of 5 or 10 mg/mL from a variety of manufacturers. Once opened, this vial must be kept refrigerated.

SUMMARY

Leucovorin (folinic acid) is the primary antidote for a patient who receives an overdose of methotrexate. Leucovorin is the biologically active, reduced form of folic acid, the synthesis of which is prevented by methotrexate. Only leucovorin (folinic acid) is an acceptable antidote for a patient with methotrexate toxicity, but either folic acid or leucovorin is acceptable for a patient poisoned by methanol. Following a methanol overdose, folic acid enhances the elimination of formate (Table A13-1).

ANTIDOTES IN DEPTH (A14)

GLUCARPIDASE (CARBOXYPEPTIDASE G$_2$)

Silas W. Smith

Glucarpidase (carboxypeptidase G$_2$, CPDG$_2$) is indicated for the management of methotrexate (MTX) toxicity. When given intravenously or intrathecally it rapidly enzymatically inactivates intravascular or intrathecal MTX, respectively as well as folates and folate analogues. It is not a substitute for and must be used in conjunction with leucovorin (see Antidotes in Depth A13: Leucovorin [Folinic Acid] and Folic Acid). In most cases glucarpidase administration should precede or follow the use of leucovorin by at least 2 to 4 hours, unless a carefully considered benefit-risk analysis suggests the need to more rapidly eliminate MTX and risk leucovorin inactivation.

HISTORY AND DEVELOPMENT

Soon after the discovery of the structure and synthesis of folate,[7] a *Flavobacterium* species capable of removing the glutamate moiety of folate was described.[34] This was followed by additional reports of *Bacillus* species with glutamyl peptidase activity.[33,68] From 1955 to 1996 a series of experiments demonstrated the inactivation of folate analogues (including chemotherapeutic aminopterin) by bacteria and yeasts.[49,74] Other bacteria with similar folate glutamate-cleaving ability were later identified.[41,56,72] In 1967 purification of "carboxypeptidase G," a pseudomonad derived zinc-dependent enzyme responsible for MTX cleavage, was reported.[25,35] Carboxypeptidases from other bacterial species which differed in their substrate specificity and kinetics were later isolated and purified in 1971 (*Pseudomonas stutzeri* carboxypeptidase G$_1$),[40] 1978 (*Flavobacterium* carboxypeptidase),[6] and 1992 (*Pseudomonas* sp. M-27 carboxypeptidase G$_3$).[82] By 1976 carboxypeptidase G$_1$ was scaled to pilot manufacturing production.[17] The carboxypeptidase currently used in clinical practice (carboxypeptidase G$_2$) was cloned from *Pseudomonas* strain R-16 and sequenced, characterized, and expressed in *Escherichia coli* in the early 1980s.[44-46,63] A preliminary crystal structure was provided in 1991, with a complete characterization (at 2.5 Å), description of the active site, and biochemical mechanism of action was presented in 1997.[36,58,70]

Carboxypeptidase G$_1$ was initially explored as an anticancer agent because of its ability to deprive growing tumors of folate.[9,10,15,30] Human usage of CPDG$_1$ for this purpose was reported in 1974.[10] The antidotal potential of carboxypeptidase was suggested in 1972— carboxypeptidase G$_1$ rapidly decreased MTX levels and improved survival in mice injected with lethal MTX doses.[16] CPDG$_1$ was subsequently used to selectively eliminate systemic MTX in patients treated with high dosages targeting central nervous system (CNS) malignancy.[1,2] CPDG$_1$ was first used for rescue in a patient receiving MTX with renal failure in 1978.[28] Unfortunately, the enzyme source of CPDG$_1$ was then lost.[5,84] Following the revival of the recombinant CPDG$_2$ product, it underwent nonhuman primate testing for both intravenous (IV) and intrathecal (IT) rescue for MTX overdose.[4,5] Reports of successful use in human IV and IT MTX overdose rapidly emerged.[8,14,18,20,26,28,31,32,37,47,50,51,53,59-62,64,66,67,73,76,77,79,80,84] The US FDA designated glucarpidase as an approved Orphan Product in 2003 for treatment of patients at risk of MTX toxicity.[71]

MECHANISM OF ACTION

Glucarpidase is a dimerized protein structure with two domains—a beta-sheet interaction site and a zinc-dependent catalytic domain.[58] The catalytic domain hydrolyzes C-terminal glutamate residues of folate and folate analogues such as MTX. MTX and its metabolite 7-hydroxy-MTX are thus split into inactive DAMPA and hydroxy-DAMPA plus glutamate.[80,81] Glucarpidase similarly inactivates leucovorin (folinic acid) and folate by cleavage of terminal glutamate residues (Fig. A14–1), although to a lesser degree.[6] Several clinical studies supported the mechanism of action of glucarpidase as rapid cleavage of MTX.[14,26,32,61,77]

PHARMACOKINETICS AND PHARMACODYNAMICS

In a manufacturer-sponsored study, 50 Units/kg of glucarpidase IV was given to eight volunteer subjects with normal renal function and four volunteers with severely impaired renal function.[54] In those with normal renal function the mean maximum serum concentration of glucarpidase was 3.1 μg/mL, with a mean half-life of 9.0 hours. These values were essentially unaffected by compromised renal function.

Following glucarpidase administration, a rapid decline of serum MTX concentrations by 71% to 99% occurs within minutes, with the concurrent appearance of DAMPA.[14,32,62,64,75-77] However, CPDG$_2$ does not cross the blood-brain barrier, cannot cross the cell membrane to act intracellularly, and does not act on MTX in the gut lumen.[1,16,18] Intracellular MTX is polyglutamated, which hinders transmembrane transport and increases its intracellular half-life. This MTX pool, inaccessible to CPDG$_2$ (and hemodialysis), can persist for greater than 24 hours to cause cytotoxicity and a rebound in serum MTX concentrations.[24,79]

INDICATIONS AND ROLE IN METHOTREXATE TOXICITY

Patients receiving high-dose MTX therapy are routinely "rescued" with leucovorin (eg, 10 mg orally every 6 hours).[83] Treatment nomograms and institutional algorithms recommend higher leucovorin doses when MTX concentrations are excessive or prolonged.[11,75,83] However, at MTX concentrations above 100 μmol/L (and perhaps even lower), data suggest that adequate leucovorin concentrations cannot be achieved for competitive and complete reversal of toxicity.[14,32,38,55] Also, high-dose leucovorin therapy leads to the administration of 0.004 mEq calcium per mg of leucovorin and may be associated with hypercalcemia.[84]
FIGURE A14–1. MECHANISM OF ACTION: Glucarpidase is a dimerized protein structure with two domains—a beta-sheet interaction site and a zinc-dependent catalytic domain. The catalytic domain hydrolyzes C-terminal glutamate residues of folate and folate analogues such as MTX. (A+B) MTX and its metabolite 7-hydroxy-MTX are thus split into inactive DAMPA and hydroxy-DAMPA plus glutamate. (C) Glucarpidase similarly inactivates leucovorin (folinic acid) and folate (D) by cleavage of terminal glutamate residues, although to a lesser degree.

Studies support the use of glucarpidase to treat patients who are at risk of toxicity from MTX due to either persistently elevated MTX concentrations or renal dysfunction.[14,26,61,76] As glucarpidase has not yet received marketing approval at the time of writing in either the United States or Europe, it lacks definitive administration indications. Table A14-1 summarizes the indications used in selected clinical trials and reviews, which vary by malignancy, degree of renal impairment, initial MTX dose, and serum MTX concentration. Mucositis, gastrointestinal distress, myelosuppression, hepatitis, or neurotoxicity should prompt consideration of glucarpidase in addition to aggressive leucovorin therapy. Patients with significant, persistent serum MTX concentration (essentially less than or equal to 50% the normal clearance rate), or MTX concentrations requiring high-dose leucovorin rescue or renal impairment (oliguria or creatinine greater than 1.5 times baseline) following high-dose MTX, should be candidates for glucarpidase.

Since leucovorin is contraindicated for IT administration,[22,29,69] IT glucarpidase provides an effective means to rapidly lower cerebrospinal fluid (CSF) MTX concentrations in cases of overdose or persistence.[50,79] Inadvertent or intentional MTX exposure[48,65] would also be amenable to glucarpidase, particularly prior to drug distribution. Additionally,

TABLE A14–1.   Indications for Glucarpidase Use in Clinical Trials and Reviews

Trial/Review	Malignancy	Creatinine/Creatinine Clearance	Methotrexate Concentration
NCT00001298[3,76]	Various	Unspecified	≥10 µmol/L beyond 42 h
	Various	Cr ≥1.5 times the ULN or Cr$_{CL}$ <60 mL/m²/min	≥ 2 standard deviations above the mean MTX elimination curve beyond 12 h
NCT00219791[61]	ALL, NHL, or a solid tumor (eg, osteosarcoma)	Unspecified	>5 µmol/L beyond 42 h
	ALL, NHL or a solid tumor (eg, osteosarcoma)	Cr >1.5 times the ULN and/or urine output <500 mL/24 h	>1 µmol/L beyond 42 h or >0.4 µmol/L beyond 48 h
NCT00424645	Solid tumors and hematologic malignancies	Unspecified	≥ 0.1 µmol/L at 72 ± 2 h (for MTX doses 1–3.5 g/m²) or ≥0.3 µmol/L at 72 ± 2 h (for MTX doses >3.5 g/m²)
NCT00481559	Osteosarcoma	Cr increase >2 times baseline	>50 µmol/L at 24 h, >5 µmol/L at 48 h, or >2 standard deviations above the mean MTX elimination curve beyond 12 h
	Various	Cr >1.5 times the ULN or Cr$_{CL}$ <60 mL/min beyond 12 h	>10 µmol/L beyond 42 h or >2 standard deviations above the mean MTX elimination curve beyond 2 h
Reference 14	Various	Cr >1.5 times the ULN or diuresis of <50% of input hydration	>10 µmol/L at 36 h, >5 µmol/L at 42 h, or >3 µmol/L at 48 h
Reference 75	Various	Unspecified	>10 µmol/L beyond 42 h
		Renal dysfunction	>10 µmol/L beyond 42 h; consider if 1–10 µmol/L beyond 42 h

Where time-specific methotrexate concentrations are given, these indicate time following the initiation of the MTX infusion. Cr, creatinine; Cr$_{CL}$, creatinine clearance; ALL, acute lymphoblastic leukemia; NHL, non-Hodgkin lymphoma; ULN, upper limit of normal.

glucarpidase has been proposed as an antidote for pemetrexed (a folate antimetabolite) toxicity.[12] In international patent applications, the manufacturer disclosed experiments that demonstrated glucarpidase cleavage of additional antifolates in clinical and experimental use including AAGI 13-161, edatrexate, lometrexol, pemetrexed, and raltitrexed.[42,43]

MONITORING

False elevations of MTX have been reported clinically with all of the various immunoassay techniques following glucarpidase administration.[20,27,32,53,80,84] The DAMPA product of MTX cleavage significantly cross-reacts with both the MTX radioimmunoassay (RIA) and the competitive dihydrofolate reductase binding assays.[19] Both MTX metabolites (7-hydroxy-MTX and DAMPA), appreciably interfere with the newer fluorescence polarization immunoassay (FPIA) and enzyme multiplied immunoassay technique (EMIT) assays. For DAMPA, the cross-reactivity rates are 100% (EMIT) and 36% to 44% (FPIA).[52] 7-OH-MTX cross-reactivity using EMIT is 4% to 31%, and 0.6% to 3% with FPIA.[23,52] Clinically, the concentrations of DAMPA detected are comparable to that of MTX following administration of CPDG$_2$.[18] Thus, the use of high performance liquid chromatography (HPLC) to determine actual MTX concentrations is mandated when glucarpidase is given.[13]

ADVERSE EFFECTS AND OTHER SAFETY ISSUES

Initial studies reported adverse effects in four of nine patients treated with CPDG$_1$, including development of inactivating antibodies, "sensitization" to CPDG$_1$, and anaphylactoid reactions.[1,2,10,28] Studies with the current recombinant enzyme glucarpidase (CPDG$_2$) report a much lower incidence of adverse effects than with the initial CPDG$_1$ enzyme. These typically include warmth, tingling, head pressure, flushing, shaking, and burning of the face and extremities.[77] The current manufacturer reports that 8% of patients (25 of 329) reported a total of 50 possibly related adverse events.[57] One-third of these were "allergic" reactions (burning sensation, flushing, hot flush, allergic dermatitis, feeling hot, pruritus, and hypersensitivity). Two of the adverse events were considered serious (hypertension and dysrhythmia), but both were considered more likely to be associated with MTX itself. In one recent study with glucarpidase, three of seven patients tested produced antiglucarpidase antibodies.[61] In patients administered CPDG$_2$ fused to a murine single-chain Fv antibody, 36% (11 of 30) developed anti-CPDG$_2$ antibodies, while no antimurine antibodies were detected.[39] Although antiglucarpidase antibodies might decrease clinical efficacy or predispose to allergic reaction upon re-exposure,[2,5,21,61] many patients have been successfully treated with more than one dose of glucarpidase for persistently elevated MTX concentrations.[14,18,32,51,53,61,66,80,84] Clinical

trials will explore planned repeated use (eg, NCT00727831). Late glucarpidase administration, more then 96 hours after MTX initiation may not prevent significant MTX toxicity.[3]

Since "inactive" DAMPA has a urinary solubility eight to ten times less than MTX (depending on pH),[27,76] alkalinization and saline diuresis must be continued to prevent DAMPA precipitation and further renal compromise. Because of the inability of glucarpidase to access intracellular MTX, rebound may occur.[79] Significant delayed rebound of MTX may occur up to 85 hours after glucarpidase is administered.[61] This slow egress of persistent intracellular MTX requires continued leucovorin therapy at 250 mg/m^2 IV every 6 hours for 48 hours after the last dose of carboxypeptidase. Then, leucovorin is continued until the MTX concentration is less than 50 nmol/L (0.05 μmol/L).[75]

Carboxypeptidase has a 10- to 15-fold higher affinity for MTX than for leucovorin, although its affinity for its active metabolite 5-methyltetrahydrofolate and folate are similar.[6,21,63] Leucovorin is commonly provided as a racemate, although the active enantiomer is now an approved pharmaceutical. Since glucarpidase cleaves the active *levo*-(*6S*)-leucovorin about 50% faster than the inactive *dextro*-(*6R*)-isomer,[27] glucarpidase may compromise leucovorin rescue if both antidotes are administered at similar times. Fifteen minutes post CPDG$_2$, median leucovorin and active 5-methyltetrahydrofolate concentrations dropped by 8% and greater than 97%; the remaining leucovorin was likely the inactive d-isomer.[75,78] When provided at 2 or 26 hours after a glucarpidase dose to healthy volunteers, "exposures to" active leucovorin and activated levo-5-methyl-tetrahydrofolate were 50% and 0% (administration after 2 hours) and 80% and 25% (administration after 26 hours) of anticipated, respectively.[21] Thus, because leucovorin and 5-methyltetrahydrofolate can act as competitive substrates for glucarpidase, most protocols recommend that leucovorin should not be administered for 2 to 4 hours before, and for up to 2 to 4 hours after glucarpidase is provided. Administration of glucarpidase more proximate to leucovorin would require a thoughtful benefit-risk assessment. The exigency to rapidly eliminate MTX—ascertained by the patient's clinical status, renal function, and MTX concentration—would be weighed against the risks of inactivating leucovorin and 5-methyltetrahydrofolate, particularly in cases of prolonged exposure to MTX, in which intracellular MTX inaccessible to glucarpidase would be expected.

In the setting of oral MTX overdose, gastrointestinal decontamination should be considered, as glucarpidase has no intraluminal activity. The supplied product contains lactose and Tris-HCl with zinc buffer. Lactose intolerant patients can receive glucarpidase. In those who have previously experienced allergic reactions to lactose-containing xenobiotics or the other excipients, or patients with rare hereditary problems of fructose intolerance, galactose intolerance, galactosemia, or glucose-galactose malabsorption, the anticipated clinical benefit of glucarpidase would need to be weighed against the risk of adverse effects.

DOSING

Glucarpidase is dosed in units per kilogram in both children and adults. One unit of enzyme activity catalyzes the hydrolysis of 1 μmol of MTX per minute at 37°C.[4] After reconstituting each 1000-Units vial with 1 mL of sterile sodium chloride (0.9%), a single dose of 50 U/kg is administered immediately by bolus IV injection over 5 minutes. A second dose can be administered 24 to 48 hours later if there is evidence of persistent MTX. In cases of IT MTX overdose, a fixed dose of glucarpidase (2000 Units) reconstituted in sterile 0.9% sodium chloride is administered intrathecally over 5 minutes.[50,79] With excessive MTX dosing, the

glucarpidase could be given IV and IT simultaneously. As compatibility studies have not been performed, glucarpidase should not be mixed with other agents. Glucarpidase should be refrigerated (2°C to 8°C), but not frozen.

AVAILABILITY

Glucarpidase is available in single-use glass vials containing glucarpidase (1000 Units) with lactose (10 mg), buffered to pH 6.5 to 8.0 with Tris-HCl and zinc buffer. At the time of writing, glucarpidase has not yet received US FDA or European marketing approval. Glucarpidase for IV administration may be obtained in the United States under an open-label treatment protocol (ClinicalTrials.gov identifier: NCT00481559). US emergency inquiries, supply details, and procedural details can be directed to AAIPharma: 866-918-1731 (for intravenous emergencies) or BTG: 888-327-1027 (for intrathecal emergencies). Points of contact for other countries, IRB approval, IRB emergency exemption, and intrathecal emergency-use IND procedures are detailed at the manufacturer's and FDA's websites (www.btgplc.com/BTGPipeline/273/Voraxaze.html; http://www.btgplc.com/Voraxaze/284/VoraxazeUSSupplies.html; www.fda.gov/cder/cancer/singleIND.htm.).[57] Ongoing or anticipated clinical trials (eg, ClinicalTrials.gov identifiers: NCT00481559, NCT00634322, NCT00634504, NCT00727831) or specialty cancer centers that may have access to this antidote might also serve as a resource, particularly after hours or on weekends.

SUMMARY

Glucarpidase is a bacterially derived metalloenzyme used in the treatment of MTX toxicity. It cleaves MTX in the serum compartment to rapidly reduce serum MTX concentrations. Ongoing studies are addressing the extent and consequences of concurrent enzymatic destruction of folate and leucovorin and product immunogenicity. Glucarpidase does not substitute for leucovorin, which counteracts persistent intracellular and CNS MTX. In most cases glucarpidase administration should be separated from the leucovorin administration by 2 to 4 hours.

SPECIAL CONSIDERATIONS (SC3)

EXTRAVASATION OF XENOBIOTICS

Richard Y. Wang

Extravasational injuries are among the most consequential local toxic events. When an antineoplastic leaks into the perivascular space, significant necrosis of skin, muscles, and tendons can occur with resultant loss of function. The initial manifestations may include swelling, pain, and a burning sensation that can last for hours. Days later, the area may become erythematous and indurated and can either resolve or proceed to ulceration and necrosis.[30] These early findings may sometimes be difficult to distinguish from other forms of local drug toxicity, such as irritation and hypersensitivity where either the antineoplastic or its vehicle (ethanol, propylene glycol) can cause local irritation as defined by an inflammatory response. Some of the therapeutics associated with local irritation include fluorouracil, carmustine, cisplatin, and dacarbazine. The local irritation and hypersensitivity manifestations are self-limiting and typified by an immediate onset of a burning sensation, pruritus, erythema, and a flare reaction of the vein being infused. Pretreatment with an antihistamine can prevent some of the hypersensitivity manifestations.[38] Drugs reported to cause hypersensitivity reactions include daunorubicin, doxorubicin, idarubicin, and mitoxantrone. When local reactions cannot be differentiated, it is always best to presume extravasation and manage the situation accordingly.

The occurrence of these extravasational events appears to be about 50 times more frequent in the hands of the inexperienced clinician.[14] Several factors are associated with extravasational injuries from peripheral intravenous lines, including (a) patients with poor vessel integrity and blood flow, such as the elderly, those who undergo numerous venipunctures, and those who have received radiation therapy to the site; (b) limited venous and lymphatic drainage caused by either obstruction or surgical resection; and (c) the use of venous access overlying a joint, which increases the risk of dislodgments because of movement.[13,30] Extravasational injuries from implanted ports in central venous vessels can occur from inadequate placement of the needle, needle dislodgment, fibrin sheath formation around the catheter, perforation of the superior vena cava, and fracture of the catheter.[32] When extravasation from a port is suspected and radiographic studies are not diagnostic, a CT scan of the chest with contrast is necessary for evaluation.[1]

The factors associated with a poor outcome from extravasational injuries include (a) areas of the body with little subcutaneous tissue, such as the dorsum of the hand, volar surface of the wrist, and the antecubital fossa, where healing is poor and vital structures are more likely to be involved; (b) increasing concentrations of extravasate; (c) increased volume and duration of contact with tissue; and (d) the type of chemotherapeutic.[30,31] Vesicants, such as doxorubicin, daunorubicin, dactinomycin, epirubicin, idarubicin, mechlorethamine, mitomycin, and the vinca alkaloids, result in more significant local tissue destruction. Mitomycin infusions can cause dermal ulcerations at venipuncture

sites remote from the location of administration.[28] The anthracycline antibiotics are associated with a higher incidence of significant injuries and delayed healing, which may be a result of their slow release from bound tissue into surrounding viable tissue. Doxorubicin extravasation is associated with local tissue necrosis in approximately 25% of cases. The extravasational injuries from taxanes appear similar to the vesicants, but are milder in response and more delayed in presentation.[3,29] Prevention is the best form of therapy for these injuries. Specialized nursing care and the use of indwelling central venous catheters limit the extent of these injuries.

MANAGEMENT

The treatment for extravasational injuries is somewhat controversial, varying from conservative care to early surgical debridement and the use of selective antidotes.[33] This uncertainty is a result of the limited number of clinical cases available for study and the discordance between animal studies and human experience. However, general management guidelines for an extravasation and their theoretical foundations exist (Table SC3-1).[6,9]

Once extravasation is suspected, the infusion should be immediately halted. A physician should be notified and the xenobiotic, its concentration, and the approximate amount infused should be noted. The venous access should be maintained so that aspiration of as much of the infusate as possible can be performed and an antidote can be administered, if indicated. Injection of normal saline into the catheter to dilute the extravasate may be beneficial.[17,33] The intermittent local application of ice and elevation of the extremity should be done for 48 to 72 hours so as to limit further progression of the xenobiotic and the development of dependent edema. Cooling the area is believed to prevent cell injury by reducing the amount of xenobiotic absorbed by the tissue and lowering the cellular metabolic rate.[18,37] With just cold application and strict elevation, only 13 (11%) of 119 patients with mild extravasations required surgical intervention for their injuries.[22] In the past, heat was recommended to disperse the agent, but investigations with mice treated with intradermal doxorubicin demonstrated that this practice increased the area of skin ulceration.[11,22] However, dry, warm compresses are still recommended for the vinca alkaloids and etoposide to promote systemic uptake.[6] This is combined with the immediate and local infiltration with hyaluronidase to enhance absorption (Table SC3–1). The amount of hyaluronidase administered at the site ranges from 150 to 900 Units, and the chosen concentration of the solution depends on the area to be treated. For extravasational injuries involving a small area, the initial solution of 150 Units/mL may be adequate. Otherwise, the solution may be diluted by 10-fold with 0.9% NaCl to increase the amount of volume that would be needed to treat a larger surface area. If the intravenous cannula is still accessible, 1 mL of hyaluronidase can be administered through the catheter. Wounds that are either cancerous or infected should not be treated with hyaluronidase stored in a refrigerator. Patients treated with hyaluronidase need to be monitored for allergic reactions, such as anaphylaxis, although the newer human recombinant form (Hylener) is less allergenic than previous animal derivatives.

The wound should be observed closely for the first 7 days, and a surgeon consulted if either pain persists or evidence of ulceration

TABLE SC3–1. Management of Extravasational Injuries[6,16]		
Therapy		**Purpose/Mechanism**
General	Stop infusion and maintain intravenous cannula at the site.	
	Aspirate extravasate from the site by accessing the original intravenous cannula.	Minimizes amount of antineoplastic localized at the site.
	Irrigation of subcutaneous tissue at the site with 0.9% sodium chloride by accessing the original intravenous cannula.	
	Apply dry cool compresses for 1 hour, every 8 hours for 3 days.	Localizes area of involvement and diminishes cellular uptake of the antineoplastic.
	Elevate extremity and administer analgesia.	Promotes drainage, prevents dependent edema, and provides comfort.
Specific		
Anthracyclines	Dexrazoxane 1000 mg/m^2, daily (max. 2000 mg per day), on days 1 and 2, and 500 mg/m^2 on day 3 (max. 1000 mg).	Limits free radical formation.
Mechlorethamine	IV sodium thiosulfate: Take 4mL of 25% sodium thiosulfate and add to 21mL of sterile water for injection to make an isotonic (4%) concentration.	Prevents tissue alkylation
	Infiltrate the site of extravasation.	
Mitomycin	Dimethyl sulfoxide (DMSO): 55%–99%. Applied topically and allowed to dry.	Free radical scavenger.
Vinca alkaloids and epipodophyllotoxins	Hyaluronidase: Inject, intradermally or subcutaneously, 150–900 Units into the site.	Degrades hyaluronic acid to enhance systemic absorption
.	Dry warm compresses.	Promotes systemic absorption.

secondary infection. The use of intravenous fluorescein or other dye indicators can aid in identifying viable tissue.[2] The patient may require surgical reconstruction or skin grafts depending on the extent of the injury.

ANTIDOTES

Antidotal therapy should be considered when the extravasate is known to respond poorly to conservative care. The vesicants are associated with a significantly worse outcome, and when the exposure is large, a more aggressive approach should be initiated. Otherwise, conservative supportive management may be adequate. The specific antidotal treatments can be divided into several categories based upon their mechanism of action, one of which is the reduction of the inflammatory response through the application of steroids. Hydrocortisone has been used in varying concentrations (50–200 mg) as either subcutaneous or intradermal injections for doxorubicin and the vinca alkaloids,[4,14,23,36] and as a topical cream.[17] Corticosteroids may have only a limited role in doxorubicin-induced lesions because inflammatory cells do not predominate at the wound site.[8] Corticosteroids should not be added to doxorubicin infusions, because the drugs are chemically incompatible.[35] A prophylactic approach is to inactivate the drug by affecting the pH of the environment. The administration of 5 mL of 8.4% sodium bicarbonate through the same IV line to decrease the DNA binding of doxorubicin was advocated in 1980.[5] The use of sodium bicarbonate should not be considered as a routine treatment because its intrinsic hyperosmolarity can cause tissue necrosis.[12] Sodium thiosulfate is recommended for mechlorethamine extravasations, and is believed to work by inactivating the xenobiotic by reacting with the active ethylenimmonium ring.[13,27] The site should be infiltrated with 2 mL of a sterile sodium thiosulfate 0.17 M solution for each mg of mechlorethamine and then ice compresses are applied intermittently for 48 to 72 hours.[6]

Finally, there are antidotes, such as dimethyl sulfoxide (DMSO), that scavenge the free radicals that are believed to cause tissue damage from doxorubicin. Dimethyl sulfoxide has been shown to be beneficial for anthracycline extravasations in both animal and human clinical trials.[7,10,23,27,34] The concentration of DMSO used ranged from 55–99% and was applied topically with intermittent cool compresses.[7,23,26] Some of the other beneficial properties of DMSO are its antiinflammatory, analgesic, and vasodilatory effects, and its ability to promote systemic absorption of the chemotherapeutic at local sites.[24] However, the role for DMSO in the treatment of anthracycline extravasations has become secondary because of the efficacy of dexrazoxane for these exposures and the preparations necessary to make DMSO available in the clinical setting.[21] Also, DMSO is not recommended with the use of dexrazoxane for the treatment of anthracycline extravasations. The systemic administration of dexrazoxane limits anthracycline-induced skin lesions in a murine model[19] and used successfully in patients following doxorubicin[20] and epirubicin[15,19] extravasations. Dexrazoxane was given to these patients over 3 days intravenously at a starting dose of 1000 mg/m^2. In two prospective, open-label, single-arm, multicenter clinical trials, the systemic administration of dexrazoxane within 6 hours of anthracycline extravasation resulted in the need for surgical resection of the wound site in only 1 of 54 (1.8%) patients.[25] Dexrazoxane (Totect) is approved by the FDA for use in the treatment of anthracycline extravasation.[16] This antidote is administered as an infusion over 15-30 min. at a site distant to that of the extravasation because of its irritating property. Cool compress at the site of the extravastion is discontinued for 15 minutes prior to therapy to promote the antidote's perfusion at the site. The dose of dexrazoxane (see Table SC3–1) is decreased for patients with diminished renal function (creatinine clearance < 40 mL/min). Patients need to be monitored with CBC and serum AST/ALT because dexrazoxane can cause reversible bone marrow suppression and elevated

appears.[30] However, in severe extravasations—where there is a high incidence of necrosis because of the type of drug (doxorubicin), the volume or concentration, and any area in which there may be significant long-term morbidity (over joints)—early surgical consultation is warranted. If tissue ulceration occurs, initial management may be restricted to sterile dressings to prevent secondary infections. After the area of necrotic skin has evolved to the point where it can be clearly delineated from surviving tissue, surgical debridement may be beneficial to limit

concentrations of these liver enzymes. Additional clinical evidence needs to be gathered to better define the medical management of other antineoplastic extravasations. Although the overall incidence of extravasations with antineoplastics is small, the associated morbidity may be significant. Prevention is the best form of therapy.

CHAPTER 54

MISCELLANEOUS ANTINEOPLASTICS

Richard Y. Wang

The anthracyclines,[31,70,118] nitrogen mustards,[1,27,45,64,65,70,95,112,118,129] and platinum-based antineoplastics[23,24,41,44,57,68,73,76,80,88,97,108] are discussed in this chapter because of their increased likelihood for overdose based on past reports and current clinical use.

ANTHRACYCLINES
Doxorubicin

Daunorubicin and doxorubicin share many common indications for cancer therapy, but they differ in that doxorubicin is used in solid tumors such as breast carcinoma. The clinical toxicity of the anthracyclines is limited by the use of structural analogs (eg, epirubicin, idarubin) and liposomal encapsulated formulations (pegylated liposomal doxorubicin).

■ PHARMACOLOGY

The antineoplastics derived from the bacterium *Streptomyces* are dactinomycin, daunorubicin, doxorubicin, bleomycin, mitomycin, and plicamycin. Only plicamycin crosses the blood–brain barrier. The terminal elimination half-life for doxorubicin is about 30 hours.[50] Doxorubicin and daunorubicin are both eliminated by the liver and patients with hepatic dysfunction should have their dosage decreased. Delayed drug elimination contributes to increased drug area under the drug concentration versus time curve (AUC) and peak concentration, which are associated with myelosuppression and cardiac toxicity, respectively.[75] The mechanism of therapeutic action of the anthracyclines is attributed to DNA intercalation[101] and inactivation of topoisomerase II.[117] These xenobiotics are metabolized to active metabolites, which have lesser degrees of activity than their parent compounds. A typical dose schedule for daunorubicin is 30 to 60 mg/m^2 daily for 3 days; for doxorubicin, 45 to 60 mg/m^2 every 18 to 21 days.

■ PATHOPHYSIOLOGY

The red anthracycline antibiotics—dactinomycin and doxorubicin—can be associated with cardiotoxicity, which limits their therapeutic use. The mechanism responsible for their therapeutic effects is different from that which causes cardiotoxicity.[117] The purported mechanism of cardiac toxicity is from the formation of free radicals and impaired intracellular calcium.[89,96] Doxorubicin and dactinomycin are quinone derivatives and can be reduced to free radicals. These metabolites are extremely cytotoxic through the promotion of lipid peroxidation. Paraquat and bleomycin have similar mechanisms of toxicity. The limited efficacy of free radical scavengers (α-tocopherol, *N*-acetylcysteine) for anthracycline cardiotoxicity led to an understanding of the importance of iron as a cofactor for these radical-producing reactions.[90] The anthracyclines have a high affinity for metal ions. Doxorubicin has an iron (Fe^{3+}) binding constant of 10^{41}, which is comparable to deferoxamine.[48] The heart's increased susceptibility to free radicals is attributed to its lack of sufficient enzyme activity responsible for free radical scavenging.[38]

■ CLINICAL MANIFESTATIONS

The cardiotoxic manifestations can be divided into acute and late-onset categories. The various findings described with acute toxicity include dysrhythmias, ST and T-wave changes on the electrocardiogram (ECG), diminished ejection fraction that usually resolves over 24 hours, and sudden death.[16,114] Abnormal findings on ECG are present in 41% of patients receiving doxorubicin.[7,54,74,103,114,125,130,132] They are neither dose related nor associated with the development of cardiomyopathy. Acute pericarditis and myocarditis resulting in conduction defects and congestive heart failure are also reported.[15] Animal studies with doxorubicin demonstrate beneficial effects of adrenergic antagonists for toxicity because of elevated concentrations of catecholamines,[15] although the use of β-adrenergic antagonists in the potential setting of diminished cardiac output needs to be considered.

Significant cardiotoxicity results from elevated peak serum concentrations and accounts for continuous and periodic infusions practiced in therapy. In cumulative doses, the anthracycline antibiotics cause a congestive cardiomyopathy that typically presents at 1 to 4 months after exposure depending on the toxicity of the xenobiotic.[62] The condition is irreversible and is associated with a 48% mortality.[98] This drug-induced congestive heart failure is associated with pathognomonic changes on electron microscopy that can distinguish it from infectious and ischemic etiologies. These histologic changes include reduced number of myocardial fibrils, and mitochondrial and cellular degeneration.[13] The incidence of late-onset cardiotoxicity for doxorubicin is between 1% and 10% when the cumulative dose is less than 450 mg/m^2, and becomes greater than 20% when more than 550 mg/m^2 (comparable to dactinomycin, 950 mg/m^2, and epirubicin, 720 mg/m^2) is administered.[84,124] Daunorubicin and mitoxantrone are associated with a 2% incidence at the cumulative doses of 600 mg/m^2 and 140 mg/m^2, respectively.

The best way of monitoring cardiac function during therapy is to use radionuclide cineradiography to measure the left ventricular ejection fraction.[3] Therapy should be discontinued when the ejection fraction falls below 50%. Two-dimensional echocardiography can demonstrate left ventricular wall thickening and fractional shortening from anthracycline overexposure. Newer approaches used to assess for early or subclinical signs of cardiac dysfunction from these agents include cardiac-specific contractile protein, troponin, cardiac natriuretic peptide, and radionuclide-tagged monoclonal antibody imaging.[21,25,37,69]

Factors associated with an increased risk for cardiotoxicity include mediastinal irradiation, preexisting cardiac disease in children, age more than 70 years, and the concomitant use of cyclophosphamide, paclitaxel, and other anthracyclines.[15] Also, the proximate therapeutic use of the monoclonal antibody to human epidermal growth factor receptor 2 (HER2), trastuzumab, with anthracyclines appears to enhance cardiac toxicity.[33] Children are at risk for developing increased left ventricular afterload from doxorubicin toxicity because of the drug's ability to inhibit myocardial growth, which can lead to a disproportionate ratio of left ventricular wall thickness to left

ventricular chamber size.[77] Fatalities are reported with minimum doses of 150 to 333 mg/m[2], and occur within 1 to 16 days after exposure.[31]

Myelosuppression and mucositis are other effects associated with the use of the anthracycline agents. They typically occur in 1 to 2 weeks, and patients recover.[10] The white cells are affected more than either the red cells or platelets. Patients with diminished drug clearance due to hepatic failure are at risk for the development of these findings.

Mitoxantrone is recognized to be less toxic than doxorubicin and daunorubicin. Major organs of toxicity remain the heart, bone marrow, and gut. Gastrointestinal effects are less severe and less frequent with mitoxantrone than with doxorubicin.[110] Four cases of mitoxantrone overdose are reported in the literature.[53,110] Common to these events is a 10-fold error in dosing (100 mg/m[2] instead of 10 mg/m[2]), early onset of nausea with vomiting, and myelosuppression with fever. Acute decreased cardiac contractility was observed by echocardiography in one patient who was asymptomatic.[53] Otherwise, no patients developed dysrhythmias, congestive failure, ECG changes, or elevated creatine phosphokinase levels early after exposure. Three patients developed fatal congestive heart failure (CHF) from 1 to 4 months later.[110]

■ MANAGEMENT

Dexrazoxane is a specific antidote for doxorubicin; otherwise, management is largely supportive. Monitoring for cardiotoxicity and pancytopenia is necessary. A baseline chest radiograph, electrocardiogram, and echocardiogram to determine left ventricular ejection fraction (at rest and/or with stress) are required. Endomyocardial biopsy and cardiac catheterization can assist in distinguishing other causes of cardiac dysfunction. Left ventricular function is the best predictor for cardiomyopathy.[43,104] A 10% absolute decrease in the left ventricular ejection fraction (LVEF) or a drop in LVEF of 50% from baseline is a significant finding for the discontinuation of further anthracycline therapy.[104] Although digoxin and furosemide should be used to manage acute CHF, a variable response can be expected.[110] Digoxin and low-dose verapamil benefit patients treated with doxorubicin; however, this benefit may be limited by the severity of the disorder.[47,126] At higher doses of verapamil, hypotension and heart block were observed, which limited further use.[92,116] The role for angiotensin-converting enzyme inhibitor (enalapril) as an effective treatment for congestive cardiomyopathy remains investigatory.[61,111]

Dexrazoxane is a cardioprotectant that limits the adverse cardiac effects of doxorubicin by chelating intracellular iron, which mediates the formation of free radical cellular damage. In clinical trials, patients receiving dexrazoxane had smaller decreases in LVEF per dose of doxorubicin, had fewer histologic changes on cardiac biopsy, were better able to tolerate doxorubicin doses greater than 600 mg/m[2], and had a lower occurrence of serum cardiac troponin T elevations than did patients who were not pretreated with dexrazoxane.[77,78,113] The current role of this chelator is to limit cardiotoxicity in patients receiving more than 300 mg/m[2] of doxorubicin.[106] It is administered 30 minutes before doxorubicin in a 10:1 ratio. Dexrazoxane increased the systemic clearance of epirubicin in a clinical trial, which may be an added benefit to patients with increased exposure.[8] Further investigations are required to determine the optimal use of dexrazoxane in children receiving anthracycline therapy and in patients with overdose exposures. Another cardioprotectant under investigation is monohydroxyethylrutoside. Monohydroxyethylrutoside is a semisynthetic flavonoid that can chelate iron and scavenge free radicals, although the contribution of this action to its cardioprotective effects against doxorubicin-induced toxicity remains unclear.[9] In experimental models, monohydroxyethylrutoside decreased doxorubicin-induced cardiotoxicity as measured by ST segment elevation on ECG[119] and left ventricular function.[60] Clinical trials are lacking for this agent.

■ ENHANCED ELIMINATION

The anthracyclines are highly protein bound and have a large volume of distribution, which makes them unlikely candidates for hemodialysis. However, the early institution of hemoperfusion may enhance elimination. In an animal model, serum doxorubicin clearance could be enhanced up to 20-fold with hemoperfusion.[128] Factors determining this were duration of therapy, rate of flow, and the use of a 2% acrylic hydrogel-coated cartridge. Three patients with a doxorubicin overdose were treated with hemoperfusion, one with an Amberlite cartridge, and all had a rapid reduction in their serum levels.[31] One survived a 10-fold error in dosing. In a patient with a mitoxantrone overdose of 98 mg intravenously (IV), hemoperfusion was begun within hours, but in two trials, only 0.287 and 0.236 mg of drug were removed.[53]

NITROGEN MUSTARDS
Mechlorethamine

■ PHARMACOLOGY

The nitrogen mustards are cyclophosphamide, ifosfamide, chlorambucil, mechlorethamine, and melphalan. Their indicated uses include immunosuppression (eg, controlling graft-versus-host rejection, collagen vascular diseases) and chemotherapy. The tumoricidal activity of these xenobiotics is the result of the formation of reactive intermediates that bind to nucleophilic moieties on DNA, which inactivates DNA synthesis. Unlike the other xenobiotics, cyclophosphamide and ifosfamide require P450 isoenzymes to achieve their alkylating properties. Mechlorethamine is the original compound from which all of the others were derived. It is highly reactive when it comes in contact with water and undergoes rapid chemical transformation. Local reactions caused by mechlorethamine spillage (eg, extravasation) include tissue injury and thrombophlebitis (see Special Considerations SC 3–Extravasation of Xenobiotics). Nonenzymatic hydrolysis is the major route by which the nitrogen mustards are metabolized, thus accounting for their relatively short elimination half-lives (ie, less than 3 hours).[12] Cyclophosphamide, ifosfamide, and chlorambucil have active metabolites, which prolongs their alkylating activity after administration.[66]

■ CLINICAL MANIFESTATIONS

Chlorambucil and ifosfamide can produce altered mental status and seizures from therapeutic use or from an overdose.[19,45] Both antineoplastics undergo hepatic N-dechloroethylation to produce chloroacetaldehyde, which is purported to be a nervous system toxin.[72] Encephalopathy occurs in 9% of patients receiving 5 g/m[2] of ifosfamide, and is more frequent with oral than with IV administration because of the first-pass effect and increased chloroacetaldehyde production.[81] Seizures are more commonly associated with chlorambucil. Acute overdoses reported in the literature are all from the oral route, and range in dosing from 1.5 to 6.8 mg/kg (therapeutic is 0.1 to 0.2 mg/kg).[5,20] The seizures occur within 6 hours, may appear as generalized tonic–clonic activity or staring spells, and can last for 24 hours. However, in one instance in which therapeutic dosing was increased, seizures occurred 17 hours later. This delay may be attributed to a lower serum

concentration or a slower time to peak than in the overdose setting. A similar reasoning would explain why a patient with a chronic overdose of 4.1 mg/kg over 5 days did not sustain central nervous system (CNS) toxicity.[40] Patients with increased likelihood for seizures include those with underlying seizure disorders or with nephrotic syndrome, which can alter pharmacokinetics.[102] Electroencephalograms (EEGs) demonstrated multiple paroxysms of bilaterally symmetric 2 to 3-Hz spikes and slow high-voltage rhythmic slowing that progressed to slower bursts of rhythmic spike and wave discharge in a child with an acute overdose.[20] Myelosuppression occurs in patients with both acute and chronic overdoses, and can present as late as 41 days postexposure. Recovery is expected within 1 week of the nadir, and granulocyte colony-stimulating factor (G-CSF) treatment may be necessary.[64] Renal failure from an acute overdose with ifosfamide is reversible following the immediate institution of hemodialysis.[45]

Cyclophosphamide and its analog ifosfamide induce hemorrhagic cystitis from their irritating metabolite acrolein. This occurs in approximately 5% to 10% of patients who receive therapy.[18,30] The incidence of cystitis does not appear to be related to the total dose and administration route, age, or gender. The course is usually self-limiting, although blood transfusions may be required. Water retention is observed in patients receiving more than 50 mg/kg of cyclophosphamide.[34] This effect is attributed to the activity of the alkylating metabolite on the renal tubule and is observed at 6 to 8 hours after administration. The patient typically develops decreased urinary output, increased urine osmolality, and decreased serum osmolality, which is self-limiting, lasting for about 12 to 16 hours.

In the overdose setting, cyclophosphamide can cause dysrhythmias, myocardial necrosis, hemorrhagic pericarditis, and death. ECG changes are noted at doses of 120 mg/kg and heart failure and myocarditis at doses greater than 150 mg/kg.[6,86] Diminished QRS voltage has been noted on the ECG, which is attributed to myocardial swelling from edema or hemorrhage. An ordering error led to the death of one patient and to irreversible cardiac damage in another patient from cyclophosphamide overdose. These two patients received 6520 mg daily for 4 consecutive days, when the amount was to be divided over 4 days.[100] The onset of heart failure can be sudden and patients older than 50 years of age, and those with a history of cardiac dysfunction or prior treatment with anthracyclines, are at greatest risk for cardiac toxicity.[115]

■ MANAGEMENT

Recommendations for patients with an acute chlorambucil exposure include routine gastrointestinal decontamination, a 6-hour observation, a determination of a complete blood count (CBC) and hepatic enzymes, and a follow-up CBC weekly for 4 weeks.[121] Ifosfamide-induced encephalopathy can be managed with methylene blue (50 mg IV as a 1% solution), although the mechanism by which methylene blue acts is unknown.[72,131] Seizures are reported to be more effectively managed with benzodiazepines and barbiturates than with phenytoin.[5,129]

When gross hematuria from cyclophosphamide or ifosfamide therapy persists, treatments reported to be effective in the literature can be considered. These treatments include electrocauterization, systemic vasopressin,[99] intravesical administration of silver nitrate,[72] formalin,[46,107] prostaglandin F2,[109] and hydrostatic pressure.[58] Some of the preventive therapies that seem to reduce this occurrence include adequate hydration for dilution effect, frequent bladder emptying, IV administration of 2-mercaptoethane sulfonate sodium (MESNA), and intravesical administration of N-acetylcysteine.[18] The thiol group of N-acetylcysteine is believed to directly interact with acrolein to limit its irritating effect on the bladder epithelium. MESNA is believed to work

by inactivating acrolein to an inert thioether.[59] The IV dose of MESNA is 20% of the cyclophosphamide or ifosfamide amount (wt/wt) and administered during therapy and again at 4 and 8 hours. MESNA is used during standard-dose therapy for ifosfamide and high-dose therapy for cyclophosphamide. In the overdose setting, MESNA does not protect patients from the renal toxic effects of these agents and hemodialysis is indicated. Hemodialysis effectively enhances the elimination of ifosfamide and its metabolites when instituted soon after exposure, and it is more effective than hemoperfusion (Adsorba 300 C, Gambro 300 g active carbon) in removing ifosfamide.[45]

Patients with large exposures to cyclophosphamide require baseline ECGs and echocardiograms. Intravenous fluid restriction, digoxin, and furosemide were successfully used to treat a patient with cyclophosphamide-induced congestive cardiomyopathy.[123]

PLATINOIDS
Cisplatin   Carboplatin

■ PHARMACOLOGY

The cytotoxic effects of the platinum-containing compounds were first recognized in 1965. Since then, many types have been derived. The ones of clinical significance are cisplatin, carboplatin, and oxaliplatin.[87] The latter two agents were designed to reduce the incidence of nephrotoxicity and to counter drug resistance to cisplatin. Differences in chemical structure exist among these antineoplastics. Most notably, cisplatin is an inorganic and carboplatin an organic compound. Similarities exist in their mechanism of toxicity, which is the binding of platinum to DNA to form inter- and intrastrand bonds, which lead to DNA dysfunction and strand breakage. These xenobiotics are eliminated from the body primarily in the urine and at varying rates. The amount eliminated at 24 hours is 25% for cisplatin and 90% for carboplatin. Patients with decreased creatinine clearance (< 30 mL/min) will have prolonged elimination half-lives of platinoids.[39]

■ PATHOPHYSIOLOGY

Renal failure from renal tubular necrosis occurs with cisplatin in a dose-dependent manner. Upon entering the cell, cisplatin forms a cationic complex when the chloride ions are nonenzymatically displaced by water molecules. The reactive complex covalently binds to DNA to disrupt replication and transcription, resulting in cell death. The formation of the hydrated platinum complex is favored by a low chloride concentration in the environment; thus, a sodium chloride infusion promotes the native state of cisplatin by preventing hypochloremia. The presence of alanine aminopeptidase and N-acetyl-D-glucosaminidase in the urine can be early indicators of renal tubular damage.[32,36,49]

The sensory neuropathy associated with these platinum-containing antineoplastics can be attributed to their accumulation and toxicity at the dorsal root ganglion, which depends on the water solubility and chemical reactivity of these xenobiotics.[105] Clinical pathologic evaluation demonstrates increased platinum content at the dorsal root ganglion following cisplatin therapy, which suggests that the increased

vascularity and fenestration of the endothelium at this tissue site contributes to the uptake of cisplatin.[51,63]

■ CLINICAL MANIFESTATIONS

The more common manifestations of toxicity with cisplatin during therapy are renal dysfunction, auditory impairment, and peripheral sensory neuropathy. The other antineoplastics recognized to cause a peripheral neuropathy are the Vinca alkaloids and the taxoids. Oxaliplatin-induced neuropathy is triggered or enhanced by exposure to cold and can subside over several months.[42] Myelosuppression is a dose-limiting factor for carboplatin and iproplatin, which does not occur with cisplatin. At a carboplatin dose of 800 mg/m^2, 25% of patients develop marrow toxicity.[93] The marrow effects are delayed, with nadir occurring 3 to 5 weeks after the start of therapy. Patients developing an anemia within the first week of cisplatin therapy should be evaluated for hemolytic anemia.[26]

The sources of error associated with cisplatin are frequency of administration (total dose versus over a period of time), mistaking it for carboplatin, and writing the wrong dose.[28,97] Manifestations in the overdose setting involve neurologic, visual, hearing, bone marrow, pancreatic, and renal disorders.[108] The most common renal disorder is renal failure, which is dose-related and begins at 50 mg/m^2. At this dose, approximately 30% of patients treated with cisplatin develop renal failure and a rise in serum BUN and creatinine typically occurs at 1 to 2 weeks posttreatment. Attributed to the renal toxicity is electrolyte disorders, include hypomagnesemia, hypocalcemia, and hyponatremia.[41] Hyponatremia is an uncommon finding with cisplatin exposure and is attributed to either sodium-wasting nephropathy from renal tubular dysfunction or syndrome of inappropriate secretion of antidiuretic hormone (SIADH). At doses greater than 200 mg/m^2, the development of seizures, encephalopathy, and irreversible peripheral sensory neuropathy is of concern.[11,29,56,92,93,94] At this dose, visual impairment may occur within the first week of exposure.[24,80,127] This can include temporary visual loss, with permanent loss of color discrimination. Physical examination of the anterior chamber and fundus of the eye will be normal; however, an electroretinogram will demonstrate a disorder with the postphotoreceptor neural function.[68] Some other ocular disorders are papilledema and retrobulbar neuritis. High-frequency (2000 Hz) hearing loss is evident 2 to 3 days after exposure to doses greater than 500 mg/m^2.[22]

■ MANAGEMENT

Renal protection and enhanced elimination of platinum are the two primary goals in the management of a cisplatin overdose. Expectant management for myelosuppression and neurotoxicity can follow. Hydration with 0.9% NaCl solution and an osmotic diuretic (eg, mannitol) should be administered to achieve a high urine output (eg, 1 to 3 mL/kg/h) for 6 to 24 hours postexposure. Sodium chloride diuresis both promotes the inactive state of cisplatin and decreases the urine platinum concentration to limit nephrotoxicity during therapy.[4,122] In the setting of nonoliguric renal failure, careful hydration is recommended to maintain urinary output, because platinum renal excretion is directly related to urinary flow and independent of creatinine clearance.[24] Aside from evaluating BUN and creatinine, assessment of renal function can include glomerular filtration, filtration fraction, and renal plasma flow.[52,82,83,91]

Amifostine (Ethyol™) and sodium thiosulfate are effective nephroprotectants. Amifostine's role is more preventative and its use is approved by the US Food and Drug Administration (FDA) to protect against cisplatin-induced nephrotoxicity. However, additional benefits can include the limitation of myelosuppression, mucositis, and neurotoxicity.[2] Unlike thiosulfate, amifostine is activated intracellularly by alkaline phosphatase to scavenge free radicals, regenerate glutathione, prevent cisplatin-DNA adduct formation, and facilitate DNA repair.[71] The patient requires adequate hydration during amifostine infusion because hypotension can occur. Sodium thiosulfate is effective postexposure. Thiosulfate remains in the extracellular space to bind free platinum and limit cellular damage at the renal tubules. Little or no renal toxicity occurred in patients receiving as much as 270 mg/m^2 of cisplatin when thiosulfate was given as an IV bolus of 4 g/m^2 followed by infusion of 12 g/m^2 over 6 hours.[55,95] In a 14-year-old patient with renal failure, thiosulfate was continued at 2.7 g/m^2 a day until urinary platinum concentration was below 1 μg/mL.[41] Thiosulfate may offer the additional benefit of limiting neurotoxicity and should be administered to all patients after an overdose.[79,120] The effectiveness of thiosulfate is limited by the time in which it needs to be administered after exposure (ie, 1 to 2 hours). N-acetylcysteine and BNP7787 (2,2′-dithio-bis-ethanesulfonate) are being investigated as alternative rescue agents for cisplatin toxicity.[14,35,85] Also, BNP7787 is under clinical investigation to limit peripheral neuropathy from paclitaxel therapy.

Hemodialysis is ineffective in patients with cisplatin overdoses, likely as a result of high protein binding.[17] However, in patients with renal failure, hemodialysis may be beneficial when plasmapheresis is not available. Plasmapheresis was performed in four adults and there was a fall in blood serum platinum concentrations with clinical improvement.[23,24,57,67] In one incident, a patient received an overdose of 280 mg/m^2 and was plasmapheresed on day 12 of exposure.[24] After three daily treatments, the serum platinum concentration decreased from 2900 to 200 ng/mL and the patient had noticeable improvement in gastrointestinal and visual symptoms. On day 20, the serum platinum concentration rebounded to 700 ng/mL and the symptoms worsened. Further plasmapheresis lowered the concentration to 290 ng/mL by day 27 and symptoms improved. In another event, a patient received 300 mg/m^2 of cisplatin and received four daily treatments of plasmapheresis starting on day 6 postexposure.[67] The serum platinum concentration declined from 2979 to 430 ng/mL and the patient became more awake and less nauseous. On day 11, platinum concentrations rebounded to 834 ng/mL and fell to 279 ng/mL on reinstitution of plasmapheresis. The amount of platinum removed by three trials in this patient was approximately 4.6 mg. The author of the paper contends that plasmapheresis prevented the need for hemodialysis in renal failure. Other reports have noted an improvement in patients' mental status and hearing loss following the decline in the serum cisplatin (platinum) concentration from plasmapheresis.[23,57] Thus, plasmapheresis appears to be effective in cisplatin overdose and should be instituted immediately after exposure. Patients who remain symptomatic days later also may benefit.

SUMMARY

Anthracyclines, nitrogen mustards, and the platinum-based antineoplastics are some of the antineoplastic agents reported as overdoses in patients undergoing therapy. The primary clinical manifestations of toxicity for these agents include congestive dilated cardiomyopathy (anthracyclines), encephalopathy and seizures (nitrogen mustards), and renal failure (platinum-based agents). The management for these overdoses includes supportive care, enhanced elimination using plasmapheresis for cisplatin, and antidotal therapy, such as dexrazoxane for anthracyclines and amifostine for platinum-based agents. Although rescue agents are available, their effectiveness is markedly diminished in the postexposure period. Specialists in poison information and medical toxicologists need to maintain a current level of understanding of these exposures so they can better assist their patients and interact with other healthcare professionals.

CHAPTER 55
PHARMACEUTICAL ADDITIVES

Sean P. Nordt and Lisa E. Vivero

This chapter summarizes the available literature on commonly used additives associated with direct toxicities. Data on pharmacokinetics and mechanism of toxicity are presented where data are available. Although many additives are associated with hypersensitivity reactions, including anaphylaxis, these are not discussed because of their nonpharmacologic basis. However, excipients should always be considered as possible causative agents in patients developing hypersensitivity reactions (Table 55–1).

HISTORY AND EPIDEMIOLOGY

During the last century there were several US outbreaks of toxicity associated with pharmaceutical additives (Chap. 1). The 1937 Massengill sulfanilamide disaster is the most notorious of these epidemics. Diethylene glycol, an excellent solvent that is a nephrotoxin, was substituted for the additives propylene glycol and glycerin in the liquid formulation of a new sulfanilamide antibiotic because of lower cost.[24,58,65] As a result, more than 100 people died from acute renal failure.[24] More recently, outbreaks of acute renal failure occurred when diethylene glycol was used to solubilize acetaminophen in South Africa, Bangladesh, Nigeria, and Haiti; cough syrup in Panama; and teething powder in Nigera.[19,27,29,67,76,115,126]

In December 1983, E-Ferol, a new parenteral vitamin E formulation, was introduced. It contained 25 Units/mL of α-tocopherol acetate, 9% polysorbate 80, 1% polysorbate 20, and water for injection. At the time, no premarketing testing was required for new formulations of an already approved xenobiotic. Several months after its release, a fatal syndrome in low-birth-weight infants, characterized by thrombocytopenia, renal dysfunction, cholestasis, hepatomegaly, and ascites, was described.[1,102] Thirty-eight deaths and 43 cases of severe symptoms were attributed to E-Ferol. Vitamin E was thought to be the cause and E-Ferol was recalled from the market 4 months after its release. It is now believed that the polysorbate emulsifiers were responsible.[1]

There has been concern over potential mercury toxicity from the preservative thimerosal, a mercury derivative that has been used in parenteral vaccines for 70 years. Although there are a few reports of toxicity from both large oral and injectable thimerosal dosages, no evidence has yet shown toxicity to result from routine vaccination. Potential concerns of toxicity, particularly autism, have spurred ongoing efforts to eliminate thimerosal from vaccines wherever possible.

Although these additive-related occurrences are rare, relative to the frequency of pharmaceutical additive use, they illustrate the potential of pharmaceutical additive toxicity.

Pharmaceuticals are labeled specifically to focus attention on the active ingredient(s) of a product, thus giving the misimpression that additive ingredients are inert and unimportant. Additives, or excipients as they are more properly termed, are necessary to act as vehicles, add color, improve taste, provide consistency, enhance stability and solubility, and impart antimicrobial properties to medicinal formulations. Although it is true that most cases of excipient toxicity involve exposure to large quantities, or to prolonged or improper use, these adverse events are nonetheless related to the toxicologic properties of the excipient.

Prior to selecting the specific additives and quantity necessary for a drug formulation, the drug manufacturer must consider several factors, including the active ingredient's physical form, its solubility and stability, the desired final dosage form and route of administration, and compatibility with the dispensing container materials. The same active ingredient may require different excipients to impart appropriate pharmacokinetic characteristics to different dosage forms, such as in long-acting and immediate-release formulations. Similarly, multiple-dose injection vials containing the same active ingredients as single-dose vials specifically require the addition of a bacteriostatic agent not necessary for single-dose vials.

Unlike requirements for active ingredients, there is no specific US Food and Drug Administration (FDA) approval system for pharmaceutical excipients. As such, the FDA determines the amount and type of data necessary to support the use of a specific excipient on a case-by-case basis. Under current practice, only excipients that were previously permitted for use in foods or pharmaceuticals are defined as *generally recognized as safe* (GRAS), or "GRAS listed." All components of a pharmaceutical product, including excipients, must be produced in accordance with current good manufacturing practice standards to ensure purity. The Safety Committee of the International Pharmaceutical Excipients Council developed guidelines for the toxicologic testing of new excipients.[150] Because of patent protection laws, it was not until very recently that manufacturers were required to provide a list of inactive ingredients contained in all pharmaceutical products. Although it is becoming easier to identify pharmaceutical additives in products, information on their effects and the mechanisms by which they cause adverse responses are often unknown or difficult to obtain.

BENZALKONIUM CHLORIDE
Benzalkonium chloride (BAC), or alkyldimethyl (phenylmethyl) ammonium chloride, is a quaternary ammonium cationic surfactant composed of a mixture of alkyl benzyl dimethyl ammonium chlorides. Although it is the most widely used ophthalmic preservative in the United States, it is also considered the most cytotoxic (Table 55–2).[82,88] Benzalkonium chloride is also used in otic and nasal formulations, and in some small-volume parenterals. The antimicrobial activity of BAC includes gram-positive and gram-negative bacteria, and some viruses, fungi, and protozoa. Because of its rapid onset of action, good tissue penetration, and long duration of action, BAC is preferred over other preservatives. The concentration of BAC in ophthalmic medications usually ranges from 0.004% to 0.01%.[88] Strong BAC solutions (greater than 0.1%) can be caustic (Chap. 104).

■ OPHTHALMIC TOXICITY

Corneal epithelial cells harvested from human cadavers within 12 hours of death were exposed to a medium containing 0.01% BAC.[148] The surfactant properties of BAC resulted in intracellular matrix

TABLE 55–1. Potential Systemic Toxicity of Various Pharmaceutical Excipients

dissolution and loss of epithelial superficial layers. Following exposure to the medium, mitotic activity ceased and degenerative changes to corneal epithelium were noted. During a 24-hour observation period, epithelial cell cytokinetic or mitotic activity did not occur. Patients with a compromised corneal epithelium may be at increased risk for the adverse corneal effects of BAC.[148]

TABLE 55–2. Benzalkonium Chloride Concentrations of Common Ophthalmic Medications

Medication	Percent (%)
Artificial tears (various)	0.005-0.01
Acular (ketorolac)	0.01
Betagan (levobunolol)	0.004
Betoptic (betaxolol)	0.01
Ciloxan (ciprofloxacin)	0.006
Cyclogyl (cyclopentolate)	0.01
Decadron (dexamethasone)	0.02
Garamycin (gentamicin)	0.01
Glaucon (epinephrine)	0.01
Isopto Carpine (pilocarpine)	0.01
Murocoll-2 (scopolamine/phenylephrine)	0.01
Mydriacyl (tropicamide)	0.01
Phenylephrine (various)	0.005-0.01

Ocupress (carteolol)	0.005
Polytrim (polymyxin B sulfate/trimethoprim)	0.004
Timoptic (timolol)	0.01
Tobrex (tobramycin)	0.01
Visine (tetrahydrozoline)	0.01

Two case reports demonstrate the potential toxicity of BAC and the difficulty in recognizing it. A 36-year-old woman complained of decreased vision when she inadvertently switched from Lensrins, a contact lens cleaning solution, to Dacriose, an isotonic boric acid solution preserved with BAC. After 3 days, she had inflammation, pain, and decreased visual acuity. Examination of the cornea revealed many superficial punctate erosions of the epithelium. An in vitro experiment identified significant binding of BAC to soft contact lenses.[53] In the second case, a 56-year-old man diagnosed with keratoconjunctivitis sicca was treated with topical antibiotics and artificial tears containing BAC. Following 1 year of continual use, the patient developed intractable pain, photophobia, and extensive breakdown of the corneal epithelium. Not suspecting the BAC-containing products, the patient continued to use the artificial tears solution for another 9 years despite continued pain and decreasing visual acuity. Replacement with a preservative-free saline solution resulted in resolution of pain, photophobia, and corneal changes.[88]

There was a case series of the inadvertent intraocular use of balanced salt solution (BSS) preserved with BAC instead of preservative-free BSS in 12 patients undergoing phacoemulsification, a surgical technique to remove cataract lenses. The BSS was instilled in the anterior chamber. The operating room had run out of preservative-free BSS and, unbeknownst to the surgeon, it was replaced with the BAC-containing BSS, which contained 0.013% BAC. This is in excess of recommended concentration for intraocular use and is associated with corneal endothelial injury and edema. At 6-months follow-up, only one patient had slight improvement in visual acuity with the other 11 limited to only being able to count fingers from a distance of 2 feet.[89]

■ NASOPHARYNGEAL AND OROPHARYNGEAL TOXICITY

Human adenoidal tissue was exposed to oxymetazoline nasal spray preserved with BAC at concentrations ranging from 0.005 to 0.15 mg/mL for 1 to 30 minutes.[14] Irregular and broken epithelial cells occurred with all concentrations; however, it developed earlier and more frequently with the higher concentrations. The number of beating ciliary bodies also decreased as the duration and the concentrations increased. Benzalkonium chloride may decrease the viscosity of the normal protective mucous lining of the naso- and oropharynx, resulting in cytotoxicity.

Administration of one of three nasal steroid sprays preserved with either 0.031% or 0.022% BAC in the right nostril of rats twice daily for 21 days caused squamous cell metaplasia and a decrease in the number of goblet cells, cilia, and mucus.[15] No histologic changes occurred in rats receiving the preservative-free steroid or in tissue exposed to 0.9% sodium chloride solution administered into the left nostril as the control. Similarly, in another study, epithelial desquamation, inflammation, and edema occurred when 0.05% and 0.10% BAC was applied hourly to the nasal cavities of rats for 8 hours.[85] No lesions developed in the nasal cavities of rats receiving 0.01% BAC.

In an in vitro study, cultured human nasal epithelial cells were exposed to varying concentrations of BAC compared with another preservative, potassium sorbate (PS), with phosphate-buffered saline (PBS) as a control. Cell viability was greatly reduced at the higher concentrations of BAC compared with no decrease in cell viability in the PS or PBS groups. Additionally, at concentrations used clinically loss of microvilli, destruction of cell membranes, and poor cytoskeletal alignment demonstrated by electron microscope occurred.[74]

An in vitro study of human nasal mucosa exposed mucosa to either fluticasone or mometasone preserved with either BAC or PS at various concentrations measuring ciliary beat frequency. While PS did not affect ciliary beat frequency at any concentration, BAC adversely affected ciliary beat frequency. At lower concentrations, BAC slowed ciliary beat frequency and brought it to standstill at higher concentrations.[75]

BENZYL ALCOHOL
Benzyl alcohol (benzene methanol) is a colorless, oily liquid with a faint aromatic odor that is most commonly added to pharmaceuticals as a bacteriostatic agent (Table 55-3). In 1982, a "gasping" syndrome, which included hypotension, bradycardia, gasping respirations, hypotonia, progressive metabolic acidosis, seizures, cardiovascular collapse, and death, was first described in low-birth-weight neonates in intensive care units.[20,60,94] All the infants had received either bacteriostatic water or sodium chloride solution containing 0.9% benzyl alcohol to flush intravenous catheters or in parenteral medications reconstituted with bacteriostatic water or saline.[20,60] The syndrome occurred in infants who had received greater than 99 mg/kg of benzyl alcohol (range, 99 to 234 mg/kg).[60] The World Health Organization (WHO) currently estimates the acceptable daily intake of benzyl alcohol to be not more than 5 mg/kg body weight.[22]

■ PHARMACOKINETICS

In adults, benzyl alcohol is oxidized to benzoic acid, conjugated in the liver with glycine, and excreted in the urine as hippuric acid. The immature metabolic capacities of infants diminish their ability to metabolize and excrete benzyl alcohol.[60] Preterm babies have a greater ability to metabolize benzyl alcohol to benzoic acid than do term babies, but
FIGURE 55–1. The oxidative metabolism of benzyl alcohol.

are unable to convert benzoic acid to hippuric acid, possibly because of glycine deficiency. This results in the accumulation of benzoic acid (Fig. 55-1).[60] A fatal case of metabolic acidosis was reported in a 5-year-old girl who had received 2.4 mg/kg/h diazepam preserved with benzyl alcohol for 36 hours to control status epilepticus. Elevated benzoic acid concentrations were identified in serum and urine samples. The estimated daily dosage of benzyl alcohol was 180 mg/kg.[60,90]

■ NEUROLOGIC TOXICITY

Benzyl alcohol is believed to have a role in the increased frequency of cerebral intraventricular hemorrhages and mortality reported in very-low-birth-weight (VLBW) infants (weight less than 1000 g) who received flush solutions preserved with benzyl alcohol.[73] An increased incidence of developmental delay and cerebral palsy was also noted in the same VLBW patients, suggesting a secondary damaging effect of benzyl alcohol.[12]

There are several case reports of transient paraplegia following the intrathecal or epidural administration of antineoplastics or analgesics containing benzyl alcohol as a preservative.[8,37,66,132] The local anesthetic effects are most likely responsible for the immediate paraparesis and limited duration of effects, rather than actual demyelination of nerve roots. In a study in rats, lumbosacral dorsal root action potential amplitudes were measured after exposure to 0.9% or 1.5% benzyl alcohol solutions in either 0.9% sodium chloride solution or distilled water.[66] Rats exposed to all benzyl alcohol solutions for less than 1 minute had inhibited dorsal root action potentials. This was attributed to the local anesthetic effects of benzyl alcohol. Nerve function was 50% to 90% restored after rinsing the nerves with 0.9% sodium chloride solution. Chronic intrathecal exposure to benzyl alcohol 0.9% over 7 days resulted in scattered areas of demyelinization and early remyelinization. The 1.5% benzyl alcohol solution–exposed dorsal nerve roots showed greater changes with widespread areas of demyelinization and fatty degeneration of nerve fibers.

CHLOROBUTANOL
Chlorobutanol, or chlorbutol (1,1,1-trichloro-2-methyl-2-propanol) is available as volatile, white crystals with an odor of camphor. Chlorobutanol has antibacterial and antifungal properties and is widely used as a preservative in injectable, ophthalmic, otic, and cosmetic preparations at concentrations up to 0.5% (Table 55-4). Chlorobutanol also has mild sedative and local anesthetic properties and was formerly used therapeutically as a sedative-hypnotic.[18] Because chlorobutanol is a halogenated hydrocarbon, theoretically it can sensitize the myocardium

TABLE 55–3. Benzyl Alcohol Concentration of Common Medications

Medication	Percent (%)	mL/Average Dose[a]
Ativan (lorazepam)	2.0	0.02

Tobrex (tobramycin) ophthalmic ointment	0.5	–
Vasopressin 20 Units/mL injectable	0.5	5

to catecholamines, although no cases of ventricular dysrhythmias are described in the literature to date. The lethal human chlorobutanol dose is estimated to be 50 to 500 mg/kg.[110]

CENTRAL NERVOUS SYSTEM TOXICITY

Chlorobutanol has a chemical structure similar to trichloroethanol (Fig. 74–1), the active metabolite of chloral hydrate, and is believed to exhibit similar pharmacologic properties. Central nervous system depression was reported in a 40-year-old alcoholic man who chronically abused Seducaps, formerly available in Australia and several other countries, a nonprescription hypnotic containing chlorobutanol as the active ingredient.[18] On admission to the emergency department (ED) he had drowsiness, dysarthria, slurred speech, and occasional episodes of myoclonic movements. His peak serum chlorobutanol concentration was 100 μg/mL, decreasing to 48 μg/mL over 2 weeks, with a half-life of 13 days. His speech abnormality resolved over 4 weeks. Only chlorobutanol was detected in the patient's urine or serum. In a second case, a possible central nervous system depressant effect from chlorobutanol was suggested in a 19-year-old woman treated with high doses of intravenous morphine preserved with chlorobutanol.[42] She received approximately 90 mg/h of chlorobutanol for several days. Her peak serum chlorobutanol concentration was 83 μg/mL, a concentration similar to that in the previous case report[18]; however, the coadministration of morphine precludes the effects being attributed to chlorobutanol alone.

Ketamine is neurotoxic when administered intrathecally to animals.[99,100] The potential neurotoxic effects of chlorobutanol as a preservative in ketamine compared with preservative-free ketamine was studied in rabbits.[100] Forty rabbits were given 0.3 mL intrathecally of 1% preservative-free ketamine, 1% ketamine, 0.05% chlorobutanol, or 1% lidocaine as control. The rabbits were observed and hemodynamically monitored for 8 days then euthanized. Histological evaluation of the spinal cord as well as for blood–brain barrier (BBB) lesions was performed. Seven of 10 rabbits given intrathecal chlorobutanol showed both white and grey matter histologic changes as well as diffuse BBB injury. No histologic changes were seen in either ketamine groups or the lidocaine group, and only one rabbit in each ketamine group had BBB injury. These results suggest chlorobutanol should not be administered intrathecally.[100]

A case series of five patients were given intraarterial papaverine preserved with 0.5% chlorobutanol, which is used to prevent cerebral vasospasm in patients with subarachnoid hemorrhage. Immediately after administration of papaverine in either left, right, or bilateral anterior cerebral arteries, patients had an acute decrease in neurologic status. Subsequent brain magnetic resonance images (MRIs) identified selective grey matter toxicity in the territories treated with papaverine. Postmortem brain histology analysis in one patient identified grey matter changes as well. These authors state the absence of white matter changes is not consistent with ischemic infarction but suggest direct toxic effect of either the papaverine or chlorobutanol. The manufacturer of the papaverine stated that no other reports had been made and the papaverine used came from two different lots; therefore, it is unclear if an unidentified independent variable caused these effects, but authors caution using intraarterial papaverine in patients with subarachnoid hemorrhage.[137]

OPHTHALMIC TOXICITY

Chlorobutanol is a commonly used preservative in ophthalmic preparations and is less toxic to the eye than benzalkonium chloride.[114] Chlorobutanol increases the permeability of cells by impairing cell membrane structure.[148] An in vitro experiment using corneal epithelial cells harvested from human cadavers demonstrated arrested mitotic activity following chlorobutanol exposure.[148]

LIPIDS

In general, there are three types of commercial intravenous lipid drug-delivery systems available: lipid emulsion, liposomal, and lipid complex (Table 55-5). Lipid emulsions are immiscible lipid droplets dispersed in an aqueous phase stabilized by an emulsifier (eg, egg or soy lecithin). Liposomes differ from emulsion lipid droplets in that they are vesicles comprised of one or more concentric phospholipid bilayers surrounding an aqueous core. Lipophilic drugs can be formulated for intravenous administration by partitioning them into the lipid phase of either an emulsion or liposome. Liposomes are capable of encapsulating hydrophilic therapeutic agents within their aqueous core to exploit lipid pharmacokinetic properties.[144] Attaching a therapeutic drug to a lipid to form a lipid complex is another way to take advantage of lipid pharmacokinetics.

TABLE 55–5. Lipid Carrier Formulations of Common Medications

Medication	Lipid Carrier
Propofol (Diprivan)	Emulsion
Cytarabine (DepoCyt)	Liposome
Daunorubicin (DaunoXome)	Liposome
Doxorubicin (Doxil)	Liposome (stealth)
Amphotericin B (AmBisome)	Liposome
Amphotericin B (Abelcet)	Lipid complex
Amphotericin B (Amphotec)	Cholesteryl complex

Lipid carriers are biocompatible because of their similarity to endogenous cell membranes. They can be used to stabilize labile drugs against hydrolysis or oxidation, to decrease toxicity, and to enhance therapeutic efficacy by altering drug pharmacokinetic and pharmacodynamic parameters. The biodistribution, and the rate of release and metabolism of a drug incorporated in a lipid formulation can be regulated by the type and concentration of oil and emulsifier used, pH, drug concentration dispersed in the medium, the size of the lipid particle, and the manufacturing process.[116,144] Intravenous formulations are usually isotonic and have a pH of 7 to 8.[144]

The rate of clearance of a lipid carrier from the blood depends on its physiochemical properties and the molecular weight of the emulsifier. Electrically charged lipid carriers are removed faster than neutral particles.[23,116] Smaller lipid particle size and high-molecular-weight emulsifiers decrease clearance. Stealth liposome formulations incorporate a polyethylene glycol coating that prevents rapid detection and clearance of liposomes by the reticuloendothelial system prolonging circulation time.[116] Active drug targeting can be achieved by conjugating antibodies or vectors to side chains on the emulsifier.[23,116] For a therapeutic drug available in more than one lipid-carrier formulation (eg, amphotericin B) it is important to note that any change in the lipid formulation can alter the drug's pharmacokinetic, pharmacodynamic, and safety parameters; consequently, they are not equivalent dosage formulations (see Chap. 56).

The physiochemical properties of lipid emulsions not only affect the therapeutic drugs carried by them, but the lipids themselves may also have direct pharmacologic effects on the central nervous[159] and immune systems.[87] Lipid fatty acid mediators can affect the membrane receptor channels of N-methyl-D-aspartate (NMDA) receptors, potentiating synaptic transmission. This is supported by one animal[103] and several in vitro[104,119,147] studies. Dogs given a medium-chain triglyceride emulsion intravenous infusion developed dose-related central nervous system metabolic and neurologic effects, accompanied by electroencephalographic changes consistent with encephalopathy observed when serum octanoate concentration reached 0.5 to 0.9 mM.[103] In an in vitro model, three of nine lipid emulsions tested (Abbolipid, 20% soya and safflower oil; Intralipid, 20% soya oil; and Structolipid, 20% structured triglycerides) demonstrated a dose-related activation of cortical neuronal NMDA receptor channels.[159] The lipid source for all but one (Omegaven, 10% fish oil) of the emulsions tested was made up solely or partially by soya oil. The authors could not explain why the other six lipid emulsions did not induce membrane currents. Adequate control for the nonlipid constituent contribution of these emulsions is lacking. In another in vitro study, the same authors found that NMDA-induced neuronal currents are reduced by an unknown factor in the aqueous portion of Abbolipid.[160] This suggests that lipid emulsions may pharmacologically enhance the anesthetic effect of hypnotics such as propofol. The clinical relevance of these studies remains to be assessed.

Triglycerides in parenteral nutrition emulsions are implicated in altering the immune system, leading to an increased susceptibility to infection,[52,157] and altering lung function and hemodynamics in patients with acute respiratory distress syndrome (ARDS).[87] Phospholipid activation of phospholipase A_2 may be an initiating cause.[52,87,157] However, it is not clear if these immunologic effects are a consequence of factors other than the lipid in the emulsion.

More recently, lipid emulsions have been employed in the treatment of poisonings in both animal models and human case reports (see Antidotes in Depth A 21:Intravenous Fat Emulsion).[10,118,136] Although no toxicity has been reported in these cases, all of the patients were seriously ill and any adverse effects may have been attributed to their primary exposures.

PARABENS

Methylparaben
The parabens, or parahydroxybenzoic acids, are a group of compounds widely employed as preservatives in cosmetics, food, and pharmaceuticals because of their bacteriostatic, fungistatic, and antioxidant properties (Table 55-6).[133] A survey conducted by the FDA identified the parabens as the second most common ingredients in cosmetic formulations, with water being the most common.[91] Parabens are often used in combination, because the presence of two or more parabens are synergistic.[91] Methylparabens and propylparabens are most commonly used.[133] Pharmaceutical parabens concentrations usually range from 0.1% to 0.3%.[127]

Widespread usage of parabens since the 1920s has shown that they have a relatively low order of toxicity.[91] However, because of their allergenic potential they are currently considered less suitable for injectable and ophthalmic preparations.[127] Based on long-term animal studies, the WHO has set the total acceptable daily intake of ethyl-, methyl-, and propylparabens to be 10 mg/kg body weight.[127]

In addition to allergic reactions, parabens have the potential to cause other adverse effects. Bilirubin displacement from albumin binding sites occurred with administration of methyl- and propylparabens preserved gentamicin when serum parabens concentrations were 3 to 15 μg/mL.[39]

TABLE 55–6. Paraben Concentrations of Common Medications

Medication	Percent (%)	mg/Dose
Aldomet (methyldopa) injection	0.17	8
Brofed (pseudoephedrine/ brompheniramine) elixir	0.2	20
Bupivicaine HCl 0.25% injection[a]	0.1	—
Haldol (haloperidol) injection	0.2	2

Romazicon (flumazenil) injection	0.2	4
Talwin (pentazocine) injection	0.1	1
Trandate (labetalol) injection	0.09	4
Xylocaine (lidocaine) injection	0.1	—
Zofran (ondansetron) injection	0.14	3

[a]Amount varies depending on volume used (contains 1mg/mL paraben)

Gentamicin alone has no effect on bilirubin displacement.[92] Spermicidal activity was demonstrated in an in vitro study of human semen specimens exposed to local parabens concentrations of 1 to 8 mg/mL.[141] Possible interference with conception and potential adverse effects on fertility were not investigated.

More recently concern has arisen regarding the potential estrogenic and antiandrogenic effects of the parabens and their common metabolite, *p*-hydroxybenzoic acid. Substances with these effects are commonly referred to as *endocrine disrupting substances*. However, the clinical significance of these effects has not been elucidated.[31,40,124,125,153]

PHENOL

OH
Phenol (carbolic acid, hydroxybenzene, phenylic acid, phenylic alcohol) is a commonly used preservative in injectable medications (Table 55-7). Phenol is a colorless to light pink, caustic liquid with a characteristic odor. When exposed to air and light, phenol turns a red or brown color.[36] Phenol exerts antimicrobial activity against a wide variety of microorganisms, such as gram-negative and gram-positive bacteria, mycobacteria, and some fungi and viruses.[36] Phenol is well absorbed from the gastrointestinal tract, skin, and mucous membranes, and is excreted in the urine as phenyl glucuronide and phenyl sulfate metabolites.[36] Although there are numerous reports of phenol toxicity following intentional ingestions or unintentional dermal exposures (Chap. 104), adverse reactions to its use as a pharmaceutical excipient are uncommon, most likely because of the small quantities used.[36]

■ CUTANEOUS ABSORPTION

Systemic toxicity from cutaneous absorption of phenol is reported. Ventricular tachycardia was observed in an 11-year-old boy following application of a chemical peel solution containing 88% phenol in water and liquid soap. The solution was applied to 15% of his body surface area for the treatment of xeroderma pigmentosum. Immediately following the onset of the ventricular tachycardia, the phenol-treated areas were irrigated, an infusion of 0.9% sodium chloride solution was begun, and two intravenous lidocaine boluses were given followed by a lidocaine infusion. The dysrhythmia persisted for 3 hours. The urinary phenol concentration the following day was 58.9 mg/dL.[151] In a similar case, multifocal premature ventricular contractions (PVCs) were observed in a 10-year-old boy after application of a chemical peeling solution of 40% phenol, 0.8% croton oil in hexachlorophene soap, and water for the treatment of a giant hairy nevus.[158] The PVCs were refractory to intravenous lidocaine but resolved with intravenous bretylium. No phenol concentrations were obtained to confirm systemic absorption.

Drowsiness, respiratory depression, and blue-colored urine were noted in a 6-month-old infant 12 hours after topical application of magenta paint over most of the body for seborrheic eczema.[129] Magenta paint (also known as Castellani paint) was widely used for seborrheic eczema and contained 4% phenol, magenta, boric acid, resorcinol, acetone, and methylated spirit. Further investigation found that phenol was detected in urine samples of four of 16 other infants with seborrheic eczema who had approximately 11% to 15% of their body surface area painted with magenta paint for 2 days.

POLYETHYLENE GLYCOL

Polyethylene glycols (PEGs, Carbowax, Macrogol) include several compounds with varying molecular weights (MWs) (200 to 40,000 D).[123] They are typically available as mixtures designated by a number denoting their average molecular weight. Polyethylene glycols are stable, hydrophilic substances, making them useful excipients for cosmetics, and pharmaceuticals of all routes of administration (Table 55-8). Pegylation, a process that modifies the pharmacokinetics of therapeutic liposomes and proteins (eg, peginterferon-α), is the most recent application of PEG. At room temperature, PEGs with molecular weights less than 600 are clear, viscous liquids with a slight characteristic odor and bitter taste. PEGs with molecular weights greater than 1000 are soluble solids and range in consistency from pastes and waxy flakes to powders.[123] Commercially available products used for bowel cleansing preparations and whole bowel irrigation are solutions of PEG 3350 that are sometimes combined with electrolytes and known as polyethylene glycol electrolyte lavage solutions (PEG-ELS) (see Antidotes in Depth A3: Whole Bowel Irrigation and Other Intestinal Evacuants).

The solid, high-molecular-weight PEGs are essentially nontoxic. Conversely, low-molecular-weight PEG exposures have caused adverse effects similar to the chemically related toxic alcohols ethylene and diethylene glycol[27] (see Special Considerations SC5: Diethylene Glycol).

TABLE 55–7. Phenol Concentration of Common Medications

Medication	Percent (%)	mg/Dose
Antivenom (Crotaline)	0.25	25 (per vial)

Prostigmin (neostigmine) injection	0.45	4.5
Quinidine gluconate injection	0.25	18.75

TABLE 55–8. Common Medications Containing Polyethylene Glycol (PEG)

Medication	PEG Molecular Weight (Daltons)
Chloroptic (chloramphenicol) ointment	300
Furacin (nitrofurazone) ointment	300
VePesid (etoposide) injection	300
Ativan (lorazepam) injection	400
Decadron (dexamethasone) ophthalmic ointment	400
Depo-Provera (medroxyprogesterone)	3350
Polyethylene glycol electrolyte solution	3350
Peginterferon alfa-2a (PEGASYS)	40,000

■ PHARMACOKINETICS

High-molecular-weight PEGs (greater than 1000) are not significantly absorbed from the gastrointestinal tract, but low-molecular-weight PEGs may be absorbed when taken orally.[44,138,139] Topical absorption can occur when PEGs are applied to damaged skin.[21,145] The pharmacokinetics of intravenously administered PEG 3350 has not been studied; however, it did not appear to have any systemic effects when unintentionally given by this route.[128] Once in the systemic circulation, PEGs are mainly excreted unchanged in the urine[44]; however, low-molecular-weight PEGs are metabolized by alcohol dehydrogenase to hydroxyacid and diacid metabolites. PEG may also be partially broken down to ethylene glycol, although the clinical consequence of this is unknown.[21,146]

■ NEPHROTOXICITY

In rats fed various PEGs (200, 300, and 400) in their drinking water for 90 days, a solution of 8% PEG 200 produced renal tubular necrosis in all of the animals, followed by death within 15 days; however, a 4% PEG 200 solution resulted in only two of nine rats dying within 80 days. A 16% PEG 400 solution killed all animals within 13 days; however, both 8% and 4% PEG 400 solutions had no observable effect except for a decrease in kidney weight when compared to control animals.[140]

Acute tubular necrosis with oliguria, azotemia, and high anion gap metabolic acidosis has been reported after oral and topical exposures to low-molecular-weight PEGs (200 and 300). Acute renal failure occurred in a 65-year-old man with a history of alcohol abuse and seizure disorder after ingestion of the contents of a lava lamp containing 13% PEG 200.[45] Forty-eight hours after admission (approximately 50 to 72 hours postingestion), the patient became oliguric with an anion gap metabolic acidosis and acute renal failure. Blood sample analysis confirmed traces of the lava lamp fluid; no traces were detected in the urine. After clinical complications from ethanol withdrawal and aspiration pneumonitis, the patient was discharged 3 months later with residual kidney dysfunction attributed to the PEG component of the lamp contents. Acute tubular necrosis was noted on autopsy of six burn patients treated with a topical antibiotic cream in a PEG 300 base.[21,145] Mass spectrometry detected hydroxyacid and diacid metabolites in serum and urine samples. Oxalate crystals were seen in two cases. These effects were reproduced with the topical application of PEG for 7 days to rabbits with full-thickness skin defects.[145]

■ NEUROTOXICITY

There are reports of neurologic complications, such as paraplegia and transient bladder paralysis, following intrathecal steroidal injections containing 3% PEG as a vehicle.[13,17] In an in vitro experiment, rabbit vagus nerves were exposed to concentrations of PEG 3350 ranging from 3% to 40% for 1 hour.[13] Three percent and 10% PEG had no effect on nerve action potential amplitude or conduction velocity. Twenty percent and 30% PEG significantly slowed nerve conduction and had varying effects on the amplitudes of action potentials. Forty percent PEG completely abolished action potentials. These changes were reversible and thought to be related to PEG-induced osmotic effects.

■ FLUID, ELECTROLYTE, AND ACID–BASE DISTURBANCES

Hyperosmolality was reported in three patients with burn surface areas ranging from 20% to 56% following repeated applications of Furacin, a topical antibiotic dressing containing 63% PEG 300, 32% PEG 4000, and 5% PEG 1000.[21] Polyethylene glycol produces an osmotic effect that is greater than expected for its molecular weight.[134] It is

theorized that PEG increases osmolality by sequestering water through hydrogen binding, reducing the availability of water to interact with solutes, thus increasing the chemical and osmotic activity of the solute. Hyperosmolality following the administration of a PEG-containing substance may suggest systemic PEG absorption.

Two cases of metabolic acidosis were reported following administration of therapeutic dosages of an intravenous nitrofurantoin solution containing PEG 300.[146] Similarly, an otherwise unexplained increased anion gap was reported in three patients being treated with a topical PEG-based burn cream.[21] Metabolism of PEG by alcohol dehydrogenase to hydroxyacid and diacid metabolites can explain the metabolic acidosis.[70]

PROPYLENE GLYCOL

$$\underset{CH_2-CH-CH_3}{\overset{OH \quad\ OH}{|\qquad\ |}}$$
Propylene glycol (PG), or 1,2-propanediol, is a clear, colorless, odorless, sweet, viscous liquid employed in numerous pharmaceuticals (Table 55-9), foods, and cosmetics. Propylene glycol is used as a solvent and preservative with antiseptic properties similar to ethanol. The WHO has set the daily allowable intake of PG at a maximum of 25 mg/kg,[161] or 17.5 g/d for a 70-kg person.

■ PHARMACOKINETICS

Propylene glycol is rapidly absorbed from the gastrointestinal (GI) tract following oral administration and has a volume of distribution of approximately 0.6 L/kg.[101,142] When applied to intact epidermis, the absorption of PG is minimal. Percutaneous absorption may occur following application to damaged skin (eg, extensive burn surface areas). Approximately 12% to 45% of PG is excreted unchanged in

TABLE 55–9. Propylene Glycol Concentration of Common Medications

Medication	Percent (%)	Grams (g)/ Average Dose[a]
Agenerase (amprenavir) oral solution	55	57.75
Amidate (etomidate)	35	3.6
Ativan (lorazepam) injection	80	0.64

Tridil (nitroglycerin) injection	30	0.3
Valium (diazepam) injection	40	0.4

[a]Based on dosage for 70-kg person.

[b]Based on 24-hour dosage.

the urine[43]; the remainder is hepatically metabolized sequentially by alcohol dehydrogenase to lactaldehyde, which is metabolized further by aldehyde dehydrogenase to lactic acid. Lactic acid is also formed by another metabolite, methylglyoxal.[113] Lactic acid may be additionally oxidized to pyruvic acid and then to carbon dioxide and water.[113] The terminal half-life of propylene glycol is reported to be between 1.4 and 5.6 hours in adults, and as long as 16.9 hours in neonates.[43,144]

■ CARDIOVASCULAR TOXICITY

Intravenous preparations of phenytoin contain 40% PG to facilitate the solubility of phenytoin. Nine years after intravenous phenytoin became available, several deaths were attributed to the rapid administration of phenytoin used for the treatment of cardiac dysrhythmias.[59,149,171]

Cardiovascular effects reported in these cases included hypotension, bradycardia, widening of the QRS interval, increased amplitude of T waves with occasional inversions, and transient ST elevations. Studies in cats[93] and calves[63] confirmed PG as the cardiotoxin. Bradycardia and depression of atrial conduction were not observed in cats pretreated with atropine, or in those with vagotomy following rapid intravenous infusion of PG, suggesting that these effects are vagally mediated.[93] Amplification of the QRS complex was noted in these same pre-treated cats, also suggesting a direct cardiotoxic effect of PG. Similar results were reported in calves pretreated with atropine that received oxytetracycline in a PG vehicle.[63]

■ NEUROTOXICITY

Smaller infants appear to have a decreased ability to clear PG when compared with older children and adults.[94] An increased frequency of seizures was reported in low-birth-weight infants who received PG 3 g daily in a parenteral multivitamin preparation.[94] Seizures developed in an 11-year-old boy receiving long-term oral therapy with vitamin D dissolved in PG.[6] Serum calcium, magnesium, electrolytes, and blood glucose were normal. Seizures abated after the product was discontinued. Propylene glycol possesses inebriating properties similar to ethanol. Central nervous system depression was reported following an intentional oral ingestion of a PG-containing product.[101]

A black-box warning was added to the product information for amprenavir (Agenerase), an oral protease inhibitor solution, because of concerns over its high PG (550 mg/mL) vehicle content.[131] The recommended daily dosage of amprenavir supplies 1650 mg/kg/d of PG. A 61-year-old man experienced visual hallucinations, disorientation, tinnitus, and vertigo after receiving a 750-mg dose (474 mg/kg PG) of amprenavir solution.[80]

■ OTOTOXICITY

Otic preparations can contain up to 94% PG in solutions and 10% in suspensions as part of their vehicles.[48] In animal studies, application of high concentrations of PG (greater than 10%) to the middle ear can produce hearing impairment[106,107,155] and morphologic changes, including tympanic membrane perforation, middle ear adhesions, and cholesteatoma.[106,154,166] Although the effects of PG in the human middle ear have not been studied, all medications applied to the external ear canal are contraindicated in patients with perforated tympanic membranes.

■ FLUID, ELECTROLYTE, AND ACID–BASE DISTURBANCES

Patients receiving continuous or large intermittent quantities of medications containing PG can develop high PG concentrations, particularly those with renal or hepatic insufficiency.[26,43] Propylene glycol electrolyte and metabolic disturbances are evidenced by hyperosmolarity, and

an elevated osmolar gap attributed to the osmotically active properties of PG. In most cases, an elevated anion gap, with an otherwise unexplained elevated lactate concentration, is also present. Metabolic acidosis and hyperlactatemia produced from PG metabolism.[25] These adverse effects have been reported with intravenous preparations such as lorazepam,[5,168] diazepam,[162] etomidate,[152] nitroglycerin,[43] pediatric multivitamins,[61] and topical silver sulfadiazine.[11,49,84]

Systemic absorption of PG from topical application of silver sulfadiazine cream[49] resulted in hyperosmolality in patients with burn surface areas greater than 35% of their body.[11,49,84] In one study, nine of 15 burn patients had osmolar gaps (greater than 12) after application of the cream.[84]

Hyperosmolarity occurred in five infants receiving a parenteral multivitamin that provided a daily PG dose of 3 g.[61] After 12 days, one premature infant had a PG concentration of 930 mg/dL and an osmolar gap of 136. Anion gap and lactic acid concentrations were normal. In a study of 11 intubated pediatric patients, aged 1 to 15 months, who were receiving continuous lorazepam infusions over 3 to 14 days, accumulated serum PG concentrations of 17 to 226 mg/dL did not result in significant increases in osmolar gap or serum lactate concentrations from baseline.[32] This was attributed to normal renal function and the low cumulative PG doses received (mean 60 g).

Several small studies have found a strong correlation between elevated PG concentrations and increased osmolar gap measurements in critically ill patients receiving intravenous lorazepam and/or diazepam.[5,163,167,168] An osmolar gap greater than 10 has been suggested as a marker for potential PG toxicity and also indicates when to consider obtaining a serum PG concentration.[167] An osmolar gap of 20 corresponds to a serum PG concentration of approximately 48 mg/dL.[5] This equation should be used cautiously, as larger, more comprehensive studies are needed to validate it. There are rare cases where PG accumulation did not result in an osmolar gap.[62,168] In addition, elevated anion gap measurements and lactate concentrations are seen. As PG toxicity can mimic sepsis in these critically ill patients, sepsis should always be considered as the potential etiology of increased lactate, hypotension, and worsening renal function when considering PG toxicity. Both hemodialysis and fomepizole have been used to treat PG toxicity.[117,170]

■ NEPHROTOXICITY

Human proximal tubular cells exposed in vitro to PG concentrations of 500 to 2000 mg/dL exhibited significant cellular injury and membrane damage within 15 minutes of exposure.[109] Repeated exposure for up to 6 days produced dose-dependent toxic effects at lower concentrations (76, 190, and 380 mg/dL).[108]

The chronic administration of PG may contribute to proximal tubular cell damage and subsequent decreased renal function. In a retrospective study of eight patients who developed elevations in serum creatinine concentration while receiving continuous lorazepam infusions, serum creatinine rose within 3 to 60 days (median, 9 days).[168] The magnitude of serum creatinine rise was found to correlate with the serum PG concentration and duration of infusion. Serum creatinine decreased within 3 days of discontinuing the infusion. Patients with renal dysfunction are at greater risk for accumulating PG because 45% of PG is eliminated unchanged by the kidneys[43]; the remainder is metabolized by the liver. Caution should be used when prolonged administration of a PG-containing medication is necessary in the presence of renal or hepatic dysfunction.[109]

Propylene glycol-induced renal tubular necrosis has been reported in several cases. Daily PG-vehicle dosages of 11 to 90 g/d over 14 days was associated with rising serum creatinine concentrations (from 0.7 mg/dL to 2.1 mg/dL), elevated serum lactate concentrations,

osmolar and anion gaps, and a serum PG concentration of 21 mg/dL.[169] Urine sediment analysis revealed numerous granular, muddy-brown-colored casts and no eosinophils, suggesting an acute renal tubular necrosis. A renal biopsy and electron microscopy showed extensive dilation of the proximal renal tubules, with swollen epithelial cells and mitochondria. Numerous vacuoles containing debris were also noted. A renal biopsy of another case with a serum PG concentration of 30 mg/dL showed disrupted brush borders of the proximal renal tubules after a sudden rise in serum creatinine concentration (3.1 mg/dL), nonoliguric renal failure, and metabolic acidosis. This was attributed to an average daily PG dose of 70 g for 17 days.[68]

SORBITOL

Sorbitol (D-glucitol) is widely used in the pharmaceutical industry as a sweetening agent, moistening agent, and a diluent (Table 55-10). Sorbitol occurs naturally in the ripe berries of many fruits, trees, and plants, and was first isolated in 1872 from the berries of the European mountain ash (*Sorbus aucuparia*).[111] It is particularly useful in chewable tablets because of its pleasant taste. In addition, it is widely used by the food industry in chewing gums, dietetic candies, foods, and enteral nutrition formulations. Sorbitol is approximately 50% to 60% as sweet as sucrose.[111]

TABLE 55–10. Common Medications Containing Sorbitol

Medication	Percent (%)	Grams (g)/Dose
Aluminum hydroxide/ magnesium hydroxide	10	3
Brofed elixir (brompheniramine and pseudoephedrine)	20	2
Calcium carbonate suspension	28	1.4
Chloral hydrate syrup	40	2
Fer-In-Sol drops (ferrous sulfate)	31	0.2
Guaifenisin/dextromethorphan syrup	64	6.4
Lanoxin (digoxin) elixir	21	0.1
Lasix (furosemide) solution	35	1.75
Methadone HCl solution	14	5.6
Potassium chloride solution	17.5	1.35
Sudafed (pseudoephedrine) syrup	35	1.75
Symmetrel syrup (amantadine HCl)	64	6.4
Tagamet (cimetidine) syrup	46	2.3
Tegretol (carbamazepine) syrup	17	0.85
Triaminic syrup (chlorpheniramine and pseudoephedrine)	7	0.7

■ PHARMACOKINETICS

Unlike sucrose, sorbitol is not readily fermented by oral microorganisms and is poorly absorbed from the gastrointestinal tract. Any absorbed sorbitol is metabolized in the liver to fructose and glucose.[111] Sorbitol has a caloric value of 4 kcal/g and is better tolerated by diabetics than sucrose; however, because some of it is metabolized to glucose, it is not unconditionally safe for diabetics.[111]

There is a concern of potentially fatal toxicity for individuals with hereditary fructose intolerance (HFI) receiving sorbitol-containing xenobiotics.[50] HFI is an autosomal recessive disorder caused by a deficiency of fructose-1,6-bisphosphonate aldolase in the liver, kidney, cortex, and small intestine.[81] This results in the accumulation of fructose-1-phosphate, which prevents glycogen breakdown and glucose synthesis causing hypoglycemia. The prevalence of HFI is most commonly reported to be one in 20,000 persons, but can range between one in 11,000 and one in 100,000.[2,79,81]

In individuals with HFI, the prolonged administration of sorbitol, fructose, or sucrose can result in death from liver or renal failure.[35,135] Dietary exclusion of fructose, sucrose, and sorbitol prevents the adverse effects. This condition should not be confused with the more common disorder of dietary fructose intolerance (DFI), which is caused by a defect in the glucose-transport protein 5 (GLUT5) system. This leads to the breakdown of fructose to carbon dioxide, hydrogen, and short-chain fatty acids by colonic bacteria, resulting in abdominal pain and bloating.[86] Dietary fructose intolerance symptoms are minimized by limiting sorbitol, fructose, and sucrose in the diet.

■ GASTROINTESTINAL TOXICITY

In large dosages, sorbitol can cause abdominal cramping, bloating, flatulence, vomiting, and diarrhea. Sorbitol exerts its cathartic effects by its osmotic properties, resulting in fluid shifts within the gastrointestinal tract. Iatrogenic osmotic diarrhea is reported following administration of many different liquid medication formulations containing sorbitol.[72,95] In a human volunteer study, 42 healthy adults ingested 10 g of a sorbitol solution. Sorbitol intolerance was detected in up to 55% of subjects.[78] One theoretical explanation for why all subjects did not experience the gastrointestinal adverse effects is unrecognized DFI. Diarrhea resulting from sorbitol-containing medications is common and often overlooked as a possible etiology.[30,69] Ingestion of large quantities of sorbitol (more than 20 g/d in adults) is not recommended (see Antidotes in Depth A3: Whole-Bowel Irrigation and Other Intestinal Evacuants).[111]

THIMEROSAL

$$
\mathrm{COO^- Na^+}

$$
Thimerosal (Merthiolate, Mercurothiolate), or sodium ethylmercurithiosalicylate, is an organic mercury compound that is approximately 49% elemental mercury (Hg) by weight.[130,156] It is metabolized to ethylmercury and thiosalicylate. Thimerosal has a wide spectrum of antibacterial activity at concentrations ranging from 0.01% to 0.1%; however, higher concentrations are sometimes also used.[83,105] Thimerosal has been widely used as a preservative since the 1930s in contact lens solutions, biologics, and vaccines, particularly those in multidose containers (Table 55-11). The use of thimerosal, which is necessary for the production process of some vaccines (eg, pertussis, influenza), may leave

TABLE 55–11. Thimerosal Concentration of Common Medications

[a]Multidose.

trace amounts in the final product.[9] High-dose thimerosal exposure has resulted in neurotoxicity and nephrotoxicity. Although concerns exist regarding infant exposure to low-dose thimerosal through vaccinations and its effects on neurodevelopment, including possible links to causes of autism,[16] these concerns have never been substantiated (see Chap. 96).[41]

Because specific guidelines for ethylmercury exposure have not been developed, regulatory guidelines for dietary methylmercury exposure were applied to monitor ethylmercury exposure from injected thimerosal-containing vaccines. Methylmercury is a similar, but more toxic, organic mercury compound (Chap. 96). Maximum daily recommended methylmercury exposures range from 0.1 μg Hg/kg (US Environmental Protection Agency [EPA]) to 0.47 μg Hg/kg (WHO).[3,29,34]

An FDA review of thimerosal-containing vaccines revealed that some infants, depending on the immunization schedule, vaccine formulations, and infant's weight, might be exceeding the EPA exposure limit of 0.1 μg Hg/kg/d for methylmercury. Over the first 6 months of life, a total cumulative dose of up to 187.5 μg Hg total from thimerosal-containing vaccines was possible. The US Public Health Service (USPHS) and the American Academy of Pediatrics (AAP) responded jointly by recommending the preemptive reduction or removal of thimerosal from vaccines wherever possible.[3,28] The WHO and European regulatory bodies have made similar recommendations.[51] To date, thimerosal has been removed from most US-licensed immunoglobulin products. All vaccines routinely recommended for children younger than 7 years of age are either thimerosal-free or contain only trace amounts (less than 0.5 μg Hg per dose), with the exception of some inactivated

influenza vaccines. Multidose vials requiring thimerosal preservative remain important for immunization programs in developing countries. Although efforts continue to eliminate all sources of mercury exposure, complete elimination of thimerosal from all vaccines is unlikely in the near future.[9] When a thimerosal-containing vaccine is the only alternative, the benefits of vaccination far exceed any theoretical risk of mercury toxicity.[112]

Prior to thimerosal use in pharmaceuticals, evidence for its safety and effectiveness was provided in several animal species and in 22 humans.[122] Only limited data exist on infant mercury exposure from thimerosal-containing vaccines. Clinical studies that assess the effects of thimerosal exposure on neurodevelopment and renal and immunologic function are lacking. Based on a comprehensive review of epidemiologic data from the United States,[33,54-57,156] Denmark,[77,96] Sweden,[143] and the United Kingdom,[4,71] the Institute of Medicine's (IOM's) Immunization Safety Review Committee,[112] the Global Advisory Committee on Vaccine Safety (GACVS),[165] and the European Agency for the Evaluation of Medicinal Products (EMEA)[46] have all concluded that there is no causal relationship between thimerosal-containing vaccines and autism. Continued surveillance of autistic spectrum disorders as thimerosal use declines will be conducted to evaluate any associated trends.

PHARMACOKINETICS

Limited pharmacokinetic data exist for thimerosal and ethylmercury. Once absorbed, thimerosal breaks down to form ethylmercury and thiosalicylate. Some ethylmercury further decomposes into inorganic mercury in the blood, and the remainder distributes into kidney and, to a lesser extent, brain tissue.[97,98] Because of its longer organic chain, ethylmercury is less stable and decomposes more rapidly than methylmercury, leaving less ethylmercury available to enter kidney and brain tissue.[97] Ethylmercury crosses the blood–brain barrier by passive diffusion.[98] Intracellular ethylmercury decomposes to inorganic mercury, which accumulates in kidney and brain tissues.[98] The half-life of thimerosal is estimated to be about 18 days.[99] Thimerosal is eliminated in the feces as inorganic mercury (see Chap. 96).[121]

MERCURIAL TOXICITY

Oral Administration A case report described a 44-year-old man who ingested 5 g (83 mg/kg) of thimerosal in a suicide attempt; within 15 minutes he began vomiting spontaneously. Gastric lavage was performed and chelation therapy begun with dimercaptopropane sulfonate (DMPS). Gastroscopy revealed a hemorrhagic gastritis. Polyuric acute renal failure was noted on the day of admission and persisted for 40 days. Four days after admission the patient developed a fever and a maculopapular exanthem attributed to thimerosal. The patient also developed an autonomic and ascending peripheral polyneuropathy that persisted for 13 days. Chelation therapy was continued for a total of 50 days with DMPS followed by succimer. Elevated blood and urine mercury concentration persisted for more than 140 days. The patient was discharged 148 days following the ingestion with only sensory defects in his toes. No other neurologic sequelae were noted.[120]

Oral absorption of thimerosal resulted in the fatal poisoning of an 18-month-old girl from the intra-otic instillation of a solution containing 0.1% thimerosal and 0.14% sodium borate. Tympanostomy tubes placed 1 year earlier allowed the irrigation solution to flow through the auditory tube into the nasopharynx, and subsequently to be swallowed and absorbed through the oral mucosa and gastrointestinal tract. A total of 1.2 L of solution (500 mg Hg) was instilled over

a 4-week period, resulting in severe mercury poisoning. Four days after admission, the serum mercury concentration was 163 μg/dL. The patient also received 1.7 g of boric acid. It is unclear what contribution, if any, the boric acid made to the serum mercury concentration. Chelation therapy with N-acetyl-D-penicillamine was initiated on day 51. Despite increased urinary mercury concentrations following administration of the N-acetyl-D-penicillamine, her neurologic function and blood mercury concentrations remained unchanged. The child died 3 months after admission. An autopsy was not performed.[130]

Intramuscular Administration Urine mercury concentrations of 26 patients with hypogammaglobulinemia, who received weekly intramuscular IgG replacement therapy preserved with 0.01% thimerosal were studied. The dosages of IgG ranged from 25 to 50 mg/kg, containing 0.6 to 1.2 mg of mercury per dose.[64] The total estimated dose of mercury administered ranged from 4 to 734 mg over a period of 6 months to 17 years. Urine mercury concentrations were elevated in 19 patients, ranging from 31 to 75 μg/L; however, no patients had clinical evidence of chronic mercury toxicity.[64]

Six cases of severe mercury poisoning resulting in four deaths were reported following the intramuscular administration of chloramphenicol preserved with thimerosal. A manufacturing error produced vials containing 510 mg of thimerosal (250 mg Hg) instead of 0.51 mg per vial. Two adults received 4 g and 5.5 g of mercury each and four children received 0.2 to 1.8 g each. All six patients had extensive tissue necrosis at the site of injection. Fever, altered mental status, slurred speech, and ataxia were noted. Autopsy identified widespread degeneration and necrosis of the renal tubules; however, creatine kinase concentrations were not reported, so pigment-induced nephrotoxicity cannot be excluded. Elevated mercury concentrations were found in the injection site tissues, and in the kidneys, livers, and brains.[7]

Topical Administration Thirteen infants were exposed to 9 to 48 topical applications of a 0.1% thimerosal tincture for the treatment of exomphalos. Analysis for elevated mercury concentrations was performed in 10 of 13 infants who unexpectedly died. Mercury concentrations were determined in various tissues from six of the infants. Mean tissue concentrations in fresh samples of liver, kidney, spleen, and heart ranged from 5152 to 11,330 ppb, suggesting percutaneous absorption from these repeated topical applications.[47]

Ophthalmic Administration Nine patients undergoing keratoplasty were exposed to a contact lens stored in a solution containing 0.002% thimerosal.[164] After 4 hours, the lens was removed and mercury concentrations of the aqueous humor and excised corneal tissues were determined. Mercury concentrations were elevated in both aqueous humor (range, 20 to 46 ng/mL higher) and corneal tissues (range, 0.6 to 14 ng higher) as compared with eyes that had not been fitted with contact lenses. Only residual amounts of mercury remained on the contact lenses after 4 hours of wear. The authors noted that although the aqueous humor concentrations were in the same range as those measured in 10 patients with vision loss from systemic mercury poisoning (11 to 104 ng/mL), adverse effects did not occur.

A possible drug interaction between orally administered tetracyclines and thimerosal was reported to result in acute, varying degrees of eye irritation in contact lens wearers using thimerosal-containing contact lens solutions who started treatment with tetracycline.[38]

SUMMARY

The benefits of pharmaceutical excipients include improved drug solubility, stability and palatability, antimicrobial activity, the availability of various dosage forms, the provision of products with long-term storage, and the availability of multiple-dose packaging. Excipients are often termed "inert," implying that they possess no pharmacologic or toxicologic properties of their own. While excipients are essential and efficacious, they may also be responsible for severe, and sometimes fatal, adverse effects.

The toxicity of pharmaceutical excipients should be considered for patients requiring high doses or prolonged administration of any medication containing excipients, particularly those additives known to have toxicities. Individuals with decreased renal or hepatic function or patients at the extremes of age may be at an increased risk of accumulating excipients. Under circumstances in which there is no option but to continue treating a patient with a particular xenobiotic, switching to a preservative-free product, or to another brand without the offending excipient, may obviate the need for discontinuation of an effective agent. In addition to inherent toxicities, many excipients may also be responsible for allergic reactions. Their prevalence in numerous pharmaceuticals, cosmetics, and foods may allow for sensitization. However, in the majority of cases, pharmaceutical excipients are safe and effective, and their benefits far exceed their potential for adverse effects when administered properly.

D.
ANTIMICROBIALS

ANTIBACTERIALS, ANTIFUNGALS, AND ANTIVIRALS

Christine M. Stork

Antimicrobials in the forms of antibacterials, antifungals, and antivirals have added significantly to the clinical care of infected patients since the introduction of penicillin in the 1940s. The development of drug-resistant strains of these pathogens has greatly expanded the number of antimicrobials necessary, and this has increased the overall potential for toxicity after use. Fortunately, toxicity due to acute overdose and even chronic therapeutic doses does not preclude their appropriate use in the majority of patients.

HISTORY AND EPIDEMIOLOGY

The majority of the adverse effects related to antimicrobials occur as a result of iatrogenic complications rather than intentional overdose. The diverse origins of these complications include dosing, route and decision errors, allergic reactions, adverse drug effects, and drug-drug interactions. Prevention in the form of process improvements and information regarding populations at risk for adverse drug effects is required to minimize these untoward events. Dosing errors are common in neonates and infants, necessitating careful and constant diligence on the part of all healthcare providers.

Antimicrobials are more commonly associated with anaphylactic reactions than are other xenobiotics. The reason for this is unclear, but it may be a result of their high frequency of use, repeated interrupted exposures caused by intermittent prescriptive use, or environmental contamination. A complete and clear allergy history is essential to minimize these adverse events in patients being considered for antimicrobial therapy.

Many adverse effects attributed to antimicrobials are difficult to predict even when given patient- and population-specific parameters. In some cases, a diluent or an excipient is responsible for the adverse effect, as recognized with the use of procaine penicillin G in patients with procaine allergy. Antimicrobials are involved in many of the common and severe drug interactions, primarily through the inhibition of metabolic enzymes. Patients being considered for antimicrobial therapy should be carefully assessed for the use of concomitant drug therapy that may be pharmacokinetically or pharmacodynamically affected by the chosen antimicrobial.

PHARMACOLOGY AND TOXICOLOGY

Antimicrobial pharmacology is aimed at the destruction of microorganisms through the inhibition of cell-cycle reproduction or the altering of a critical function within a microorganism. Table 56–1 lists antimicrobials and their associated mechanisms of activity. Often the mechanisms for toxicologic effects following acute overdose differ from the therapeutic mechanisms. Table 56–1 also lists the toxicologic effects and related mechanisms. Table 56–2 lists the pharmacokinetics of each class of drugs.

ANTIBACTERIALS
■ AMINOGLYCOSIDES

Gentamicin C$_1$:   R$_1$ = R$_2$ = CH$_3$
Gentamicin C$_2$:   R$_1$ = CH$_3$, R$_2$ = H
Gentamicin C$_{1a}$: R$_1$ = R$_2$ = H

Aminoglycoside antimicrobials that are in current use in the United States include amikacin, gentamicin, kanamycin, neomycin, netilmicin, streptomycin, and tobramycin.

Since aminoglycosides are only available in parenteral, topical, and ophthalmic forms, overdoses are almost exclusively the result of dosing errors. Fortunately, overdoses are rarely life threatening, and most patients can be safely managed with minimal intervention.[28,136] The adverse effects of aminoglycosides are generally class based, although subtle differences may exist in the potency with which the adverse effects occur (Table 56–3).

Large intravenous doses of aminoglycosides are both sufficiently effective and safe for use in single daily doses.[4] Rarely, acute aminoglycoside overdose results in nephrotoxicity, ototoxicity, or vestibular toxicity.[131,157] In one reported case, postmortem analysis confirmed complete loss of hair cells in the inner and outer cochlear (Chap. 20).

TABLE 56–1. Antimicrobial Pharmacology and Adverse Effects

Antimicrobial	Antimicrobial Mechanism of Action	Acute Overdose	Chronic Administration
Antibacterials			
Aminoglycosides	Inhibits 30s ribosomal subunit	Neuromuscular blockade—inhibits the release of acetylcholine from presynaptic nerve terminals and acts as an antagonist at acetylcholine receptors	*Nephrotoxicity/ototoxicity*—forms an iron complex that inhibits mitochondrial respiration and causes lipid peroxidation
Penicillins, cephalosporins, and other β-lactams	Inhibits cell wall mucopeptide synthesis	Seizures—agonist at picrotoxin binding site causing GABA antagonism	*Hypersensitivity*—immune *Other*—see text
Chloramphenicol	Inhibits 50s ribosomal subunit and inhibits protein synthesis in rapidly dividing cells	Cardiovascular collapse	"Gray baby syndrome" Same as mechanism of action
Fluoroquinolones	Inhibits DNA topoisomerase and DNA gyrase	Same as mechanism of action; binds to cations (Mg^{2+}), seizures	Not entirely known; binds to cations (Mg^{2+}), tendon rupture, hyper- and hypoglycemia
Linezolid	Inhibits bacterial protein synthesis through inhibition of *N*-formylmethionyl-t RNA	None clinically relevant	MAOI activity: vasopressor response to tyramine; serotonin syndrome with SSRI and possibly meperidine
Macrolides, lincosamides, and ketolides	Inhibit 50s ribosomal subunit in multiplying cells	Prolong QT; block delayed rectifier potassium channel	Not entirely known; cytotoxic effect; exacerbation of myasthenia gravis
Nitrofurantoin	Bacterial enzymatic inhibitor	Gastritis	Dermatologic, hematologic, pancreatitis, partotitis, hepatitis, crystaluria, pulmonary fibrosis
Sulfonamides	Inhibit *para*-aminobenzoic acid and/or *para*-amino glutamic acid in the synthesis of folic acid	None clinically relevant	*Hypersensitivity*—metabolite acts as hapten leading to hemolysis/methemoglobinemia—exposure to UVB causes free radical formation
Tetracycline	Inhibits 30s and 50s ribosomal subunits; binds to aminoacyl transfer RNA	None clinically relevant	Unknown
Vancomycin	Inhibits glycopeptidase polymerase in cell wall synthesis	"Red-man syndrome"—anaphylactoid	Unknown
Antifungal			
Amphotericin B	Binds with ergosterol on cytoplasmic membrane to cause pores to facilitate organelle leak	Same as mechanism of action	*Nephrotoxicity*—vehicle deoxycholate may be involved; nephrocalcinosis
Triazoles and imidazoles	Increases permeability of cell membranes	None clinically relevant	None clinically relevant ?CYP inhibition

γ-aminobutyric acid; MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor; UVB, ultraviolet B.

Aminoglycosides may exacerbate neuromuscular blockade, particularly at times corresponding to high-peak serum aminoglycoside concentrations (Chap. 68).[187] Aminoglycosides inhibit the release of acetylcholine from presynaptic nerve terminals by antagonism of the aminoglycoside of the presynaptic calcium channel. Risk factors for enhanced neuromuscular blockade include patients with abnormal neuromuscular junction function, such as those with myasthenia gravis and botulism.

Adverse Effects Associated With Therapeutic Use Adverse effects, including nephrotoxicity and ototoxicity, correlate more closely with elevated trough serum concentrations than with elevated peak concentrations.[120,166]

Less common adverse effects associated with chronic use include electrolyte abnormalities, allergic reactions, hepatotoxicity, anemia, granulocytopenia, thrombocytopenia, eosinophilia, retinal toxicity, reproductive dysfunction, tetany, and psychosis.[62,125,142,229,244] When aminoglycosides are administered at high doses or during once-daily dosing, sepsis-like reactions, including chills and malaise, can occur.[51] This is likely a result of excipients that are delivered to the patient during the infusion.

Nephrotoxicity The mechanism of nephrotoxicity and ototoxicity is incompletely understood, but appears to include the formation of reactive oxygen species in the presence of iron. Mitochondrial respiration is inhibited, lipid peroxidation occurs, and stimulation of

TABLE 56–2. Antimicrobial Pharmacokinetics

Xenobiotic	Absorption	Volume of Distribution (L/kg)	Elimination Route	$t_{1/2}$ (h)
Antibacterial				
Aminoglycosides	Parenteral	0.25	Renal	2–3
Penicillins, cephalosporins, and other β-lactams	Oral, parenteral	Variable	Renal (predominant)	Variable
Chloramphenicol	Oral, parenteral, otic	0.5–1.0	90% hepatic, 10% renal	1.6–3.3
Fluoroquinolones	Oral, parenteral	Variable	Renal	3–5
Ketolides	Oral	2.9 L/kg	63% renal, 37% hepatic (50% of which is CYP3A4)	10–13
Macrolides	Oral, parenteral	Variable	Hepatic	Variable
Sulfonamides	Oral, parenteral	Variable	Hepatic	Variable
Tetracyclines	Oral	Variable	Hepatic	6–26
Vancomycin	Parenteral	0.2–1.25	Renal	4–6
Antifungal				
Triazoles and imidazoles	Oral	Variable	Hepatic	Variable
Amphotericin B	Parenteral	4.0	Hepatic	360
Antiviral				
Acyclovir	Parenteral, oral, topical	0.8	Renal	2.2–20

glutamate activated *N*-methyl-D-aspartate (NMDA) receptors may play a role.[108,253] The incidence of nephrotoxicity with aminoglycoside therapy is estimated at 5% to 10%.[9] Although the aminoglycosides are almost completely excreted prior to biotransformation in the kidney, a small fraction of filtered aminoglycoside is transported by absorptive endocytosis across the apical membrane of proximal tubular cells where it becomes sequestered within lysosomes. The aminoglycoside then binds to and destroys phospholipids contained on brush border membranes in the proximal renal tubule.[9]

When this happens, acute tubular necrosis occurs after 7 to 10 days of standard-dose therapy. Laboratory abnormalities include granular casts, proteinuria, elevated urinary sodium, and increased fractional excretion of sodium. Usually renal dysfunction is reversible; however, irreversible toxicity is reported. Functional renal injury occurs days prior to elevations in serum creatinine concentration, and for this reason a delay in diagnosis is common.[217] Risk factors for the development of nephrotoxicity include increasing age, renal dysfunction, female sex,

TABLE 56–3. Predominant Aminoglycoside Toxicity

Cochlear	Cochlear and Vestibular	Vestibular	Renal

			Tobramycin

previous aminoglycoside therapy, liver dysfunction, large total dose, long duration of therapy, frequent doses, high trough concentrations, presence of other nephrotoxic drugs, and shock.[9,170] Because the uptake of aminoglycosides into organs is saturable, appropriate once-daily high-dose regimens are less problematic than several lesser doses given in a single day.

Ototoxicity Ototoxicity can occur after acute or prolonged exposure to aminoglycosides.[105] Both cochlear and vestibular dysfunction are correlated with high trough aminoglycoside concentrations. Because aminoglycosides bioaccumulate in the endolymph and perilymph spaces, they have prolonged contact time with sensory hair cells. Vestibular toxicity, caused by destruction of sensory receptor portions of the inner ear or destruction of hair cells in the utricle and saccule, occurs in 0.4% to 10% of patients. Symptoms include vertigo or tinnitus. Table 56–3 details the relative characteristic toxicity of various aminoglycosides.

Full-tone audiometric testing may first show high-frequency hearing loss, which may subsequently progress. Given the inability of cochlear hair cells to regenerate, all hearing loss that develops is permanent. Electronystagmography is the diagnostic tool of choice for vestibular dysfunction, and up to 63% of patients with early findings of vestibular dysfunction may improve after discontinuation of the drug.[124] Simultaneous administration of other ototoxic xenobiotics enhances the ototoxicity of aminoglycosides (Chap. 20).

Withdrawal of the offending xenobiotic is indicated in patients with either nephrotoxicity or ototoxicity caused by an aminoglycoside antibiotic. Supportive care is the mainstay of therapy. Experimental treatments in animal models include the use of deferoxamine, glutathione, and NMDA receptor antagonists in an attempt to chelate and/or detoxify a reactive intermediate.[181,231] The antibiotic ticarcillin forms a renally eliminated complex with aminoglycosides in the blood to provide protection against tobramycin-induced renal toxicity. In humans, ticarcillin removes 50% more tobramycin in 48 hours than two hemodialysis sessions.[79] However, ticarcillin therapy is generally of limited value because in most instances

the serum concentration of the aminoglycoside has decreased before any therapeutic measures can be used. The use of ticarcillin should be considered only early after large overdose in patients with either demonstrated toxicity or renal failure where the risks of toxicity are significant.

■ PENICILLINS
Penicillin nucleus

Penicillin is derived from the fungus *Penicillium* and many semisynthetic derivatives have clinical utility. Penicillins, as a class, contain a 6-aminopenicillanic acid nucleus, composed of a β-lactam ring fused to a five-member thiazolidine ring. Classic available penicillins include penicillin G, penicillin V, and the antistaphylococcal penicillins (nafcillin, oxacillin, cloxacillin, and dicloxacillin). Penicillins developed to enhance the spectrum of antibiotic efficacy, particularly against gram-negative bacilli, include the second-generation penicillins (ampicillin, amoxicillin, bacampicillin, and mezlocillin), third-generation penicillins (carbenicillin and ticarcillin), and fourth-generation penicillins (piperacillin). Table 56–1 lists the pharmacologic mechanism of penicillins and Table 56–2 lists their pharmacokinetic properties.

Acute oral overdoses of penicillin-containing drugs are usually not life threatening.[237] The most frequent complaints following acute overdose are nausea, vomiting, and diarrhea.

Seizures occur in persons given large intravenous or intraventricular doses of penicillins.[40,127,139,164] More than 50 million units intravenously in less than 8 hours are generally required to produce seizures in adults.[222] Penicillin-induced seizures appear to be mediated through an interaction of the drug with the picrotoxin-binding site on the neuronal chloride channel near the γ-aminobutyric acid (GABA) binding site (Chap. 13). Binding of the penicillin produces an allosteric change in the receptor that prevents GABA from binding, resulting in a relative lack of inhibitory tone.[66] Penicillin analogs (such as imipenem) also cause seizures, presumably through a similar mechanism.

Treatment of patients who develop penicillin-induced seizures include GABA agonists such as the benzodiazepines and barbiturates, if needed. Patients who receive an intraventricular overdose may require cerebrospinal fluid exchange or perfusion to attenuate seizure activity (see Special Considerations SC 2: Intrathecal Administration of Xenobiotics).[139] There are rare reports of hyperkalemia resulting in electrocardiographic abnormalities after the rapid intravenous infusion of potassium penicillin G to patients with renal failure and amoxicillin overdose resulting in frank hematuria and renal failure.[37,94] There is also a single case report of penicillin-associated hearing loss.[33]

Adverse Effects Associated With Therapeutic Use   Penicillins are associated with a myriad of adverse effects after therapeutic use, the most common of which are allergic reactions. Penicillins are commonly implicated in immune-related reactions such as bone marrow suppression, cholestasis, hemolysis, interstitial nephritis, and vasculitis.[6,92,114,230] Rare effects include pemphigus after penicillin use and corneal damage after the use of methicillin.[23,263]

Acute Allergy   Penicillins are the pharmaceuticals most commonly implicated in the development of acute anaphylactic reactions. Anaphylactic reactions are severe life-threatening immune-mediated (IgE) reactions involving multiple organ systems that occur most often immediately after exposure to a trigger. Table 56–4 lists the classifications of anaphylactic reactions. Anaphylaxis to penicillin typically

TABLE 56–4. Classification of Anaphylactic Reactions

Grade	Description
I	Large local contiguous reaction (>15 cm)
II	Pruritus (urticaria) generalized
III	Asthma, angioedema, nausea, vomiting
IV	Airway (asthma, lingual swelling, dysphagia, respiratory distress, laryngeal edema)
	Cardiovascular (hypotension, cardiovascular collapse)

occurs after IgE antibody formation, which requires prior exposure. Life-threatening clinical manifestations include angioedema, tongue and airway swelling, bronchospasm, bronchorrhea, dysrhythmias, cardiovascular collapse, and cardiac arrest.[80] The pathophysiology of systemic anaphylaxis is complex and involves multiple pathways. IgE antibodies are cross-linked on the surface of mast cells and basophils, resulting in local and systemic release of preformed mediators of anaphylactic response, including leukotrienes C_4 and D_4, histamine, eosinophilic chemotactic factor, and other vasoactive substances, such as bradykinin, kallikrein, prostaglandin D_2, and platelet-activating factor.

The incidence of penicillin hypersensitivity is 5% overall, with 1% of penicillin reactions resulting in anaphylaxis. The risk for a fatal hypersensitivity reaction after penicillin administration is two per 100,000 (0.002%) patient exposures.[251] All routes of penicillin administration can result in anaphylaxis; however, it occurs most commonly after intravenous administration.

Treatment is supportive with careful attention to airway, breathing, and circulation. If the penicillin was ingested, the patient may theoretically benefit from oral activated charcoal 1 g/kg. This is unlikely to prevent anaphylaxis, as only a few molecules need be absorbed to trigger the immunologic response. Initial drug therapy for anaphylaxis includes epinephrine 0.01 mg/Kg (up to 0.5 mL) of 1:1000 dilution subcutaneously (SC) every 10 to 20 minutes. Through β-receptor stimulation, epinephrine bronchodilates and increases cardiac output. In addition, β-receptor stimulation results in decreased peripheral vascular tone. Oxygen and inhaled β_2-adrenergic agonists are warranted in severe cases, as are corticosteroids. H_1-receptor antagonists may be sufficient in patients with mild allergic reactions who do not have pulmonary manifestations or airway concerns.

H_2-receptor antagonism as a treatment for anaphylaxis is controversial. H_2-receptors, when stimulated in the peripheral vasculature, cause vasodilation; in the heart, they cause positive inotropy, positive chronotropy, and coronary vasodilation; and in the lung, they cause increased mucus production.[212] Theoretically, H_2-receptor antagonists can lead to a decrease in myocardial activity at a time when H_1-receptor stimulation is causing hypotension, coronary vasoconstriction, and bronchospasm. However, in vitro and animal models demonstrate decreases in coronary circulation and decreases in the overall anaphylactic response following administration of H_1 blockers.[16,27] Cimetidine and ranitidine are useful for the treatment of pruritus and flushing after acute allergic reactions involving the skin.[154,168] Cimetidine use following anaphylaxis may result in clinical improvement, particularly hypotension and tachycardia.[72,264] There is one case, however, of chronic ranitidine administration, which was postulated to result in heart block after an anaphylactic response to latex.[189] Available data indicate that treatment using H_2-receptor antagonists should only be

considered when other therapies have failed and the patient is adequately H_1-receptor blocked. Aminophylline, although mentioned in some references for the treatment of anaphylaxis, is inadequately studied and should not be routinely used. Finally, glucagon may be of some benefit, particularly in patients who are maintained on β-adrenergic antagonists (Chap. 61 and A-19).

Amoxicillin-Clavulanic Acid and Hepatitis Cholestatic hepatitis occurs 1 to 6 weeks after initiation of therapy with amoxicillin-clavulanate.[7] The incidence of hepatotoxicity typically is estimated at 1.1 to 2.7 per 100,000 prescriptions.[91] The mechanism of hepatotoxicity is not clear, but may be related to clavulanate, a β-lactamase inhibitor used to prevent the bacterial destruction of β-lactam antimicrobials, or one of its metabolites. Treatment is supportive and clinical findings typically resolve after the discontinuation of therapy. However, prolonged hepatitis, ductopenia (vanishing bile duct syndrome), and pancreatitis rarely occur.[53,199] Behavorial disturbance with disorientation, agitation, and visual hallucinations is also reported temporally related to use.[19]

Hoigne Syndrome and Jarisch-Herxheimer Reaction The most common adverse effects occurring after administration of large intramuscular or intravenous doses of procaine penicillin G are the Hoigne syndrome and the Jarisch-Herxheimer reaction.[12,90,102,122,163] Hoigne syndrome is characterized by extreme apprehension and fear, illusions, or hallucinations; changes in auditory and visual perception; tachycardia; systolic hypertension; and, occasionally, seizures that begin within minutes of injection.[250] These effects occur in the absence of signs or symptoms of anaphylaxis. The cause of this syndrome is unknown. Procaine is implicated as the causative agent because of this syndrome's similarity to events that occur after the administration of other pharmacologically similar local anesthetics.[214,223,246] Hoigne syndrome is six times more common in men than women.[226] The reason for this increased prevalence is unclear, but autosomal dominance and influences of prostaglandin and thromboxane A_2 activity in this population may be responsible.[12]

The Jarisch-Herxheimer reaction is a self-limited reaction that develops within a few hours of antibiotic therapy for the treatment of early syphilis or Lyme disease. Clinical findings include myalgias, chills, headache, rash, and fever, which spontaneously resolve within 18 to 24 hours, even with continued antibiotic therapy.[169] The pathogenesis of this reaction is likely an acute antigen release by lysed bacteria.[178]

■ CEPHALOSPORINS

Cephem nucleus
Cephalosporins are semisynthetic derivatives of cephalosporin C produced by the fungus *Acremonium,* previously called *Cephalosporium.* Cephalosporins have a ring structure similar to that of penicillins. Cephalosporins are generally divided into first, second, third, and fourth generations based on their antimicrobial spectrum. First-generation cephalosporins include cefadroxil, cefazolin, cephalexin, cephapirin, and cephradine. Second-generation cephalosporins include cefaclor, cefamandole, cefonicid, cefotetan, cefoxitin, cefprozil, and cefuroxime. Third-generation cephalosporins include cefdinir, ceftazidime, cefixime, ceftibuten, cefoperazone, ceftizoxime, cefotaxime,

ceftriaxone, and cefpodoxime. Finally, of the fourth-generation cephalosporins, cefepime was the first to be marketed.

Effects occurring after acute overdose of cephalosporins resemble those occurring after penicillin exposure. Some cephalosporins also have epileptogenic potential similar to penicillin.[255] Case reports demonstrate seizures after inadvertent intraventricular administration.[39,146,265] Management of cephalosporin overdose is similar to that of penicillin overdose. Table 56–1 lists the pharmacologic mechanism of cephalosporins and Table 56–2 lists their pharmacokinetic properties.

Adverse Effects Associated With Therapeutic Use Cephalosporins rarely cause an immune-mediated acute hemolytic crisis.[78] Cefaclor is the cephalosporin most commonly reported to cause serum sickness, although this can occur with other cephalosporins.[132,156] Also like penicillins, first-generation cephalosporins are associated with chronic toxicity, including interstitial nephritis and hepatitis.[262] Cefepime is reported in a single case to cause reversible coma and electroencephalogram (EEG) confirmed nonconvulsive seizures.[2]

Cross-Hypersensitivity The cephalosporins contain a six-member dihydrithiazine ring instead of the five-member thiazolidine penicillin ring. The extent of cross-reactivity between penicillins and cephalosporins in an individual patient is largely determined by the type of penicillin allergic response experienced by the patient. The incidence of anaphylaxis to cephalosporins is between 0.0001% and 0.1%, with a threefold increase in patients with previous penicillin allergy.[133] Ten percent of patients with prior penicillin-related anaphylactic reactions will have positive skin test for cephalosporin hypersensitivity.[205] A negative skin test predicts a negative allergic response on oral cephalosporin challenge in penicillin-allergic patients. Finally, the incidence of delayed hypersensitivity reactions after cephalosporin use is 1% to 2.8% in the general population and 8.1% in those with prior penicillin delayed hypersensitivity. Cross-reactivity may be greater with the first- and second-generation cephalosporins that are more structurally similar to penicillin or that are contaminated by penicillin.[8] Antibody binding after cephalosporin exposure occurs at the determinants located on the side-chain groups of the cephalosporin.[14] In fact, IgE directed against a methylene substituent linking the side chain to the penicillin molecule is identified.[107] These determinants are quite distinct among cephalosporins, which cause the pattern of cross-hypersensitivity among cephalosporins to be much less well defined than among the penicillins. Caution should be used when considering cephalosporins in penicillin- or cephalosporin-allergic patients; however, if a risk-to-benefit analysis demonstrates a clear benefit to the patient without equivalent alternatives, the cephalosporin should be given.

***N*-methylthiotetrazole Side-Chain Effects** Cephalosporins containing an *N*-methylthiotetrazole (nMTT) side chain (moxalactam, cefazolin, cefoperazone, cefmetazole, cefamandole, cefotetan) have toxic effects unique to their group structure. As these cephalosporins undergo metabolism, they release free nMTT, which is responsible for their effects (Fig. 56–1).[165] Free nMTT inhibits the enzyme aldehyde dehydrogenase and, in conjunction with ethanol, can cause a disulfiram-like reaction (Chap. 79).[43]

The nMTT side chain is also associated with hypoprothrombinemia, although a causal relationship is controversial.[101] It is thought that nMTT depletes vitamin K-dependent clotting factors by inhibition of vitamin K epoxide reductase.[183] In a study of children 1 month to 1 year of age who were maintained on a prolonged antibiotic regimen, a significant degree of vitamin K depletion was found.[25] Treatment of patients suspected of hypoprothrombinemia caused by these cephalosporins consists of fresh-frozen plasma, if bleeding is evident, and vitamin K_1 in doses required to resynthesize vitamin K cofactors (Chap. 59).
FIGURE 56-1. Characteristic structures of cephalosporins emphasizing the nMTT side chain.

■ OTHER β-LACTAM ANTIMICROBIALS
Included in this group are monobactams such as aztreonam and carbapenems such as imipenem and meropenem. Table 56–1 lists the pharmacologic mechanism of these drugs, and Table 56–2 lists their pharmacokinetic properties.

Effects occurring after acute overdose of other β-lactam antimicrobials resemble those occurring after penicillin exposure. Imipenem has epileptogenic potential in both overdose and therapeutic dosing (see section Adverse Effects Associated With Therapeutic Use).[48,148] Management guidelines for other β-lactam overdoses are similar to those for penicillin overdoses.

Adverse Effects Associated With Therapeutic Use The risk factors for imipenem-related seizures include central nervous system disease, prior seizure disorders, and abnormal renal function.[190] The mechanism for seizures appears to be GABA antagonism (similar to the penicillins) in conjunction with enhanced activity of excitatory amino acids.[67,235]

Cross-Hypersensitivity Aztreonam is a monobactam that does not contain the antigenic components required for cross-allergy with penicillins, and generalized cross-allergenicity is not expected.[215] However, aztreonam cross-reacts in vitro with ceftriaxone, thought to be the result of the similarity in their side-chain structure.[192] Cross-allergenicity has also been noted between imipenem and penicillin, although the incidence has yet to be determined.

■ TRIMETHOPRIM-SULFAMETHOXAZOLE

Trimethoprim and sulfamethoxazole work as antibacterials in tandem effectively preventing tetrahydrofolic acid synthesis in bacterial cells. Significant toxicity after acute overdose is not expected; however, a myrid of effects occur after chronic therapeutic use. Trimethoprim/sulfamethoxazole combinations are commonly reported to result in cutaneous allergic reactions, hematologic disorders, methemoglobinemia, hypoglycemia, rhabdomyolysis, and psychosis.[134,135,234,254,260]

■ CHLORAMPHENICOL
Chloramphenicol was originally derived from *Streptomyces venezuelae* and is now produced synthetically. Antimicrobial activity exists against many gram-positive and gram-negative aerobes and anaerobes. Table 56–1 lists the pharmacologic mechanism of chloramphenicol, and Table 56–2 lists its pharmacokinetic properties.

Acute overdose of chloramphenicol commonly causes nausea and vomiting. Effects are caused by its ability to inhibit protein synthesis in rapidly proliferating cells. Metabolic acidosis occurs as a result of the inhibition of mitochondrial enzymes, oxidative phosphorylation, and mitochondrial biogenesis.[88] Infrequently, sudden cardiovascular collapse can occur 5 to 12 hours after acute overdoses. In case series, cardiovascular compromise was more frequent in patients with serum concentrations greater than 50 μg/mL.[88,172,242] Because concentrations are not readily available, all poisoned patients should be closely observed for at least 12 hours after exposure. Orogastric lavage may be useful for recent ingestions when the patient has not vomited, and activated charcoal 1 g/kg should be given orally.

Extracorporeal means of eliminating chloramphenicol are not usually required because of its rapid metabolism (see Table 56–2). However, both hemodialysis and charcoal hemoperfusion decrease elevated serum chloramphenicol concentrations and may be of benefit in patients with large overdoses, or in patients with severe hepatic or renal dysfunction.[87,167,227] Exchange transfusion also lowers chloramphenicol serum concentrations in neonates.[233] Surviving patients should be closely monitored for signs of bone marrow suppression.

Adverse Effects Associated With Therapeutic Use Chronic toxicity of chloramphenicol is similar to that which occurs following acute poisoning. The classic description of chronic chloramphenicol toxicity is the "gray baby syndrome."[87,88,167,233] Children with this syndrome exhibit vomiting, anorexia, respiratory distress, abdominal distension, green stools, lethargy, cyanosis, ashen color, metabolic acidosis, hypotension, and cardiovascular collapse.

The majority (90%) of a dose of chloramphenicol is metabolized via glucuronyl transferase, forming a glucuronide conjugate. The remainder is excreted renally unchanged. Infants, in particular, are predisposed to the gray baby syndrome because they have a limited capacity to form a glucuronide conjugate of chloramphenicol and, concomitantly, a limited ability to excrete unconjugated chloramphenicol in the urine.[97,261]

There are two types of bone marrow suppression that occur after use of chloramphenicol. The most common type is dose dependent and occurs with high serum concentrations of chloramphenicol.[118,119,221] Clinical manifestations usually occur within several weeks of therapy and include anemia, thrombocytopenia, leukopenia, and very rarely, aplastic anemia. Bone marrow suppression is generally reversible on discontinuation of therapy. A second type of bone marrow suppression caused by chloramphenicaol occurs through this inhibition of protein synthesis in the mitochondria of marrow cell lines.[175] This type causes the development of aplastic anemia, which is not dose related and generally occurs in susceptible patients within 5 months of treatment and has an approximately 50% mortality rate (Chap. 24).[77,268] The dehydro and nitroso bacterial metabolites of chloramphenicol injure human bone marrow cells through inhibition of myeloid colony growth, inhibition of DNA synthesis, and inhibition of mitochondrial protein synthesis.[129]

Other adverse effects associated with chloramphenicol include peripheral neuropathy[195]; neurologic abnormalities, such as confusion and delirium[150]; optic neuritis[59]; nonlymphocytic leukemia[225]; and contact dermatitis.[140]

■ FLUOROQUINOLONES
Ciprofloxacin

The fluoroquinolones are a structurally similar, synthetically derived group of antimicrobials that have diverse antimicrobial activities. They include balofloxacin, ciprofloxacin, clinafloxacin, enoxacin, fleroxacin, gatifloxacin, gemifloxacin, grepafloxacin, levofloxacin, lomefloxacin, moxifloxacin, nadifloxacin, nalidixic acid, norfloxacin, ofloxacin, pefloxacin, rufloxacin, sparfloxacin, temafloxacin, tosufloxacin, and trovafloxacin. Like other antimicrobials, the fluoroquinolones rarely produce life-threatening effects following acute overdose, and most patients can be safely managed with minimal intervention.[11] Table 56–1 lists the pharmacologic mechanism of fluoroquinolones, and Table 56–2 lists their pharmacokinetic properties.

Rarely, acute overdose of a fluoroquinolone results in renal failure or seizures.[143] The mechanism of renal failure after fluoroquinolone exposure is controversial. In animals, ciprofloxacin and norfloxacin cause nephrotoxicity, especially in the setting of neutral or alkaline urine.[61,218] In humans, renal failure is reported after both acute and chronic exposure to fluoroquinolones. A hypersensitivity reaction is postulated to explain pathologic changes consistent with interstitial nephritis.[116,202] Treatment includes discontinuation of the fluoroquinolone and supportive care. Improvement in renal function is usually noticed within several days.

Seizures are reported with ciprofloxacin and may be a result of the inhibition of GABA.[228,245] Others postulate that seizures result from the ability of fluoroquinolones to bind efficiently to cations, particularly magnesium. This hypothesis is related to the inhibitory role of magnesium at the excitatory NMDA-gated ion channel (Chap. 13).[68,219] Treatment is supportive, using benzodiazepines and, if necessary, barbiturates to increase inhibitory tone.

Adverse Effects Associated With Therapeutic Use Several fluoroquinolones are substrates and/or inhibitors of cytochrome CYP isozymes. This can result in drug interactions, which are especially important with drugs that have a narrow therapeutic index.

Serious adverse effects related to fluoroquinolone use consist of central nervous system toxicity, as discussed, cardiovascular toxicity,[126] hepatotoxicity, and notable musculoskeletal toxicity.

Fluoroquinolones cause prolongation of the QT interval and may cause torsades de pointes.[40,126,213] Although the mechanism is unclear, sequestering of magnesium, resulting in clinical hypomagnesemia, is postulated.[219] Treatment of patients presenting with QT prolongation is supportive, with careful attention to magnesium supplementation if necessary.

The fluoroquinolones rarely result in potentially fatal hepatotoxicity.[54,89,99,144,158,206] This adverse effect is most notable with trovafloxacin. In vitro models show trovafloxacin to be uniquely capable of altering gene expression that regulates oxidative stress and RNA processing leading to mitochondrial damage.[152] Consequently, trovafloxacin (Trovan) is now reserved only for the treatment of patients with life-threatening infections in whom the benefits are thought to outweigh the risks. In addition, the manufacturer has initiated a limited distribution system that allows drug shipment only to pharmacies within inpatient healthcare facilities.

Fluoroquinolones should be used with caution in children and pregnant women because of their potential adverse effects on developing cartilage and bone. Damage to articular cartilage is demonstrated in young dogs and rats, although the extent varies among different fluoroquinolones.[45,238] There are very limited data regarding damage to articular cartilage as a result of using fluoroquinolones in humans; however, children given ciprofloxacin on a compassionate basis developed complaints of swollen, painful, and stiff joints after 3 weeks of therapy.[128] All signs and symptoms abated within 2 weeks of discontinuation of therapy. However, 29 additional children treated with ofloxacin or ciprofloxacin showed no differences with respect to cartilage thickness, cartilage structure, edema, cartilage-bone borderline, or synovial fluid.[65] Women who received quinolones during pregnancy had larger babies and more caesarean deliveries because of fetal distress than did controls.[22] However, there were no congenital malformations, delay to developmental milestones, or musculoskeletal abnormalities found.

Fluoroquinolones are also implicated as a cause of tendon rupture, which is reported to occur up to 120 days after the start of treatment and even after the discontinuation of therapy.[191] The fluoroquinolone should be discontinued in patients, particularly athletes who complain of symptoms consistent with painful and swollen tendons.

Other adverse effects include acute psychosis, dysglycemia (hyper- and hypoglycemia), rash, tinnitus, eosinophilia, serum sickness, and photosensitivity.[44,103,173,188,232]

■ MACROLIDES AND KETOLIDES
Erythromycin

The macrolide antimicrobials include various forms of erythromycin (base, estolate, ethylsuccinate, gluceptate, lactobionate, stearate), azithromycin, clarithromycin, troleandomycin, and dirithromycin. Ketolides are similar in pharmacology to macrolides; telithromycin is the only available agent at this time. Table 56–1 lists the pharmacologic mechanism of macrolides and ketolides, and Table 56–2 lists their pharmacokinetic properties.

Acute oral overdoses of macrolide antimicrobials are usually not life threatening and symptoms, which are generally confined to the gastrointestinal tract, include nausea, vomiting, and diarrhea. A single case of pancreatitis is reported.[241] Erythromycin lactobionate causes QT prolongation and torsades de pointes after intravenous use.[184] Oral erythromycin is also implicated in causing prolongation of the QT and torsades de pointes, especially in patients concurrently taking cytochrome P450 (CYP) 3A4 inhibitors.[196] In vitro models demonstrate erythromycin's ability to slow repolarization in a concentration-dependent manner.[177] The cause of prolonged QT interval was once thought to be from hypokalemia-induced promotion of intracellular efflux of potassium.[197] Data, however, demonstrate that the QT interval prolongation results from blockade of delayed rectifier potassium currents (Chaps. 22 and 23).[208] QT prolongation and torsades de pointes are common after intravenous erythromycin lactobionate.[184] More pronounced prolongation occurs in patients with underlying heart disease and correlates with the infusion rate.[106] Epidemiologic studies note an increased incidence of ventricular dysrhythmias in women treated with erythromycin.[75]

Although there are no acute overdose data regarding ketolide antimicrobials, effects are expected to be similar to macrolide antimicrobials. Therapeutic use of telithromycin is reported to result in QT prolongation, hepatotoxicity, toxic epidermal necrolysis and anaphylaxis.[1,17,27,29,74,185]

Adverse Events Associated With Therapeutic Use *Drug Interactions.* Erythromycin is the prototypical macrolide and, as such, has received the most attention with respect to potential and documented drug interactions.[115] Clarithromycin, erythromycin, and troleandomycin are all potent inhibitors of the CYP3A4 enzyme system; azithromycin does not inhibit this enzyme.[64] Erythromycin inhibits cytochrome P450 after metabolism to a nitroso intermediate, which then forms an inactive complex with the iron (II) of cytochrome P450. Chapter 12 (Appendix) lists substrates for the CYP3A4 system. Clinically significant interactions occur with erythromycin and warfarin, carbamazepine, terfenadine or cyclosporine.[46,111,115,194] Inhibition of cisapride metabolism results in increased concentrations of the parent drug, which is capable of causing prolongation of the QT interval and causing torsades de pointes.[35] Cases of carbamazepine toxicity are documented when combined with the use of erythromycin.[111] Erythromycin also inhibits CYP1A2, producing clinically significant interactions with clozapine, theophylline, and warfarin.[204]

Macrolides may also interact with the absorption and renal excretion of drugs that are amenable to intestinal P-glycoprotein excretion, or interfere with normal gut flora responsible for metabolism. This may be part of the underlying mechanism of cases of macrolide-induced digoxin toxicity (Chap. 64).[182]

End-Organ Effects The most common toxic effect of macrolides after chronic use is hepatitis, which may be immune mediated.[49] Erythromycin estolate is the agent most frequently implicated in causing cholestatic hepatitis.[96,123]

Large doses (more than 4 g/d) of macrolide antimicrobials are also associated with reversible high-frequency sensorineural hearing loss.[41] Renal impairment may be a risk factor.[211,236] There are rare case reports in which ototoxicity did not resolve following discontinuation of therapy.[149] There are insufficient data concerning the ototoxic

potential of the other macrolide antimicrobials. Other, rare toxic effects associated with macrolides include cataracts after clarithromycin use in animals and acute pancreatitis in humans.[82,249] Allergy is rare and reported at a rate of 0.4% to 3%.[70] Telithromycin contains a carbamate side chain that may interfere with the normal function of neuronal cholinesterase. It should be used cautiously in patients with myasthenia gravis, particularly patients receiving pyridostigmine because of the risk of cholinergic crisis.[240]

Clindamycin is a lincosamide with similar structure and clinical effects to macrolides. Clindamycin phosphate is commonly used topically while clindamycin hydrochloride is available for intravenous use. Data regarding acute overdose is limited and the majority of the chronic toxicity is seen after use of systemic doses of clindamycin phosphate. The most consequental toxicity is gastrointestinal resulting in esophageal ulcers, diarrhea, and colitis.[203]

■ SULFONAMIDES
Sulfamethoxazole

Sulfonamides antagonize *para*-aminobenzoic acid or *para*-aminobenzyl glutamic acid, which are required for the biosynthesis of folic acid. Table 56–1 lists the pharmacologic mechanism of sulfonamides, and Table 56–2 lists their pharmacokinetic properties. Acute oral overdoses of sulfonamides are usually not life threatening, and symptoms are generally confined to nausea, although allergy and methemoglobinemia occur rarely.[86] Treatment is similar to acute oral penicillin overdoses.

Adverse Effects Associated With Therapeutic Use The most common adverse effects associated with sulfonamide therapy are nausea and cutaneous hypersensitivity reactions. Hypersensitivity reactions are thought to be caused by the formation of hapten sulfamethoxazole metabolites, *N*-hydroxy-sulfamethoxazole and nitroso-sulfamethoxazole. The degree of hapten binding is mitigated in vitro by cysteine and glutathione.[176] The incidence of adverse reactions to sulfonamides, including allergy, is increased in HIV-positive patients and is positively correlated to the number of previous opportunistic infections experienced by the patient.[147] This may be caused by a decrease in the mechanisms available for detoxification of free radical formation, as cysteine and glutathione levels are low in these patients.[257] Whether supplementation with a glutathione precursor such as *N*-acetylcysteine will reduce the incidence of these reactions is unknown.[3]

Methemoglobinemia and hemolysis also rarely occur.[76,155] The mechanism for adverse reactions is not entirely clear. However, when sulfamethoxazole is exposed to ultraviolet B (UVB) radiation in vitro, free radicals are formed that can participate in the development of tissue peroxidation and hemolysis.[268] This finding may be of particular importance in treating patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency associated with decreased in reducing capabilities.[5]

The sulfonamides are associated with many chronic adverse effects. Bone marrow suppression is rare, but the incidence is increased in patients with folic acid or vitamin B12 deficiency, and in children, pregnant women, alcoholics, dialysis patients, and immunocompromised patients, as well as in patients who are receiving other folate antagonists. Other adverse effects include hypersensitivity pneumonitis, stomatitis, aseptic meningitis, hepatotoxicity, renal toxicity, and central nervous system toxicity.[30]

■ TETRACYCLINES
Tetracycline

Tetracyclines are derivatives of *Streptomyces* cultures. Currently available tetracyclines include demeclocycline, doxycycline, methacycline, minocycline, oxytetracycline, and tetracycline. Table 56–1 lists the pharmacologic mechanism of tetracyclines, and Table 56–2 lists their pharmacokinetic properties. Significant toxicity after acute overdose of tetracyclines is unlikely. Gastrointestinal effects consisting of nausea, vomiting, and epigastric pain have been reported.[42]

Adverse Effects Associated With Therapeutic Use Tetracycline should not be used in children during the first 6 to 8 years of life or by pregnant women after the 12th week of pregnancy because of the risk of development of secondary tooth discoloration in children or developing children in utero.

Other effects associated with tetracyclines include nephrotoxicity, hepatotoxicity, skin hyperpigmentation in sun-exposed areas, and hypersensitivity reactions.[49,100,121,239] More severe hypersensitivity reactions, drug-induced lupus, and pneumonitis are reported after minocycline use, as are cases of necrotizing vasculitis of the skin and uterine cervix, and lymphadenopathy with eosinophilia.[160,220,224] Demeclocycline rarely causes nephrogenic diabetes insipidus (Chap. 16).[50] Of historical interest, outdated older formulations of tetracycline were reported to cause hypouricemia, hypokalemia, and a proximal and distal renal tubular acidosis.[57]

■ VANCOMYCIN
Vancomycin

Vancomycin is obtained from cultures of *Nocardia orientalis* and is a tricyclic glycopeptide. Vancomycin is biologically active against numerous gram-positive organisms. Table 56–1 lists the pharmacologic mechanism of vancomycin, and Table 56–2 lists its pharmacokinetic properties.

Acute oral overdoses of vancomycin rarely cause significant toxicity and most cases can be treated with supportive care alone. Multiple-dose activated charcoal and potentially high-flux hemodialysis can be considered for patients with large overdoses when the patient is expected to have prolonged clearance.[141,248]

Adverse Effects Associated With Therapeutic Use Patients who receive intravenous vancomycin may develop the "red man syndrome" through an anaphylactoid reaction.[93] Symptoms include chest pain, dyspnea, pruritus, urticaria, flushing, and angioedema.[207] Signs and symptoms spontaneously resolve, typically within 15 minutes. Other symptoms attributable to red man syndrome include hypotension, cardiovascular collapse, and seizures.[13,179]

The incidence of red man syndrome appears to be related to the rate of infusion and is approximately 14% when 1 g is given over 10 minutes, whereas it is 3.4% when given over 1 hour.[179,186] A trial in 11 healthy persons studied the relationship between intradermal skin hypersensitivity and the development of red man syndrome. Each of the 11 subjects underwent skin testing that was followed 1 week later by an intravenous dose of vancomycin 15 mg/kg over 60 minutes. Following intravenous vancomycin, all subjects developed dermal flare responses and erythema, and 10 of 11 subjects developed pruritus within 20 to 45 minutes. After the infusion was terminated, symptoms resolved within 60 minutes.[193]

The signs and symptoms of red man syndrome are related to the rise and fall of histamine concentrations.[110,151] Tachyphylaxis occurs in patients given multiple doses of vancomycin.[109,256] Animal models demonstrated a direct myocardial depressant and vasodilatory effect of vancomycin.[60] More serious reactions result when vancomycin is given via intravenous bolus, further supporting a rate-related anaphylactoid mechanism.[24]

Patients most often experience red man syndrome after vancomycin is administered intravenously. In rare cases, oral administration of vancomycin can also result in the syndrome.[21] Treatment includes increasing the dilution of vancomycin and slowing intravenous administration. Antihistamines may be useful as pretreatment, especially prior to the first dose.[198] A placebo-controlled trial in adult patients studied the incidence of these symptoms in patients given 1 g of vancomycin over 1 hour, as well as the effect of diphenhydramine in the prevention of the syndrome.[256] There was a 47% incidence of reaction without diphenhydramine and a 0% incidence with diphenhydramine.

Chronic use of vancomycin may cause reversible nephrotoxicity, particularly in patients with prolonged excessive steady-state se rum levels.[10,201] Concomitant administration of aminoglycoside antimicrobials may increase the risk of nephrotoxicity.[209] Vancomycin also causes, though rarely, thrombocytopenia and neutropenia.[56,58,73]

ANTIFUNGALS

Numerous antifungals are available. Toxicity related to the use of antifungals is variable and is based generally on their mechanism of action.

■ AMPHOTERICIN B
Amphotericin B is a potent antifungal derived from *Streptomyces nodosus*. Amphotericin B is generally fungistatic against fungi that contain sterols in their cell membrane. Table 56–1 lists the pharmacologic mechanism of amphotericin B, and Table 56–2 lists its pharmacokinetic

properties. Development of lipid and colloidal formulations of amphotericin B attenuate the adverse effects associated with amphotericin B.[104] In these preparations, the amphotericin B is complexed with either a lipid or cholesteryl sulfate. On contact with a fungus, lipases are released to free the complexed amphotericin B, resulting in focused cell death.[113]

There are several case reports of amphotericin B overdose in infants and children. Significant clinical findings include hypokalemia, increased aspartate aminotransferase concentrations, and cardiac complications. Dysrhythmias and cardiac arrest have occurred following doses of 5 to 15 mg/kg of amphotericin B.[36,58,137] Care should be used in the doses of amphotericin B administered according to dosage form, as these are not interchangeable. For example, intravenous therapy for fungal infections includes a usual dose of 0.25 to 1 mg/kg/d of amphotericin B or 3 to 4 mg/kg/d of amphotericin B cholesteryl. The potential for significant dosage errors and their sequelae is readily apparent in this comparison.

Adverse Effects Associated With Therapeutic Use Infusion of amphotericin B results in fever, rigors, headache, nausea, vomiting, hypotension, tachycardia, and dyspnea.[161] Pretreatment with acetaminophen, diphenhydramine, ibuprofen, and hydrocortisone is helpful in alleviating the febrile symptoms, as are slower rates of infusion and lower total daily doses.[95,247] Doses greater than 1 mg/kg/d and rapid administration of drug in less than 1 hour are not recommended. Infusion concentrations of amphotericin B greater than 0.1 mg/mL can result in localized phlebitis. Slower infusion rates, hot packs, and frequent line flushing with dextrose in water may help to alleviate symptoms.

Eighty percent of patients exposed to amphotericin B will sustain some degree of renal insufficiency (Chap. 27).[47] Initial distal renal tubule damage causes renal artery vasoconstriction ultimately resulting in azotemia.[83] Studies in animals show depressed renal blood flow and glomerular filtration rate, and increased renal vascular resistance. It is unclear why this occurs, but at this time, renal nerves, angiotensin II, nitric oxide, and tubuloglomerular feedback are excluded.[210,216] The toxic effects associated with amphotericin B may also be caused by the deoxycholate vehicle.[267] After large total doses of amphotericin B, residual decreases in glomerular filtration rate may occur even after discontinuation of therapy. This is hypothesized to be the result of nephrocalcinosis. Potassium and magnesium wasting, proteinuria, decreased renal concentrating ability, renal tubular acidosis, and hematuria also occur (Chap. 16).[15,161] Strategies to reduce renal toxicity after amphotericin B include intravenous saline or magnesium and potassium supplementation.[34,84,112] Liposomal formulations of amphotericin B resulted in fewer patients with breakthrough fungal infections, infusion-related fever, rigors, or nephrotoxicity.[258] However, chest pain is uniquely reported after use of the liposomal agent.[130]

Other adverse effects reported after treatment with amphotericin B include normochromic, normocytic anemia secondary to decreased erythropoietin release;[159] respiratory insufficiency with infiltrates; and, rarely, dysrhythmias, tinnitus, thrombocytopenia, peripheral neuropathy, and leukopenia.[153,159,161]

Exchange transfusion may be useful in neonates and infants and should be considered after large intravenous exposures. In adults, extracorporeal elimination is not expected to be useful because of the low water solubility and high blood-protein binding of the drug.

■ AZOLE ANTIFUNGALS: TRIAZOLE AND IMIDAZOLES
Fluconazole

Common triazole antifungals include fluconazole, itraconazole, and voriconazole. Common imidazoles include clotrimazole, econazole, ketoconazole, and miconazole. Triazole antifungals are active to treat an array of fungal pathogens, whereas imidazoles are used almost exclusively in the treatment of superficial mycoses and vaginal candidiasis. Severe toxicity is not expected in the overdose setting. Hepatotoxicity, thrombocytopenia, and neutropenia are uncommon.[31] Rare case reports implicate voriconazole in the development of toxic epidermal necrolysis.[117] The majority of toxic effects noted after the use of these drugs result from their drug interactions. Fluconazole, itraconazole, ketoconazole, and miconazole competitively inhibit CYP3A4, the enzyme system responsible for the metabolism of many drugs. Table 56–5 lists other organ system manifestations associated with antifungal agents and other antimicrobials.

ANTIPARASITICS

Antiparasitics such as thiabendazole, mebendazole, albendazole, diethylcarbazine, ivermectin, metrifonate, niclosamide, oxamniquine, piperazine, priziquantel, and pyrantel pamoate generally have a low level of toxicity in the overdose setting. Common symptoms after therapeutic use are gastrointestinal in nature and include abdominal pain, nausea, vomiting, and diarrhea. A single case of ivermectin-associated hepatic failure is reported 1 month after a single dose.[252]

ANTIVIRAL

Acyclovir is well tolerated in therapeutic doses and overdoses, although data are limited. In 105 dogs ingesting 40 to 2195 mg/kg, gastrointestinal symptoms were most common with one dog developing mild creatinine increases.[200] Depressed mental status and nephrotoxicity are also reported after therapeutic use in humans.[32]

ANTIMICROBIALS SPECIFIC TO THE TREATMENT OF HUMAN IMMUNODEFICIENCY VIRUS AND RELATED INFECTIONS

The evaluation and management of patients infected with the human immunodeficiency virus (HIV) and associated acquired immune deficiency syndrome (AIDS) is ever evolving at a rapid and progressive pace. Medications used to manage this disorder have dramatically increased life expectancy as new, more powerful antiviral agents and drug combinations become available. Drug therapy for HIV commonly consists of a combination of drugs from different classes (nucleoside reverse transcriptase inhibitor [NRTI], nonnucleoside reverse transcriptase inhibitor [NNRTI], and protease inhibitor) in order to take advantage of the unique mechanism that each drug offers in inhibiting viral replication and minimizing drug resistance. Resistance patterns to the typical drugs used in attenuating viral replication and proliferation are a substantial issue and will continue to be addressed with yet more evolution in management in the foreseeable future. This section focuses on overdoses and major toxic effects from HIV-directed antiviral therapy, as well as from drugs that are specifically used in the management of opportunistic infections.[20] Table 56–6 lists the common antibiotic agents used to treat HIV-related opportunistic infections, and Table 56–7 lists common adverse drug effects and overdose effects, if known, for antimicrobials that are specific in their use for HIV-related infections.

■ SPECIFIC ANTIRETROVIRAL CLASSES

Nucleoside Analog Reverse Transcriptase Inhibitors The nucleoside analog reverse transcriptase inhibitors inhibit the reverse transcription

TABLE 56–5. Consequential Organ System Manifestations Associated With Antimicrobials

Antimicrobial	System	Signs, Symptoms, Laboratory
Antibacterials		
Bacitracin	Immune	Hypersensitivity reactions
Clindamycin	Immune	Hypersensitivity reactions
	Gastrointestinal	Nausea, vomiting, diarrhea
	Nervous	Dizziness, headache, vertigo
Colistimethate (colistin sulfate)	Renal	Decreased function, acute tubular necrosis
	Nervous	Peripheral paresthesias, confusion, coma, seizures, neuromuscular blockade
Lincomycin	Gastrointestinal	Nausea, vomiting, diarrhea
	Immune	Hypersensitivity reactions
Metronidazole	Neurologic	Peripheral neuropathy, seizures
	Gastrointestinal	Nausea, vomiting
	Other	Disulfiram reactions
Nitrofurazone	Immune	Hypersensitivity reactions
	Other	Ointment contains polyethylene glycols (renal dysfunction)
Nitrofurantoin	Gastrointestinal	Nausea, vomiting, diarrhea
	Hepatic	Jaundice
	Immune	Rash, acute and chronic pulmonary hypersensitivity
	Neurologic	Peripheral neuropathy
Novobiocin	Immune	Rash
	Gastrointestinal	Nausea, vomiting, diarrhea
	Hematologic	Pancytopenia, hemolytic anemia
Polymyxin B sulfate	Neurologic	Muscle weakness, seizures
	Renal	Azotemia, proteinuria
Selenium sulfide	Cutaneous	Contact dermatitis, alopecia (rare)
Silver sulfadiazine	Cutaneous	Contact dermatitis
	Hematologic	Anemia, aplastic anemia
Spectinomycin	Immune	Rash (rare)
Antifungals		
Benzoic acid	Gastrointestinal	Nausea, vomiting, diarrhea
Carbol-fuchsin solution (phenol/ resorcinol/ fuchsin)	Gastrointestinal	Nausea, vomiting, diarrhea
Gentian violet	Gastrointestinal	Nausea, vomiting, diarrhea
	Immune	Rash (rare)
Griseofulvin	Renal	Proteinuria, nephrosis
	Hepatic	Increased enzymes
	Gastrointestinal	Nausea, vomiting, diarrhea
	Immune	Granulocytopenia
	Other	Disulfiram reactions, increased porphyrins
Nystatin	Gastrointestinal	Nausea, vomiting, diarrhea
Salicylic acid	Gastrointestinal and dermal	Higher concentrations are caustic
Undecylenic acid and undecylenate salt	Gastrointestinal	Nausea, vomiting, diarrhea

TABLE 56–6. Antimicrobials Used to Treat Common Opportunistic Infections[20]

Antimicrobial	Opportunistic Infection
Albendazole	Microsporidiosis
Amphotericin B	Aspergillosis
	Coccidioidomycosis
	Cryptococcosis
	Histoplasmosis
	Leishmaniasis
	Paracoccidioidomycosis
	Penicilliosis
Antimony (pentavalent)	Leishmaniasis
Atovaquone	*Pneumocystis jiroveci*
Azithromycin	*Mycobacterium avium* complex
Clarithromycin	Mycobacterium avium complex
Caspofungin	Aspergillosis
Clindamycin	*Pneumocystis jiroveci*
	Toxoplasma gondii
Dapsone	*Pneumocystis jiroveci*
Ethambutol	*Mycobacterium avium* complex
Fluconazole	Coccidioidomycosis
	Histoplasmosis
Flucytosine	Cryptococcosis
Foscarnet	Cytomegalovirus
Fumagillin	Microsporidiosis
Ganciclovir	Cytomegalovirus
Itraconazole	Histoplasmosis
Leucovorin	*Pneumocystis jiroveci*
	Toxoplasma gondii
Nitazoxanide	Cryptosporidiosis
	Microsporidiosis
Paromomycin	Cryptosporidiosis
Pentamidine	*Pneumocystis jiroveci*
Primaquine	*Pneumocystis jiroveci*
Pyrimethamine	*Toxoplasma gondii*
Rifabutin	*Mycobacterium avium* complex
Sulfadiazine	*Toxoplasma gondii*
Trimethoprin-sulfamethoxazole	*Pneumocystis jiroveci*
	Toxoplasma gondii
	Isosporiasis
Trimetrexate	*Pneumocystis jiroveci*
Valganciclovir	Cytomegalovirus
Voriconazole	Aspergillosis

of viral RNA into proviral DNA. Currently available drugs include abacavir (ABC), emtricitabine (FTC), didanosine (ddI), lamivudine (3TC), stavudine (d4T), tenofovir (TDF), zidovudine (AZT, ZDV), and zalcitabine (ddC).

Acute Overdose Effects. Many intentional overdoses of reverse transcriptase inhibitors occur without major toxicologic effect. The most serious adverse effect anticipated after acute overdose of an NRTI is

TABLE 56–7. Antimicrobials Used in the Treatment of HIV-Related Infections[20]

Antimicrobial	Overdose Effects	Common Adverse Drug Effects
Albendazole	No reported cases	Increased AST/ALT, nausea, vomiting, and diarrhea. Hematologic, rare—encephalopathy, renal failure, rash
Antimony (pentavalent)	Acute tubular necrosis	Acute tubular necrosis. Multiorgan system failure
Atovaquone	No clinical relevant effects in reported cases[55]	Rashes, anemia, leukopenia, increased AST/ALT
Caspofungin	No reported cases	Phlebitis, headache, hypokalemia, increased AST/ALT, fever
Flucytosine	No reported cases	Bone marrow suppression, hepatotoxicity, nausea, vomiting, diarrhea, and rash
Foscarnet	No reported cases	Azotemia, hypocalcemia and renal failure (common); anemia, leukopenia, thrombocytopenia, fever, headache, seizures, genital and oral ulcers, fixed-drug eruptions, nausea, vomiting, diarrhea, headaches, seizures, coma, diabetes insipidus, hypophosphatemia, hypokalemia, and hypomagnesemia
Fumagillin	No reported cases	Neutropenia and thrombocytopenia
Ganciclovir	No clinical relevant effects in reported cases[138]	Leukopenia, worsening of renal function; can also cause nausea, vomiting, diarrhea, increased AST/ALT, anemia, thrombocytopenia, headache, dizziness, confusion, seizures
Nitazoxanide	No reported cases	Hypotension, headache, abdominal pain, nausea, vomiting; may cause green-yellow urine discoloration
Pentamidine	40 times dosing error in a 17-month-old child resulted in cardiac arrest[259]	Hypoglycemia (early) followed by hyperglycemia, azotemia; can cause hypotension, torsades de pointes, phlebitis, rash, Stevens-Johnson syndrome, hypocalcemia, hypokalemia, anorexia, nausea, vomiting, metallic taste, leukopenia, and thrombocytopenia
Primaquine	No reported cases	Granulocytopenia, hemolytic anemia, methemoglobinemia, leukocytosis; hypertension
Pyrimethamine	No reported cases	Agranulocytosis, aplastic anemia, thrombocytopenia, and leukopenia
Rifabutin	High doses (>1 g daily): arthralgia/arthritis	Nausea, vomiting, diarrhea; can cause hepatotoxicity, neutropenia, thrombocytopenia, and hypersensitivity reactions
Sulfadiazine	Acute renal failure and hypoglycemia[63]	Rash, Stevens-Johnson syndrome, toxic epidermal necrolysis, erythema multiforme; headaches, depression, hallucinations, ataxia, tremor, crystalluria, hematuria, proteinuria, and nephrolithiasis
Trimetrexate	No reported cases; treat similar to methotrexate (Chap. 53)	Myelosuppression, nausea, vomiting, histaminergic reactions
Valganciclovir	No reported cases; expect to be similar to ganciclovir	Anemia, neutropenia, thrombocytopenia; nausea, vomiting, headache, peripheral neuropathy

AST/ALT, serum alanine aminotransferase or serum aspartate aminotransferase.

the development of a lactic acidemia, which appears to be more common in women.[52,81,162] Following incorporation of the nucleoside analog into mitochondrial DNA by RNA polymerase, DNA polymerase γ is inhibited. This results in decreased production of mitochondrial DNA electron transport proteins, which ultimately inhibits oxidative phosphorylation (Chap. 12). Organ system toxicity follows in addition to the development of acidemia. The reported mortality in patients with NRTI-associated metabolic acidosis associated with elevated lactate is 33% to 57%.[81] Resolution of symptoms in survivors is 1 to 24 weeks. Patients with NRTI-associated acidemia may recover more quickly after the use of cofactors such as thiamine, riboflavin, L-carnitine, vitamin C, and antioxidants.[38,71] The indications for the use of these drugs are unclear at this time; however, because of the relative lack of toxicity, they may be considered.

Chronic Effects. Development of acidemia is more commonly associated with therapeutic use of reverse transcriptase inhibitors than with acute overdose. The mechanism is likely identical to that described above. Other common adverse effects are somewhat agent specific and include hematologic toxicity after zidovidine,[71,98] pancreatitis with didanosine,[145] hypersensitivity after abacavir,[70] and sensory peripheral neuropathy after zalcitabine, stavudine, and didanosine.[171]

Nonnucleoside Reverse Transcriptase Inhibitors NNRTI bind directly to reverse transcriptase enzymes enabling allosteric inhibition of enzymatic function.[243] Delavirdine (Rescriptor), etravirine (Intelence), efavirenz (Sustiva), and nevirapine (Viramune) comprise the currently available agents.

There are no substantial acute overdose data on these drugs, although they generally appear to be safe in overdose. Treatment should include

supportive care until more information is available. The NNRTIs are also limited in toxicity after chronic use. Nevirapine and delavirdine use commonly results in hypersensitivity reactions such as rash.[69] Efavirenz is reported to result in dizziness and dysphoria. Otherwise, toxicity can result from the ability of these drugs to either inhibit or enhance CYP isozymes in the metabolism of other drugs.

Protease Inhibitors Protease inhibitors inhibit the vital enzyme (proteinase), which is required for viral replication.[85] Currently available drugs include atazanavir (Reyatax), darunavir (Prezista), fosamprenavor (Lexiva), indinavir (Crixivan), lopinavir (Kaletra), nelfinavir (Viracept), ritonavir (Norvir), saquinavir mesylate (Invirase), and tipranavir (Aptivus).

Data after protease inhibitor overdose are limited. A review of data submitted to the manufacturer of indinavir found that of 79 reports, the complaints were nausea, vomiting, abdominal pain, and nephrolithiasis. Protease inhibitors as a class commonly result in gastrointestinal symptoms and rash.[85] A unique finding is an altered fat distribution pattern that, over time, results in lymphodystrophy central obesity, "buffalo hump," breast enlargement, cushingoid appearance, and peripheral wasting.[85]

Entry/Fusion Inhibitors This class of drugs interferes with the binding or entry of the HIV viron into the cell.[26] No acute overdose data are available for this class, but after chronic use, hypersensitivity, hepatotoxicity, and infusion reactions seem to be of greatest concern.[18,174,180] The currently available agents include enfuvirtide (Fuzeon) and maraviroc (Selzentry).

Integrace Inhibitor This class of drugs prevents the activity of the enzyme in HIV to function normally. This enzyme is responsible for the incorporation of the virus into DNA. The currently available agent is raltegravir (Isentress). No information is currently available regarding its toxicity.

SUMMARY

Adverse effects attributable to antimicrobials are largely related to chronic administration, although rarely acute toxicity does occur. Acute toxic effects of antimicrobials are more common following intravenous administration, drug interactions, or iatrogenic overdose. Vigilance on the part of the healthcare provider will prevent the majority of acute toxic manifestations following antimicrobial use.

CHAPTER 57
ANTITUBERCULOUS MEDICATIONS

Christina H. Hernon and Edward W. Boyer

Tuberculosis and antituberculous therapy have ever increasing global implications. More and more people are exposed to more combinations of antituberculous and antiretroviral drugs throughout the world. Vigilance for depression and suicide risk are particularly important to evaluate as complications of the diseases under treatment and as complications of the therapy. Isoniazid remains the most commonly used and the most consequential in overdose.

HISTORY AND EPIDEMIOLOGY

The global burden of tuberculosis is enormous. Approximately two billion people, one-third of the total population of the world, are infected with *Mycobacterium tuberculosis.* An estimated 8.8 million new cases of disease are diagnosed and 1.6 million persons die from tuberculosis annually.[3] In 2007, the incidence of tuberculosis (TB) in the United States was the lowest recorded (13,000 cases) since the inception of national reporting in 1953.[22] The introduction of isoniazid (INH) into clinical practice in 1952 produced a steady decline in the number of TB cases in the United States over the subsequent 30 years. However, between 1985 and 1991, there was a resurgence in TB cases in the United States resulting primarily from the effects of human immunodeficiency virus (HIV), homelessness, deterioration in the healthcare infrastructure, and an increased presence of foreign-born persons. With the initiation and implementation of containment strategies, the spread of the infection has been slowed by aggressive case identification and patient-centered management, including directly observed therapy, social support, housing, and substance abuse treatment. These methods have decreased the incidence rate in the United States as well as worldwide. In 2005, the tuberculosis incidence was stable or declining worldwide, although the total number of new TB cases continues to increase slowly. Also in that year, extensively-drug-resistant tuberculosis (XDR-TB) was recognized, with between 4% and 19% of multidrug resistant tuberculosis (MDR-TB) strains being resistant to both INH and rifampin, all fluoroquinolones, and at least one of three injectable drugs (capreomycin, kanamycin, and amikacin).[7,21,94] At present, populations that remain at risk for tuberculosis include HIV-positive patients, the homeless, injection drug users, healthcare workers, prisoners, prison workers, and Native Americans. In addition, the tuberculosis rate in foreign-born persons is nearly 10 times higher than in US-born persons. In the US population, countries of birth generating the highest number of tuberculosis cases are Mexico, the Philippines, India, and Vietnam.[7,21] The use of second-line (reserve) drugs and multidrug antituberculous regimens for MDR-TB and XDR-TB resulted in an increased incidence of adverse drug effects, increasing to 40-70% and sometimes requiring discontinuation of the treatment. Hepatotoxicity, peripheral neuropathy, and ocular neuropathy are often irreversible and potentially fatal. Psychosocial conditions, chronic illness, and adverse drug effects involving anxiety,

depression, and psychosis all contribute to an escalated risk of suicidality, intentional overdose, and noncompliance with therapy.[128]

ISONIAZID

■ PHARMACOLOGY

Isoniazid (INH, or isonicotinic hydrazide) is structurally related to nicotinic acid (niacin, or vitamin B_3), nicotinamide-adenosine dinucleotide (NAD), and pyridoxine (vitamin B_6) (Fig. 57–1). The pyridine ring is essential for antituberculous activity. Isoniazid itself does not have direct antibacterial activity. It is a prodrug that undergoes metabolic activation by KatG, a catalase-peroxidase in *M. tuberculosis* that produces a highly reactive intermediate,[95,130] which in turn interacts with InhA, a mycobacterial enzyme that functions as an enoyl-acyl carrier protein (enoyl-ACP) reductase.[92,93] This activated form of INH is either an anion or radical that is stabilized by the pyridine ring. Enoyl-ACP reductase catalyzes the NADH-dependent reduction of the double bonds in the growing fatty acid chain linked to acyl carrier proteins. InhA is required for the synthesis of very-long-chain lipids, mycolic acids (containing between 40 and 60 carbons) that are important components of mycobacterial cell walls.

This INH metabolite enters the binding site of InhA where it reacts with the reduced form of nicotinamide adenine dinucleotide (NADH).[95] The covalently linked INH-NADH complex remains bound to the active site of InhA, irreversibly inhibiting the enzyme.[76,92]

■ PHARMACOKINETICS AND TOXICOKINETICS

When therapeutic doses of 300 mg are administered orally, INH is rapidly absorbed, reaching peak serum concentrations typically within 2 hours.[60,87,88] Isoniazid diffuses into all body fluids with a volume of distribution of approximately 0.6 L/kg and has negligible binding to serum proteins. After the drug penetrates infected tissue, it persists in concentrations well above those generally required for bacteriocidal activity.[88]

Isoniazid is metabolized via a cytochrome P450—mediated process, with approximately 75% to 95% of INH renally eliminated in the form of its hepatic metabolites within 24 hours of administration.[89] The primary metabolic pathway for INH is via *N*-acetylation performed by hepatocytes and mucosal cells in the small intestine. Polymorphic *N*-acetyltransferase-2 (NAT2), the enzyme responsible for this conversion, exhibits Michaelis-Menten kinetics, although the activity of an individual's enzymes is determined by an autosomal dominant inheritance pattern, with homozygous fast acetylators (FF), heterozygous fast acetylators (FS), and homozygous slow acetylators (SS). Patients are distinguishable phenotypically as slow and fast acetylators. The fast acetylation isoform is found in 40% to 50% of American whites and African Americans, whereas the fast acetylator isoenzymes are found in 80% to 90% of Asians and Inuits.[35,39] These isoforms are distinguishable by the following characteristics: (1) slow acetylators have less presystemic clearance, or first-pass effect, than do fast acetylators; (2) fast acetylators metabolize INH five to six times faster than slow acetylators; and (3) serum INH concentrations are 30% to 50% lower in fast acetylators than in slow acetylators. The elimination half-life of INH is approximately 70 minutes in fast acetylators, and 180 minutes in slow acetylators. Twenty-seven percent of INH is excreted unchanged in urine by slow acetylators, as compared with 11% excretion in fast acetylators. The clearance of INH averages 46 mL/min.[10,122] Isoniazid is acetylated into acetylisoniazid and then hydrolyzed into isonicotinic acid and acetylhydrazine. Subsequent acetylation of acetylhydrazine into diacetylhydrazine or hydrolysis into hydrazine occurs.
FIGURE 57–1. INH and related compounds.

Additionally, a small portion of isoniazid is directly hydrolyzed into isonicotinic acid and hydrazine, and this pathway is of greater quantitative significance in slow acetylators than in rapid acetylators. Hepatic microsomal oxidation of the acetylhydrazine intermediate into reactive intermediates has been proposed as the cause of hepatotoxicity, but continuing research suggests that hydrazine plays perhaps an even greater role in hepatic injury.[46,80,119] Figure 57–2 illustrates the metabolism of INH.

◼ PATHOPHYSIOLOGY

Mechanism of Toxicity Toxic effects of INH are caused by two additive mechanisms. First, INH alters the metabolism of pyridoxine (vitamin B$_6$), the coenzyme needed for transamination, transketolization, and decarboxylation biotransformation reactions. Isoniazid creates a functional deficiency of pyridoxine by at least two mechanisms (Fig. 57–3). Hydrazone INH metabolites inhibit pyridoxine phosphokinase, the enzyme that converts pyridoxine to its active form, pyridoxal-5'-phosphate.[25,59,78] In addition, INH reacts with pyridoxal phosphate to produce an inactive hydrazone complex that is renally excreted.[78,122] Urinary excretion of pyridoxine and its metabolites increases with increasing INH dosage, reflecting the effect of INH on pyridoxine metabolism. The consequences of pyridoxine depletion include impaired activity of pyridoxine-dependent enzyme systems, as well as a decrease in catecholamine synthesis. In addition, INH either replaces nicotinic acid in the synthesis of NAD or reacts with NAD to form inactive hydrazones. Isoniazid disrupts cellular reduction/oxidation capabilities through both of these mechanisms.

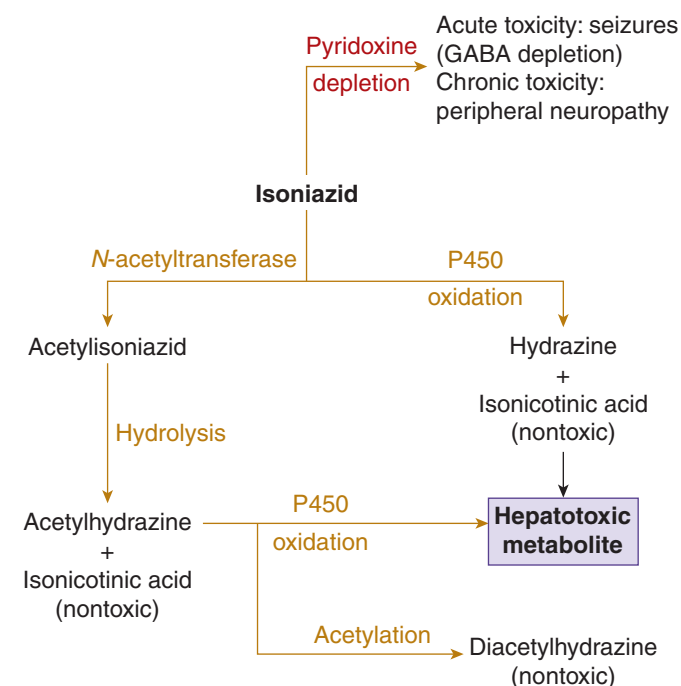
Second, isoniazid interferes with the synthesis and metabolism of γ-aminobutyric acid (GABA), the primary inhibitory neurotransmitter in the central nervous system (CNS). Two pyridoxine-dependent enzymes control GABA metabolism: glutamic acid decarboxylase


FIGURE 57–2. Metabolism of INH. Acetylator status is determined by polymorphism in *N*-acetyltransferase.

(GAD) and GABA aminotransferase. The former catalyzes GABA synthesis from glutamate, while the latter degrades the neurotransmitter. The inhibitory effects are greater on GAD, which leads to both decreased GABA and elevated glutamate concentrations.[124] Depletion of GABA is thought to be the etiology of INH-induced seizures.[5] Structurally similar chemicals exert similar acute toxic effects. Monomethylhydrazine, a metabolite produced from gyromitrin isolated from the *Gyromitra* species ("false morel") mushroom, and the hydrazines used in liquid rocket fuel have a similar mechanism of action (see Chap. 117).

The use of isoniazid in pregnancy is of concern since it is a class C drug, crosses the placenta, and produces umbilical cord serum concentrations comparable to maternal serum concentrations.[13,14,61] Mammalian teratogen studies suggest that isoniazid is not a human teratology, although fetal deformities following acute overdose of INH have been reported.[70,122] Administration of INH to pregnant women was not associated with cancer in their offspring. Although isoniazid
FIGURE 57–3. The effect of isoniazid on γ-aminobutyric acid (GABA) synthesis.

readily enters breast milk, breast-feeding during therapy is considered acceptable.[100,122]

INTERACTIONS WITH OTHER DRUGS AND FOODS

Drug—drug interactions associated with isoniazid are mediated through alteration of hepatic metabolism of several cytochrome P450 (CYP) isoenzymes. The majority of these interactions are inhibitory, with decreased (CYP)-mediated transformations—particularly demethylation, oxidation, and hydroxylation (see Chap. 12 Appendix). Clinically relevant adverse effects with elevated concentrations of theophylline (CYP1A2), phenytoin (CYP2C9/CYP2C19), warfarin (CYP2C9/CYP2C19), valproic acid, and carbamazepine (CYP3A4) are due to decreased hepatic metabolism of these drugs.[33,106,126] The CYP2E1 cytochrome subtype, however, exhibits a complex response to isoniazid; a therapeutic dose of INH induces expression of CYP2E1, but simultaneously binds, stabilizes, and inhibits its metabolic activity. Eventual dissociation of isoniazid from the isoenzyme active site creates an increased intracellular concentration of CYP2E1 available to metabolize potential substrates. The formation of the acetaminophen metabolite responsible for toxicity, NAPQI (*N*-acetyl-*p*-benzoquinoneimine), is catalyzed by CYP2E1. Isoniazid-mediated effects in acetaminophen-induced hepatotoxicity are uncertain because of differences in acetylator status (fast, slow) and variations in CYP2E1 activity.[24,106]

Isoniazid interacts with numerous foods. Isoniazid is a weak monoamine oxidase inhibitor, and tyramine reactions to foods (aged cheeses, wines) and serotonin syndrome from meperidine are reported in patients taking INH. Clinical effects include flushing, tachycardia, and hypertension.[32,45,69,112] Furthermore, INH inhibits the enzyme histaminase, leading to exacerbated reactions following the ingestion of histamine in scombrotoxic fish.[56,77,106] Table 57–1 summarizes additional INH drug and food interactions.

CLINICAL MANIFESTATIONS OF INH TOXICITY

Acute Toxicity Isoniazid produces the triad of seizures refractory to conventional therapy, severe metabolic acidosis, and coma. These clinical manifestations may appear as soon as 30 minutes following ingestion.[54,58,117] The case fatality rate of a single acute ingestion may be as high as 20%.[15,18] Although vomiting, slurred speech, dizziness, and tachycardia may represent early manifestations of toxicity, seizures may be the initial sign of acute overdose.[72] Seizures may occur following the ingestion of greater than 20 mg/kg of INH, and invariably occur with ingestions greater than 35 to 40 mg/kg. Patients with underlying seizure disorders may develop seizures at lower doses.[15] Hyperreflexia or areflexia may herald INH-induced seizures. Consciousness may return between seizures or status epilepticus can occur.[30,83] Because GABA, the primary inhibitory neurotransmitter, is depleted in acute INH toxicity, seizure activity may persist until GABA concentrations are restored, even with anticonvulsant therapy.

Acute INH toxicity is often associated with seizures and an anion gap metabolic acidosis associated with a high serum lactate concentration. Typically, arterial pH ranges between 6.80 and 7.30, although survival in the setting of an arterial pH of 6.49 was reported.[54] Paralyzed animals poisoned with INH do not develop elevated lactate concentrations, a finding that suggests the lactate arises from intense muscular activity.[25,84]

Protracted coma typically occurs with acute severe INH toxicity. Coma may last as long as 24 to 36 hours and persist beyond the termination of seizure activity as well as the resolution of acidemia. The etiology of coma is unknown.[11,54] Additional sequelae from acute INH toxicity include rhabdomyolysis, renal failure, hyperglycemia, glycosuria, and ketonuria, along with hypotension and hyperpyrexia.[4,8,19,85,122,123]

Chronic Toxicity. Chronic therapeutic INH use is associated with a variety of adverse effects. Overall incidence of adverse reactions to isoniazid is estimated to be 5.4%.[89] The most disconcerting is hepatocellular necrosis.[41] Although asymptomatic elevation of aminotransferases is common in the first several months of treatment, laboratory testing may reveal the onset of hepatitis up to 1 year after starting INH therapy. In 1978, following several deaths among patients receiving INH therapy, the US Public Health Service reported the incidence of clinically evident hepatitis as 1% of those taking INH; of that subgroup, 10% died, for an overall mortality of 0.1%.[17,66] Research performed since the resurgence of TB, however, identified a considerably lower rate of hepatotoxicity. Clinically relevant hepatitis occurred in only 11 patients in a population of 11,141 persons receiving INH and close monitoring, an incidence of 0.1%.[82] Additional studies suggest that the death rate from INH hepatotoxicity is only 0.001% (two of 202,497 treated patients).[98] Hepatotoxicity is associated with chronic overdosage, increasing age, comorbid conditions such as malnutrition, and combinations of antituberculous drugs that may serve as cytochrome inducers. Overt hepatic failure often occurs if INH therapy is continued after onset of hepatocellular injury in both adults and children.[37,38,51,74,109,125] The incidence of hepatitis is two to four times higher in pregnant women than in nonpregnant women.[43]

Isoniazid-induced hepatitis can arise via two pathways.[37,127] The first involves an immunologic mechanism resulting in hepatic injury that is thought to be idiopathic.[103,122] The association of hepatitis with lupus erythematosus, hemolytic anemia, thrombocytopenia, arthritis, vasculitis, and polyserositis supports an immunologic process.[102,122] However, symptoms commonly found in autoimmune disorders such as fever, rash, and eosinophilia are usually absent with drug-induced lupus erythematosus, and rechallenge with isoniazid often fails to provoke recurrence of hepatocellular injury.[37,102,127] The second, more common mechanism involves direct hepatic injury by INH or its metabolites. The metabolites believed responsible for hepatic injury are acetylhydrazine and hydrazine (see Figure 57–2).[46,80,118]

Peripheral neuropathy and optic neuritis are known adverse drug effects of chronic INH use. Neurotoxicity is probably caused by pyridoxine deficiency aggravated by the formation of pyridoxine-INH hydrazones.[39] Peripheral neuropathy, the most common complication of INH therapy, presents in a stocking-glove distribution that progresses proximally. Although primarily sensory in nature, myalgias and weakness may occur.[110] Peripheral neuropathy is generally observed in severely malnourished, alcoholic, uremic, or diabetic patients; it is also associated with slow acetylator status, an effect that leads to increased INH concentrations and, consequently, increased pyridoxine depletion.[48] Optic neuritis may occur with isoniazid therapy, usually concurrent with other medications such as ethambutol or etarencept, and presents as decreased visual acuity, eye pain, and dyschromatopsia; visual field testing may reveal central scotomata and bitemporal hemianopsia.[49,58,64] Isoniazid is also associated with such findings of CNS toxicity as ataxia, psychosis, hallucinations, and coma.[1,9,47,97]

DIAGNOSTIC TESTING

Acute INH toxicity is a clinical diagnosis that may be inferred by history and confirmed by measuring serum INH concentrations.[105] Acute toxicity from INH has been defined as a serum INH concentration greater than 10 mg/L 1 hour after ingestion, greater than 3.2 mg/L 2 hours after ingestion, or greater than 0.2 mg/L 6 hours after the ingestion.[83] Because serum INH concentration measurements are not widely available, clinicians cannot rely on serum concentrations to confirm the diagnosis or initiate therapy. Because of the risk of hepatitis associated with chronic INH use,

TABLE 57–1. Adverse Reactions and Drug Interactions of Antituberculous Drugs

Drug	Major Adverse Reactions	Drug Interactions Clinical Effect	Monitoring	Comments
Isoniazid (INH)	*Acute:* seizures, acidosis, coma, hyperthermia, oliguria, anuria *Chronic:* elevation of liver enzyme concentrations autoimmune hepatitis, arthritis, anemia, hemolysis, eosinophilia, peripheral neuropathy, optic neuritis, vitamin B$_6$ deficiency (pellagra)	Rifampin, PZA, ethanol: hepatic necrosis Acetaminophen: hepatic necrosis Warfarin: increased INR Theophylline: tachycardia, vomiting, seizures, acidosis Phenytoin: increased phenytoin concentrations Carbamazepine: altered mental status Meperidine: hypertension Lactose: decreased INH absorption Antacids: decreased INH absorption Red wine/soft cheese: tyramine reaction Fish (scombroid): flushing, pruritus	Liver enzymes, ANA, CBC	HIV enteropathy may decrease absorption; INH should not be given with lactose-containing drug formulations because lactose can form hydrazones and lower INH concentrations
Rifampin	*Acute:* diarrhea, periorbital edema *Chronic:* hepatitis, reddish discoloration of body fluids	Protease inhibitors: decreased serum concentration of protease inhibitor Delavirdine: increased HIV resistance Cyclosporine: graft rejection Warfarin: decreased INR Oral contraceptives: ineffective contraception Methadone: opioid withdrawal Phenytoin: higher frequency of seizures Theophylline: decreased theophylline concentrations Verapamil: decreased cardiovascular effect	If administered with HIV antiretrovirals, viral titers should be followed. Liver enzymes; monitor serum concentrations of drugs (i.e., phenytoin, cyclosporine) or clinical markers of efficacy (i.e., coagulation times)	Interactions of rifampin with several HIV medications are very poorly described; changes in dosing or dosing interval for both rifampin and antiretroviral drugs may be required; teratogenic
Ethambutol	*Chronic:* optic neuritis, loss of red-green discrimination, loss of peripheral vision		Visual acuity, color discrimination	Contraindicated in children too young for formal ophthalmologic examination
Pyrazinamide (PZA)	*Chronic:* hepatitis, decreased urate excretion	INH: increased rates of hepatotoxicity (when extended courses or high dose pyrazinamide used)	Liver enzymes	Courses of therapy of 2 months or less recommended
Cycloserine	*Chronic:* depression, paranoia, seizures, megaloblastic anemia	INH: increased frequency of seizures	CBC, psychiatric monitoring	
Ethionamide	*Chronic:* orthostatic hypotension, depression	Cycloserine: may increase CNS effects	Blood pressure, pulse, orthostasis	
para-Aminosalicylic acid	*Chronic:* malaise, GI upset, elevated liver enzymes, hypersensitivity reactions, thrombocytopenia		Liver enzymes, CBC	
Capreomycin	*Chronic:* hearing loss, tinnitus, proteinuria, sterile abscess at IM injection sites		Audiometry, renal function tests	

ANA, antinuclear antibodies; HIV, human immunodeficiency virus.

hepatic aminotransferases should be regularly monitored once therapy is started. In critically ill patients, serum should be assessed for acidosis, renal function, creatine phosphokinase (CPK), and urine myoglobin indicating rhabdomyolysis and possible renal failure.

■ MANAGEMENT

Acute Toxicity The initial management requires termination of seizure activity with pyridoxine, benzodiazepines, fluid resuscitation, stabilization and correction of vital signs and maintenance of a patent airway. Gastrointestinal (GI) decontamination should be performed by administering activated charcoal to patients who are awake and able to comply with therapy.[108] Orogastric lavage is relatively contraindicated because of the risk of seizures, unless the patient is intubated. Delayed absorption of INH has not been observed, suggesting that late GI decontamination with activated charcoal will probably be ineffective in preventing toxicity.[104]

The antidote for INH-induced neurologic dysfunction is pyridoxine. Pyridoxine rapidly terminates seizures, corrects metabolic acidosis, and

reverses coma. The efficacy of pyridoxine is correlated with the administered dose; one study identified recurrent seizures in 60% of patients who received no pyridoxine and in 47% of those who received 10% of the ideal pyridoxine dose, and no seizures in patients who received the full dose of pyridoxine.[121] To treat acute toxicity, the pyridoxine dose in grams should equal the amount of INH ingested in grams, with a first dose of up to 5 g intravenously in adults. Unknown quantities of ingested INH warrant initial empiric treatment with a pyridoxine dose of no more than 5 g (pediatric dose: 70 mg/kg to a maximum of 5 g). Pyridoxine should be administered at a rate of 1 g every 2 to 3 minutes. Seizures that persist beyond administration of the initial dose should receive an additional similar dose of pyridoxine (see Antidotes in Depth A15—Pyridoxine).[6]

Hospital pharmacies may stock insufficient quantities of intravenous pyridoxine to treat even a single patient with a large INH ingestion.[101] In the event that intravenous formulations are unavailable in sufficient quantities, pyridoxine tablets may be crushed and administered with fluids via nasogastric tube.[101]

Conventional anticonvulsants, although generally used as first-line agents, demonstrate variable effectiveness in terminating INH-induced seizures. Benzodiazepines may be used to potentiate the antidotal efficacy of pyridoxine, particularly if optimal doses of the antidote are unavailable. The benzodiazepines act synergistically with pyridoxine, as well as possess inherent GABA-agonist activity, but as single agents they may be ineffective in the treatment of acute INH poisoning because of their reliance on GABA to exert their activity.[26,27,58,121] Phenytoin has no intrinsic GABAergic effect and is not recommended as therapy for patients with INH-induced seizures.[58,83,96] Barbiturates, which have potent GABA-agonist activity, are expected to be as effective as the benzodiazepines, although the risk of respiratory depression is greater with this class of anticonvulsant. The efficacy of propofol in terminating INH-induced seizures has not been evaluated in humans.

Although hemodialysis has been used to enhance elimination of INH in acute overdose, with clearance rates reported as high as 120 mL/min, hemodialysis is rarely indicated for initial management. It is usually reserved for patients who develop INH-overdose-induced renal failure.[19,122]

Asymptomatic patients who present to the emergency department (ED) within 2 hours of ingestion of toxic amounts of INH should receive prophylactic administration of 5 g of oral or intravenous pyridoxine. This recommendation is based on the observation that INH reaches its peak serum concentration within 2 hours of ingestion of therapeutic doses. Asymptomatic patients may be observed for a 6-hour period for signs of toxicity. Acute toxicity is unlikely to manifest more than 6 hours beyond ingestion.

Chronic Toxicity Hepatitis (defined as aminotransferase concentrations two to three times baseline concentrations) resulting from therapeutic INH administration mandates termination of therapy; malnourished patients may require nutritional support. After resolution of liver injury, INH may be restarted, provided aminotransferase concentrations are closely monitored.[37,109] Pyridoxine does not reverse hepatic injury; consequently, surveillance for and recognition of hepatocellular injury remains essential. Cases of hepatitis refractory to medical therapy may require liver transplantation.[40,55,125]

Neurologic toxicity, including peripheral neuropathies, cerebellar findings, and psychosis, is commonly treated with as much as 50 mg/d of oral pyridoxine, although doses as low as 6 mg/d appear to be effective.[1,9,97,113] Because of its effectiveness in preventing neurologic toxicity, pyridoxine is often used concurrently with INH therapy.

RIFAMYCINS
Rifampin

■ PHARMACOLOGY

Rifamycins are a class of macrocyclic antibiotics derived from *Amycolatopsis mediterranei*. Xenobiotics in this class include rifampin (a semisynthetic derivative), rifabutin, and rifapentine, of which the first two are most commonly used.[89] Rifampin inhibits the initial steps in RNA chain polymerization through the formation of a stable drug-enzyme complex with RNA polymerase. Disruption of RNA synthesis interrupts protein synthesis, leading to cell death. Whereas mycobacterial RNA polymerase is susceptible to rifampin, eukaryotic RNA polymerase is not. High concentrations of rifamycin antibiotics, however, can affect mammalian mitochondrial RNA synthesis, as well as reverse transcriptases and viral DNA-dependent RNA polymerases.[89]

■ PHARMACOKINETICS AND TOXICOKINETICS

When administered orally, rifampin reaches peak serum concentrations in 0.25 to 4 hours; foods, but not antacids, interfere with absorption.[88] Rifampin is secreted into the bile and undergoes enterohepatic recirculation. Although the recirculating antibiotic is deacetylated, the metabolite retains antimicrobial activity. The half-life of rifampin, which is normally between 1.5 and 5 hours, increases in the setting of hepatic dysfunction. After therapy is started, however, rifampin induces its own metabolism to shorten its half-life by approximately 40%. Rifampin is distributed widely into body compartments, and imparts a reddish color to all body fluids, including the cerebrospinal fluid (CSF),[89] and in this setting has been erroneously identified as xanthochromia suggesting subarachnoid hemorrhage to the clinician.[58] Because mycobacteria rapidly develop resistance to rifampin, it should not be used as single-agent therapy against tuberculosis.[89]

Rifampin therapy carries greater teratogenic risk than other antituberculous therapies, with 4.4% incidence of malformation. Anencephaly, hydrocephalus, and congenital limb abnormality and dislocations have been reported.[14,115] Rifampin is associated with hemorrhagic disease of the newborn[14] but is nevertheless compatible with breast-feeding, as only minute amounts of rifampin are secreted into breast milk.[14,114]

■ DRUG—DRUG INTERACTIONS

Rifamycins are potent inducers of CYP isoenzymes, which result in numerous drug interactions (Chap. 12 (Appendix)). Of the rifamycins, rifampin has greater activity in inducing CYP3A4 than rifapentine; rifabutin has the least inductive activity of the class.[71] Rifampin also induces CYP1A2, CYP2C9, and CYP2C19.[126] Additionally, the ability of rifampin to induce CYP3A4 is strongly correlated with p-glycoprotein concentrations. P-glycoprotein is a transmembrane protein that functions as a

cellular efflux pump of endogenous and exogenous xenobiotics; variations in expression of p-glycoprotein significantly affects the bioavailability of many drugs and subsequent drug—drug interactions (see Chap. 12 Appendix).[42] Concurrent administration of rifampin thus affects the metabolism of an array of drugs such as warfarin, cyclosporine, phenytoin, opioids, and oral contraceptives.[42,107,126] Enzyme and p-glycoprotein induction by rifampin therefore may be responsible for a variety of pathophysiologic processes, including insufficient anticoagulation in patients receiving oral anticoagulants, acute graft rejection in transplant patients, graft-versus-host disease, difficulty controlling phenytoin concentrations, methadone withdrawal, and unplanned pregnancy. Effects arising from CYP3A4 induction begin within 5 to 6 days after rifampin is started, and persist for up to 7 days after therapy is stopped.[89]

■ RIFAMYCINS AND HIV

There is an increased risk of tuberculosis in patients with HIV, and concurrent highly active antiretroviral therapy (HAART) and antituberculous therapy decreases mortality. However, there are many factors that influence the efficacy and feasibility of treating these illnesses. There is decreased absorption of nearly all antituberculous drugs in patients with advanced HIV due to chronic diarrhea, intestinal pathogens, and general malabsorption. Also, there are many drug—drug interactions between antituberculous and HIV medications due to alterations in absorption, cytochrome isoenzymes, p-glycoprotein transporters, and noncytochrome metabolism.[42,52,119]

Rifampin accelerates the clearance of protease inhibitors (such as saquinavir, lopinavir) thereby decreasing the serum concentration, resulting in lower trough concentrations, which correlate with antiviral effect, increased frequency of drug-resistant mutations in the protease gene, and promotion of outgrowth of drug-resistant HIV strains.[16,116,119] The reduction of serum concentrations of protease inhibitors is of such magnitude that coadministration of rifampin with protease inhibitors could lead to loss of HIV suppression and to the emergence of resistant HIV strains.[16] Increasing the dose of protease inhibitor is associated with significant adverse drug effects and therapeutic intolerance, and cannot overcome the significant clearance of protease inhibitors, even when combined with the standard "boosting strategy" of adding ritonavir, a potent CYP3A4 inhibitor that can increase the concentration of other protease inhibitors 20-fold to attain a therapeutic effect.[20,90,119] It may be possible that "super boosted protease inhibitors" with high-dose ritonavir may be tolerable and effective. Research is ongoing.

Rifampin also induces the metabolism and clearance of nucleoside reverse transcriptase inhibitors (NRTIs, such as stavudine, lamivudine, zidovudine) without influencing cytochrome P450 mechanisms. Resulting decreased serum concentrations of NRTIs, however, do not significantly interfere with drug efficacy. The efficacy of NRTIs is not related to the serum concentration of drug, but is instead related to the intracellular concentration of the active metabolite, a triphosphate derivative. Even though rifampin decreases serum zidovudine concentrations by 47%, active metabolite is present within cells in sufficient levels for activity. Rifampin, therefore, has minimal effect on the efficacy of nucleoside reverse transcriptase inhibitors.[16] Table 57-1 lists the drug interactions of rifampin.

Combining rifampin with nonnucleoside reverse transcriptase inhibitors (NNRTIs, such as efavirenz, nevirapine) should be considered on a case-by-case basis, as NNRTIs vary widely in their role as substrates, inducers, or inhibitors of cytochrome P450 systems, particularly CYP3A4. As a result, it is often difficult to anticipate the degree and effect of drug—drug interactions with rifamycins. It is clear, however, that rifamycins have a role in the treatment of HIV-associated tuberculosis, and that drug interactions are often modest and surmountable with dose adjustment or drug substitution.[90]

Rifampin suppresses the transformation of antigen-stimulated lymphocytes, as well as normal T-cell function, leading to decreased sensitivity to tuberculin, in turn resulting in false-negative purified protein derivative (PPD) test results.

■ CLINICAL MANIFESTATIONS

Acute Toxicity The most common side effects of acute rifampin overdose are GI symptoms consisting of epigastric pain, nausea, vomiting, and diarrhea.[37,89] The presence of diarrhea distinguishes rifampin ingestion from overdose of other antimycobacterial agents. Three reported deaths have been described from rifampin or rifampicin ingestion; an autopsy performed on one of these patients demonstrated the presence of pulmonary edema, although no causation was implied.[12,62,91] Other effects include flushing, angioedema, and obtundation. Children who receive an overdose of rifampin can develop facial or periorbital edema. Anterior uveitis is occasionally observed, as are neurologic effects consisting of generalized numbness, extremity pain, ataxia, and muscular weakness.[50] Isolated rifamycin overdose infrequently produces serious acute effects.

■ CHRONIC TOXICITY

When rifampin was originally introduced as an antituberculous drug, hepatitis was more frequently observed in patients taking combination therapy of rifampin and INH than in those taking INH alone. These findings potentially arise from the ability of rifampin to induce cytochromes responsible for INH hepatotoxicity and not from direct hepatic injury by rifampin itself. Liver injury, when attributable to rifampin alone, is predominantly cholestatic, suggesting that clinical surveillance for hepatic injury is important as is regular biochemical monitoring.[37,86] Rifampin alters the metabolism of other xenobiotics, such as INH, pyrazinamide, and acetaminophen, to increase their potential for hepatotoxicity.[37,81] Although some reports highlight increased compliance and typically mild and transient hepatotoxicity with combined rifampin and pyrazinamide treatment for latent tuberculosis infection, other recent studies suggest a significant risk of fatal hepatotoxicity, and the Centers for Disease Control and Prevention (CDC) recommends generally avoiding this combination of drugs.[75]

A condition similar to a viral syndrome may result from a hypersensitivity reaction that is associated with rifampin therapy. The syndrome, which occurs in 20% of patients receiving high doses or intermittent (less than twice weekly) dosing, includes fever, chills, and myalgias. Eosinophilia, hemolytic anemia, thrombocytopenia, and interstitial nephritis can develop in severe cases, and acute renal injury is likely related to hypersensitivity. Renal failure is rarely oliguric and is usually self-limited; patients usually recover with supportive care, although rechallenge with rifampin should be undertaken only with caution.[86]

The concomitant administration of rifampin and protease inhibitors results in increased rates of arthralgias, uveitis, leukopenia, and skin discoloration. Identical side effects occurred during the simultaneous administration of rifampin and CYP3A4 inhibitors such as clarithromycin, suggesting that toxic effects arise from elevated serum rifampin concentrations.[16] Current recommendations are that rifampin not be given with protease inhibitors, except for ritonavir in rare circumstances. In patients already on protease inhibitors, rifabutin may be used in place of rifampin.[90]

■ THERAPEUTIC TESTING AND MANAGEMENT

Management of patients with acute rifampin overdose is primarily supportive. Stabilization of vital signs and administration of activated charcoal are usually adequate, although clinicians should remain vigilant for coingestants. For chronic toxicity, recognition of interactions between

rifampin and other drugs is critical. Hepatic function should be monitored because of the ability of rifampin to augment the hepatotoxicity of other xenobiotics. Treatment for hepatic injury involves withholding rifampin therapy and reassessing the appropriateness of other xenobiotics administered to the patient. Supportive care for hepatotoxicity may be required. Influenza-like symptoms and renal failure secondary to rifampin may respond to decreasing the interval between administration of the drug.[86] Although rifampin interacts with protease inhibitors, the utility of therapeutic drug monitoring is uncertain because the correlation of clinical events with serum concentrations of rifampin and antiretroviral drugs is unknown.[16]

ETHAMBUTOL
■ PHARMACOLOGY

Ethambutol is effective against *Mycobacterium tuberculosis* and *Mycobacterium kansasii* as well as some strains of Mycobacterium avium complex; however, it has no effect on other bacteria. Ethambutol inhibits arabinosyl transferases, interfering with biosynthesis of arabinogalactan and liparabinomannan, which are required for polymerization of arabinan within mycobacterial cell walls.[63,89]

■ PHARMACOKINETICS AND TOXICOKINETICS

Only the D(+) isomer is used therapeutically, but both enantiomers are bacteriocidal.[58] The drug is taken up rapidly by growing cells, where bacteriostatic effects appear approximately 24 hours after ethambutol is incorporated by mycobacteria.[89] About 80% of an oral dose is absorbed gastrointestinally, but both foods and antacids decrease absorption.[16,89] Maximum serum concentrations are reached within 4 hours of oral administration and are proportional to the dose. Ethambutol is approximately 20% to 30% protein bound and has a half-life of between 4 and 6 hours.[68,89] Three-fourths of a standard dose is excreted unchanged into the urine by a combination of glomerular filtration and tubular secretion. Consequently, ethambutol accumulates in patients with renal compromise, making adjustments in dosing necessary.[89] Increasingly, mutations in the Mycobacterium embB gene confer resistance to ethambutol, as high as 14.2%, with acquired resistance reaching nearly 40%.[63]

Ethambutol is considered safe for use during pregnancy as a first-line drug. Although a 2.2% incidence of congenital abnormalities was identified in women undergoing ethambutol therapy, no consistent pattern of abnormalities occurred in their offspring.[14] Ethambutol is excreted into breast milk in approximately a 1:1 ratio with serum, but is considered to be compatible with breast-feeding.[14]

■ CLINICAL MANIFESTATIONS AND MANAGEMENT

Acute overdose of ethambutol is generally well tolerated, although a death has been reported.[62] More commonly, nausea, abdominal pain, confusion, visual hallucinations, and optic neuropathy occur following acute ingestions of greater than 10 g.[36] Although stabilization of vital signs and GI decontamination with activated charcoal remain the hallmarks of therapy, clinicians must remain vigilant for coingestants, particularly INH. Hemodialysis is rarely used as treatment for multidrug ingestions including ethambutol.[36]

Although peripheral neuropathy and cutaneous reactions occur with chronic therapy, the most significant effect of the therapeutic use of ethambutol is unilateral or bilateral ocular toxicity presenting as painless blurring of vision, decreased perception of color, and loss of peripheral vision. These effects are largely dose and duration related, and are typically reversible with drug discontinuation.[23,29] Optic neuritis develops in approximately 15% of patients receiving 50 mg/kg/d, 5% of patients receiving 25 mg/kg/d, and fewer than 1% of those receiving 15 mg/kg/d.[86] Patients may develop subclinical ocular disease within 30 days of starting ethambutol.[129] The loss of peripheral vision and color discrimination that accompanies the optic neuropathy caused by ethambutol distinguishes this condition from the optic neuropathy secondary to INH.[58,86]

Management of chronic toxicity from ethambutol involves cessation of therapy, although improvement may be hastened by treatment with hydroxocobalamin.[58,89] Recovery is less likely in older patients and is related to the degree of visual impairment.[120]

Ethambutol is a strong metal-chelator and inactivation of zinc and copper may be related to its induction of retinal cell vacuoles and enlarged lysosomes, which interfere with membrane permeabilization, possibly causing abnormal cell function and cell death.[29,65] The visual abnormalities induced by ethambutol are similar to those caused by a hereditary condition known as Leber optic neuropathy. Both ethambutol and Leber hereditary optic neuropathy can affect oxidative phosphorylation through impairment of mitochondrial function.[28,65] Ethambutol is suspected of mimicking this condition by binding intracellular copper, altering mitochondrial function, and producing neuronal injury.[57,65] Alternatively, optic neuritis may be related to zinc metabolism. Ethambutol chelates intracellular zinc to induce reversible vacuolar degeneration in retinal cultures. Progressive degeneration leads to irreversible neuronal destruction.[29] The effect of this injury is a shift in the threshold for wavelength discrimination without changing the absolute sensitivity of the cone system, which leads to a loss of red-green discrimination.[111]

■ DIAGNOSTIC TESTING

All patients should receive neuro-ophthalmic testing prior to ethambutol therapy. The use of visual-evoked potentials is especially useful in identifying subclinical optic nerve disease. Furthermore, patients should receive regular visual acuity examinations, and clinicians should encourage patients to report any visual subjective symptoms. The use of ethambutol may be relatively contraindicated in children who are unable to comply with an ophthalmic examination.[58,86]

PYRAZINAMIDE
■ PHARMACOLOGY AND PHARMACOKINETICS

Pyrazinamide (PZA) is a structural analog of nicotinamide with a mechanism of action similar to that of isoniazid (INH). Like INH, PZA is a prodrug. Pyrazinamide requires deamidation to anionic pyrazinoic acid by pyrazinamidase, an endogenous cytoplasmic bacterial enzyme. In this form, PZA has no antibacterial activity, but once exposed to acidic conditions, it becomes protonated to the uncharged, active form of the drug, 5-hydroxypyrazinoic acid, which enters the cell, accumulates, and kills the bacteria by disruption of mycolic acid biosynthesis.

Pyrazinamide is effective against both active and dormant bacteria and its use in antituberculous regimens shortens the course of therapy; however, resistance rapidly develops if used as single-agent therapy, and it should therefore only be used with other antituberculous medications.[89] Pyrazinamide is synergistic with rifampin, and has greatest efficacy if administered during the first 2 months of treatment with both INH and rifampin; this regimen effectively shortens the treatment course to only 6 months.[131] After oral administration, PZA is rapidly absorbed, with maximum concentrations occurring within 1 to 2 hours of administration, and a half-life of approximately 9 hours. Hepatic metabolism to pyrazinoic acid and 5-hydroxypyrazinoic acid occurs with the metabolites subsequently renally excreted.[89]

When introduced in the 1950s, PZA was administered in doses of 40 to 50 mg/kg for extended periods of time. The dosages produced hepatitis, with clinical manifestations of highly elevated aminotransferase and bilirubin concentrations. Of patients taking high-dose PZA, elevations in aminotransferases were identified in 20%, and symptomatic hepatitis was identified in 10%, with a small number of those who developed hepatitis dying from a fulminant course. As a result of these findings, PZA was believed to be highly hepatotoxic and its use was discouraged. The resurgence of multidrug-resistant mycobacteria, however, has forced clinicians to reassess the role of PZA. Modern dosing regimens of 30 mg/kg for brief courses of 2 months infrequently produce hepatic injury, with some studies suggesting that addition of PZA to multidrug TB regimens confers no additional risk for hepatotoxicity.[37]

Pyrazinamide is rarely used in pregnancy because the risk of birth defects is poorly defined. Animal studies suggest that PZA has no teratogenic potential at therapeutic doses.[2] Pyrazinamide is minimally excreted into breast milk and is presumed safe for breast-feeding.[14] It is considered a category C drug in pregnancy.

■ CLINICAL MANIFESTATIONS AND MANAGEMENT

Proper dosing of PZA and short courses of therapy are the two most important factors in preventing toxicity. Treatment for hepatotoxicity involves cessation of PZA therapy in conjunction with supportive care.[37] Pyrazinamide inhibits the renal excretion of uric acid, and hyperuricemia is observed. More than 90% of children treated with short courses developed elevated uric acid concentrations.[99] Most patients, regardless of age, remain asymptomatic and do not develop symptoms of gout, but polyarthralgias responsive to probenecid may be observed. Toxic effects from acute overdose of pyrazinamide have not been reported.

CYCLOSERINE

Cycloserine, previously avoided because of its adverse effects, is being used increasingly as secondary-line treatment with other tuberculostatic agents when treatment with primary agents (INH, rifampin, ethambutol, and streptomycin) fails or as initial therapy when drug susceptibility testing indicates either MDR-TB or XDR-TB. Cycloserine is a structural analog of alanine, and demonstrates inhibition of D-alanine racemase and D-alanine ligase, which are involved in peptidoglycan cell wall synthesis.[53] After oral doses, 70% to 90% of the drug is absorbed and peak concentrations are reached in 3 to 8 hours. Cycloserine is distributed throughout all tissues and body fluids and easily crosses the blood—brain barrier. Less than 35% of the antibiotic is metabolized, and remaining drug is excreted unchanged in the urine.[31,89]

Toxicity is dose dependent and occurs in as many as 50% of patients taking cycloserine. Cycloserine is a partial agonist at the NMDA/glycine receptor, which may contribute to neurologic effects such as

somnolence, headache, tremor, dysarthria, vertigo, confusion, irritability, and seizures.[53] Psychiatric manifestations include paranoid reactions, depression, and suicidal ideation. Reversible hypersomnolence and asterixis have been reported with cycloserine, corroborated by magnetic resonance imaging (MRI) suggestive of reversible thalamic neurotoxicity.[67] Cycloserine is contraindicated in patients with a history of either seizures or depression. If used, cycloserine should be introduced slowly to avoid CNS toxicity.[31,58,86] Toxicity is potentiated by alcohol, usually appears within the first 2 weeks of therapy, and ceases upon termination of the drug. Because cycloserine is renally excreted, patients with renal failure may be predisposed to toxicity; it is removed by hemodialysis.[31] Although no teratogenic effects were noted in three women exposed to cycloserine during the first trimester, cycloserine is not recommended for use during pregnancy. Cord blood concentrations are approximately 70% of serum concentrations, and no adverse effects occurred in breast-fed infants. Consequently, cycloserine is considered to be safe in women who are breast-feeding.[14] Reports of overdose are lacking in the English medical literature.

OTHER ANTIMYCOBACTERIALS
Ethionamide   Aminosalicylic acid

■ ETHIONAMIDE

Ethionamide, a congener of INH, is a prodrug with a mycotoxic intermediary metabolite thought to have a similar mechanism of action as INH, causing cell death from disruption of mycolic acid biosynthesis. Ethionamide is rapidly absorbed, widely distributed, and crosses the blood—brain barrier. Oral doses yield peak serum concentrations within approximately 3 hours of administration. The half-life of the drug is approximately 2 hours. The most common adverse symptoms associated with ethionamide are GI irritation and anorexia. Toxic effects such as orthostatic hypotension, depression, and drowsiness are common. Rash, purpura, and gynecomastia are observed, as are tremor, paresthesias, and olfactory disturbances. Approximately 5% of patients receiving ethionamide develop hepatitis; patients on this medication should be screened intermittently for hepatic injury. Treatment for toxicity involves withholding ethionamide therapy.[89] Birth defects were observed in seven of 23 newborns exposed to ethionamide, in utero, although a consistent pattern of anomalies was lacking. Data regarding the presence and safety of breastfeeding on ethionamide also are lacking.[14] Ethionamide is too toxic to be used as first-line therapy, but when needed should only be administered with another antimycobacterial medication, as resistance develops rapidly when ethionamide is used alone.[89] Reports of mortality from ethionamide overdose are absent from the English literature.[34]

■ *PARA*-AMINOSALICYLIC ACID

para-Aminosalicylic acid (PAS) is a structural analog of para-aminobenzoic acid and is thought to inhibit enzymes responsible for folate

biosynthesis in mycobacteria but not in other organisms.[89] Despite common adverse effects, PAS is being used to a greater extent in the multidrug treatment plans for treating extensively drug-resistant tuberculosis.[79] PAS is readily absorbed from the gut and is rapidly distributed into all tissues, especially the pleural fluid and caseous material. *para*-Aminosalicylic acid has a half-life of approximately 1 hour and is renally excreted. Adverse effects of PAS are seen in 10% to 30% of patients and include anorexia, nausea, vomiting, diarrhea, sore throat, and malaise. Between 5% and 10% of patients receiving PAS develop hypersensitivity reactions characterized by high fever, rash, and arthralgias. Hematologic abnormalities of agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, and acute hemolytic anemia have been observed.[89] *para*-Aminosalicylic acid may be removed by hemodialysis in patients with renal failure.[73] Adverse effects associated with chronic therapy may be treated by its withdrawal. Data regarding the safety of PAS in pregnancy and breast-feeding are lacking.[14]

■ CAPREOMYCIN

Capreomycin is a cyclic polypeptide being used more frequently now because of its antibacterial activity against multidrug-resistant and intracellular tuberculosis bacilli. Tuberculosis strains resistant to more than one aminoglycoside may be susceptible to this polypeptide. Capreomycin interferes with ribosomes and inhibits protein translation, but may also act by other mechanisms such as alterations in topoisomerase or the glyoxylate shunt pathway.[44] Due to poor absorption after oral dosing, capreomycin must be administered intramuscularly. Toxicity associated with capreomycin use includes hearing loss, tinnitus, proteinuria, and electrolyte disturbances, although severe renal failure is rare. Eosinophilia, leukocytosis, and rashes have been described. Pain and sterile abscesses at the site of capreomycin injection are reported.[89] Data are lacking regarding the safety of capreomycin in pregnancy and breast-feeding.[14]

Many other antibiotics and immunomodulators that have been primarily overlooked or rejected for the management of tuberculosis are increasingly being used as part of multidrug regimens against resistant strains. Discussed more extensively in other chapters, these include fluoroquinolones such as ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, sparfloxacin, macrolides such as clarithromycin, aminoglycosides such as amikacin, streptomycin, kanamycin, capreomycin, interferon, amoxicillin-clavulanate, linezolid, and clofazimine (see Chap. 56).[79]

SUMMARY

In overdose many certain antituberculous drugs become significant toxicologic threats. Patients acutely poisoned with INH require immediate and appropriate action to reverse seizures, acidosis, and coma beginning with the specific antidote pyridoxine. Pyridoxine is effective therapy, alone or if necessary augmented by benzodiazepines. Although less common than previously believed, hepatocellular injury resulting from therapeutic dosing of INH requires regularly scheduled, frequent evaluations to prevent fulminant hepatic failure.

With the increasing prevalence of multidrug-resistant and extensively-drug-resistant tuberculosis strains, antituberculous medications previously avoided or ignored are now being used typically in combination with two or more other antituberculous medications. Despite reduced dosages compared with those previously used, in some cases significant adverse effects remain a concern. In particular, rifampin causes numerous drug—drug interactions, some involving several anti-HIV therapies. Because antituberculous therapies are commonly needed in the HIV-infected population, potential interactions between rifampin and antiretroviral agents should remind clinicians to remain vigilant for

unanticipated adverse effects. Patients receiving ethambutol, pyrazinamide, and other antituberculous medications benefit from careful surveillance for specific adverse effects such as decreased visual acuity, hepatic injury, and psychiatric manifestations. Despite the toxicity of this class of drugs, poisonings are often responsive to intervention when recognized early and treated appropriately.

PYRIDOXINE

Mary Ann Howland
Pyridoxine (vitamin B$_6$), a water-soluble vitamin, is administered as an antidote for overdoses of isonicotinic acid hydrazide (isoniazid, INH), *Gyromitra esculenta* mushrooms, hydrazine, methylated hydrazines, and ethylene glycol. With the exception of ethylene glycol, all of these xenobiotics produce seizures by the competitive inhibition of pyridoxal-5′-phosphate (PLP). Pyridoxine overcomes this inhibition and may also enhance the less-toxic pathway of ethylene glycol metabolism to form benzoic and hippuric acid, instead of oxalic acid.[6] Hydrazine and methylated hydrazines (1,1-dimethylhydrazine [UDMH], monomethylhydrazine [MMH]) are used as rocket fuels, and MMH is also found in *Gyromitra esculenta* mushrooms.[3]

HISTORY

Pyridoxine deficiency characterized by seborrheic dermatitis, cheilosis, stomatitis, and glossitis was first identified in 1926 but was mistakenly attributed to the absence of vitamin B$_2$ (see Chap. 41).[31] Ten years later, the deficiency was fully characterized and correctly recognized as a deficiency to vitamin B$_6$.[31] A rare genetic abnormality that produced pyridoxine-responsive seizures in newborns was first described in 1954.[5]

CHEMISTRY

The active form of pyridoxine is PLP.[31] The alcohol pyridoxine, the aldehyde pyridoxal, and the aminomethyl pyridoxamine are all naturally occurring, related compounds that are metabolized by the body to PLP.[31] Pyridoxine was chosen by the Council on Pharmacy and Chemistry to represent vitamin B$_6$.[31] Pyridoxine hydrochloride was chosen as the commercial preparation because of its stability.[53]

PHARMACOLOGY

Pyridoxal-5′-phosphate is an important cofactor in more than 100 enzymatic reactions, including decarboxylation and transamination of amino acids, and the metabolism of tryptophan to 5-hydroxytryptamine [serotonin] and methionine to cysteine.[23,31] Iatrogenic pyridoxine

deficiency in animals produces seizures associated with reduced brain concentrations of PLP, glutamic acid decarboxylase, and γ-aminobutyric acid (GABA).[16]

PHARMACOKINETICS

Pyridoxine is not protein bound, has a volume of distribution of 0.6 L/kg, and easily crosses cell membranes; in contrast, PLP is nearly entirely plasma protein bound and essential for the synthesis and metabolism of GABA.[53] At extrahepatic sites pyridoxine is rapidly metabolized to pyridoxal, PLP, and 4-pyridoxic acid, with only 7% excreted unchanged in the urine.[53] After intravenous infusion of 100 mg of pyridoxine over 6 hours, PLP concentration increases rapidly in serum and in erythrocytes.[53] Pyridoxal-5′-phosphate rises from 37 nmol/L to 2183 nmol/L in serum and from undetectable to 5593 nmol/L in erythrocytes, with peak concentrations achieved at the end of the infusion.[53] Oral pyridoxine, in doses of 600 mg, is 50% absorbed within 20 minutes of ingestion by a first-order process with rapid achievement of peak serum concentrations of pyridoxine, PLP, and pyridoxal.[52] The concentration of PLP appears to be tightly controlled in the serum and related to alkaline phosphatase activity.[24,52] Oral doses of pyridoxine from 10 to 800 mg result in PLP concentrations of 518 to 732 nmol/L 4 hours after ingestion.[52] Chronic alcoholic patients have lower baseline serum PLP concentrations, as acetaldehyde enhances the degradation of PLP in erythrocytes, through stimulation of an erythrocyte membrane-bound phosphatase that hydrolyzes phosphate-containing B$_6$ compounds.[30]

MECHANISM OF HYDRAZIDE- AND HYDRAZINE-INDUCED SEIZURES

The role of pyridoxine as an antidote to poisoning from INH and methylated hydrazines like MMH is based on overcoming the interference of these xenobiotics with the normal function of pyridoxine as a coenzyme. INH produces a syndrome resembling cerebral vitamin B$_6$ deficiency, which results in seizures.[43] Specifically, INH and other hydrazides and hydrazines inhibit the enzyme pyridoxine phosphokinase that converts pyridoxine to PLP (see Fig. 57–3).[23] In addition, hydrazides directly combine with PLP, causing inactivation through the production of hydrazones that are rapidly excreted by the kidney.[23,49] PLP is a coenzyme for L-glutamic acid decarboxylase, which facilitates the synthesis of GABA from L-glutamic acid. Animal studies suggest that interference with PLP disrupts the formation of GABA.[23,49,50] The decreased GABA formation and increased glutamic acid reduces cerebral inhibition, which may contribute in part to the seizures resulting from exposure to INH and methylated hydrazines.[41,51]

ANIMAL STUDIES

In a dog model of INH-induced toxicity, pyridoxine reduced the severity of seizures, increased the duration of seizure-free periods, and prevented the mortality of a previously lethal dose of INH in a dose-dependent fashion.[13,14] Lower molar ratios prevented deaths and higher molar ratios prevented both deaths and seizures.[14] When used

as single treatments for INH-induced seizures phenobarbital, pento-barbital, phenytoin, ethanol, and diazepam were ineffective in controlling seizures and mortality, but when combined with pyridoxine, each protected the animals from seizures and death.[13] Other small-animal experiments have documented the effectiveness of pyridoxine against MMH-induced seizures when used alone[23,34,46] and when used in combination with diazepam.[20] Anticonvulsant efficacy is also demonstrated in cat[42] and monkey[44] models.

Rat studies with intraperitoneal UDMH also demonstrate the protective effects of pyridoxine given intraperitoneally 90 minutes after exposure.[15] Pyridoxine prevented seizures and death in a model that produced 94% mortality and 100% seizures without pyridoxine.[15] When intraperitoneal UDMH was followed in 20 minutes by pyridoxine intravenously (IV) in rats, 17% died at 24 hours, compared with a 100% mortality without pyridoxine.[15] Other studies in dogs and monkeys also demonstrate the effectiveness of pyridoxine in preventing seizures and mortality, and in treating seizures.[4] Pyridoxine intramuscularly (IM) protected the monkeys from death and stopped the seizures caused by IV UDMH.

HUMAN DATA

Clinical experience with the use of pyridoxine for INH overdose in humans demonstrates favorable results.[2,11] Rapid seizure control with no morbidity or mortality was achieved when the ratio in grams of pyridoxine administered to INH ingested ranged from 0.14 to 1.3, although in practice, most patients receive approximately gram-for-gram amounts. In five patients, the use of gram-for-gram amounts of pyridoxine resulted in the complete control of seizures and a resolution of the metabolic acidosis.[48] In eight patients with intentional INH overdoses, basic poison management, intensive supportive care, and a mean dose of 5 g of pyridoxine IV resulted in no fatalities.[8] Seizures were controlled in a 22-month-old boy given 100 mg of IV pyridoxine, after an estimated INH ingestion of 5 g.[43] Variable results are reported when relatively small doses of pyridoxine are used.[32] Seizures were reported in two patients following the ingestion of INH-pyridoxine combination tablets, although the actual amount of pyridoxine ingested was not noted.[45]

In addition to controlling seizures, the administration of pyridoxine also appears to restore consciousness. Two patients, who remained obtunded for as long as 72 hours after the apparent resolution of the seizures, were reported to awaken immediately after 3 to 10 g of IV pyridoxine was administered.[10] A third patient who was lethargic awakened with IV pyridoxine. This suggests that mental status abnormalities associated with INH overdose, and possibly hydrazine overdoses, may be responsive to pyridoxine and also may require repetitive dosing.[11,48] Patients treated with large doses of pyridoxine awaken more rapidly even after experiencing sustained seizure activity or status epilepticus.

Monomethylhydrazine poisoning can be encountered in a variety of clinical situations. In the aerospace industry, where MMH is used as a rocket propellant, percutaneous or inhalational poisoning may occur. Ingestion of the false morel mushroom, *G. esculenta*, can also produce toxicity when its major toxic compound, gyromitrin, is metabolized to MMH[3,18] (Chap. 117).

The neurologic effects of MMH poisoning are similar to those of INH toxicity and include seizures and respiratory failure.[16] Severe liver damage similar to INH-induced hepatotoxicity is also described.[9] As in the case of INH hepatotoxicity, there is no evidence that MMH-induced hepatotoxicity can be treated by administration of pyridoxine.[9]

A patient who was exposed to hydrazine became comatose 14 hours later and remained comatose for 60 hours until 25 mg/kg of pyridoxine aroused him.[25] Another case report describes improvement in the mental status of a confused, lethargic, and restless man who had ingested a

mouthful of hydrazine and was treated with a 10-g dose of pyridoxine.[22] This improvement developed over 24 hours and may have been unrelated to pyridoxine therapy. A severe sensory peripheral neuropathy lasting for 6 months developed 1 week following the overdose and was most likely a result of the hydrazine ingestion and not the pyridoxine. Six patients exposed to an Aerozine-50 (hydrazine and UDMH) spill were effectively treated with pyridoxine after developing twitching, clonic movements, hyperactivity, or gastrointestinal (GI) symptoms.[19] A patient exposed to UDMH during an explosion developed extensive burns, diverse neurologic manifestations and electroencephalogram (EEG) findings that resolved rapidly with the delayed administration of IV pyridoxine.[17]

ETHYLENE GLYCOL

PLP is a cofactor in the conversion of glycolic acid to nonoxalate compounds (Chap. 107). Patients poisoned with ethylene glycol should receive 100 mg/d of pyridoxine IV in an attempt to shunt metabolism preferentially away from the production of oxalic acid. This approach is supported by an animal model[6] and by the study of primary hyperoxaluria,[21] but has not been studied adequately in humans with ethylene glycol poisoning.[36]

SAFETY ISSUES

Pyridoxal-5′-phosphate is clearly neurotoxic to animals and humans when administered chronically in supraphysiologic doses.[25,27,37] Delayed peripheral neurotoxicity occurred in patients taking daily doses of 200 mg to 6 g of pyridoxine for 1 month.[35,40,41] Healthy volunteers given 1 or 3 g/d developed a small- and large-fiber distal axonopathy, with sensory findings and quantitative sensory threshold abnormalities occurring after 1.5 months in the high-dose and 4.5 months in the low-dose regimens. Once symptoms occurred, the pyridoxine was immediately stopped, but symptoms progressed for 2 to 3 weeks, leading to speculation that it took time for the reversal of neuronal metabolic manifestations (see chapter 18).[7]

Pyridoxine may also induce a sensory neuropathy when massive doses are administered, either as a single dose or over several days.[1,26,47] Ataxia occurred in dogs receiving 1 g/kg of pyridoxine.[47] Larger doses of pyridoxine produce incoordination, ataxia, seizures, and death.[47] Death after pyridoxine administration was sometimes delayed for 2 to 3 days.[47] Two patients treated with 2 g/kg of IV pyridoxine (132 and 183 g, respectively) over 3 days developed severe and crippling sensory neuropathies.[1] One year later, both patients were unable to walk. Inadequate information is available to determine the maximal single acute nontoxic dose in humans; however, there appears to be a wide margin of safety. Doses of pyridoxine ranging from 70 to 375 mg/kg or doses equivalent to the milligram-per-kilogram historical dose of ingested INH have been administered without adverse effects.[28,48]

The 0.5% chlorobutanol preservative in IV pyridoxine, which equates to doses of 250 to 500 mg of chlorobutanol when 5 and 10 g doses of pyridoxine are administered, might produce CNS depression.[12] However, a dose of 5 g IV pyridoxine administered over 5 min to five healthy volunteers produced only a transient minor increase in base deficit, without any CNS depression noted.[29]

DOSING

Considering all of the available data, a safe and effective pyridoxine regimen for INH overdoses in adults is 1 g of pyridoxine for each gram of INH ingested, to a maximum of 5 g or 70 mg/kg in a child.[48]

These doses are sufficient in the majority of patients, but the dose can be repeated if necessary. The best way to administer pyridoxine in a patient after an INH overdose has not been established. For a patient who is actively seizing, pyridoxine may be given by slow IV infusion at approximately 0.5 g/min until the seizures stop or the maximum dose has been reached. When the seizures stop, the remainder of the dose should be infused over 4 to 6 hours to maintain pyridoxine availability while the INH is being eliminated. The dose should be repeated if seizures persist or recur, or if the patient exhibits mental status depression. If IV pyridoxine is unavailable, oral pyridoxine should be administered.[39]

For hydrazine and methylated hydrazines (ie, MMH, UDMH) poisoning, there is no established dose.[51] Using the same dosage regimen as for INH is theoretically reasonable, but has never been tested in humans.

AVAILABILITY

Pyridoxine HCl is available parenterally at a concentration of 100 mg/mL with 1 mL in a 2 mL vial with 0.5% chlorobutanol as the preservative and 1.4 μg/1 mL aluminum from APP Pharmaceuticals.[38] Thus, a 5 g IV dose of pyridoxine requires fifty 100 mg/mL vials. This is an exception to the rule that appropriate doses of medications rarely require multiple dosages of this magnitude and also emphasizes the necessity of keeping an adequate supply available in the emergency department, as well as in the pharmacy.[33] Oral pyridoxine is available in many tablet strengths from 10 to 500 mg depending on the manufacturer.

SUMMARY

Pyridoxine should not be the sole therapy used for INH or MMH poisoning. A benzodiazepine should be used with pyridoxine in an attempt to achieve synergistic control of seizures. If the seizures do not respond to both of these measures, they can be repeated, followed by IV agents such as propofol, pentobarbital, or phenobarbital, and, if necessary, neuromuscular blockade and general anesthesia. When neuromuscular blockade is achieved without extinguishing the seizure activity, irreversible neuronal damage may result. Although metabolic acidosis is probably a result of the seizures and should therefore resolve once the underlying condition is controlled, severe or refractory metabolic acidosis may require titration of blood pH using IV sodium bicarbonate.

CHAPTER 58
ANTIMALARIALS

J. Dave Barry

The malaria parasite has caused untold grief throughout human history. The name originated from Italian *mal aria* (bad air), since the ancient Romans believed the disease was caused by the decay in marshes and swamps, and was carried by the malodorous "foul" air emanating from these areas.[5] In the 1880s both the Plasmodium protozoa as well as its mosquito vector were identified.[5] Today, 40% of world's population lives in areas where malaria is endemic. More than 500 million people suffer acute malaria infection, and one to three million die from the infection each year.[5,41,129] Included among those at risk of becoming infected are 50 million travelers from industrialized countries who visit the developing countries each year. Despite using prophylactic medications (Table 58–1), 30,000 of these travelers will acquire malaria.[97]

HISTORY AND EPIDEMIOLOGY

The bark of the cinchona tree, the first effective remedy for malaria, was introduced to Europeans more than 350 years ago.[114] The toxicity of its active ingredient, quinine, was noted from the inception of its use. Pharmaceutical advances occurred, funded largely by the military during World War II (chloroquine, proguanil, amodiaquine, pyrimethamine) and later during the Vietnam conflict (mefloquine, halofantrine).[109,114] Chloroquine, hydroxychloroquine, primaquine, amodiaquine, mefloquine, and halofantrine are all related to quinine, but have different patterns of toxicity. Other drugs used to treat malaria include the folate inhibitors proguanil and pyrimethamine (frequently used in combination with atovaquone), the sulfonamide sulfadoxine, or the sulfone dapsone, as well as tetracyclines and the macrolides (Chap. 56).

With the introduction of each new drug, resistance developed, particularly in Oceania, Southeast Asia, and Africa.[109,114] In some places, quinine is once again the first-line therapy for some types of malaria.[58] In the last two decades, the search for active xenobiotics has returned to a natural product, the Chinese herb qinghaosu.[86,110] The active ingredient, artemisinin, in the form of an artemisinin-based combination therapy (ACT), is recommended by the World Health Organization (WHO) as the preferred treatment of malaria in drug-resistant areas.[5,129] With increased leisure travel, a greater number of North Americans are taking prophylactic medications with potential toxicity.

QUINOLINE DERIVATIVES

■ QUININE
The therapeutic benefits of the bark of the cinchona tree have been known for centuries. As early as 1633, cinchona bark was used for its antipyretic and analgesic effects,[73] and in the 1800s it was used for the treatment of "rebellious palpitations."[114] Quinine, the primary alkaloid in cinchona bark, was the first effective treatment for malaria. Due to a reported curare-like action, quinine has been used as a treatment for muscle cramps. Due to its extremely bitter taste similar to that of heroin, quinine is used as an adulterant in drugs of abuse. Small quantities of quinine can be also found in some tonic waters.

High doses of quinine and other cinchona alkaloids are oxytocic, potentially leading to abortion or premature labor in pregnant women. Because of this, quinine has been used as an abortifacient (Chap. 28).[74] Chloroquine continues to be used for this purpose in some parts of the developing world.[7,90] Neither is safe for this purpose because of their narrow toxic-to-therapeutic ratio.

Pharmacokinetics and Toxicokinetics See Table 58–2 for the pharmacokinetic properties of quinine. Quinine and quinidine are optical isomers and share similar pharmacologic effects as class IA antidysrhythmics and antimalarials. Both are extensively metabolized in the liver, kidneys, and muscles to a variety of hydroxylated metabolites. Quinine undergoes transplacental distribution and is secreted in breast milk.

Pathophysiology Quinine overdose affects multiple organ systems through a number of different pathophysiologic mechanisms. Studies evaluating mechanisms of toxicity have focused on those organ systems primarily affected. Outcomes appear to be most closely related to the degree of cardiovascular dysfunction.[38]

Quinine and quinidine share anti- and prodysrhythmic effects primarily from an inhibiting effect on the cardiac sodium channels and potassium channels (Chaps. 23 and 63).[39] Blockade of the sodium channel in the inactivated state decreases inotropy, slows the rate of depolarization, slows conduction, and increases action potential duration. Inhibition of this rapid inward sodium current is increased at higher heart rates (called *use-dependent blockade*), leading to a rate-dependent widening of the QRS complex.[114,123]

Inhibition of the potassium channels suppresses the repolarizing delayed rectifier potassium current, particularly the rapidly activating component,[123] leading to prolongation of the QT interval. The resultant increase in the effective refractory period is also rate dependent, causing greater repolarization delay at slower heart rates and predisposing to torsades de pointes. As a result, syncope and sudden dysrhythmogenic death may occur. An additional α-adrenergic blocking effect contributes to the syncope and hypotension occuring in quinine toxicity.

Inhibition of the adenosine triphosphate (ATP)-sensitive potassium channels of the pancreatic β cells results in the release of insulin, similar to the action of sulfonylureas (Chap. 48).[30] Patients at increased risk of quinine-induced hyperinsulinemia include those patients receiving high-dose intravenous (IV) quinine, intentional overdose, and patients with other metabolic stresses, such as concurrent malaria, pregnancy, malnutrition, and alcohol consumption.[18,59,81,84,85,94]

The mechanism of quinine-induced inhibition of hearing appears to be multifactorial.[109] Microstructural lengthening of the outer hair cells of the cochlea and organ of Corti occurs.[43] Additionally, vasoconstriction and local prostaglandin inhibition within the organ of Corti may contribute to decreased hearing.[109] Inhibition of the potassium channel may impair hearing and produce vertigo, as it is known that the homozygous absence of gene products that form part of some potassium channels (Jervell and Lange-Nielson syndrome) causes deafness and prolonged QT intervals (Chap. 20 and 22).[108]

Although older theories suggested that quinine caused retinal ischemia, the preponderance of evidence points to a direct toxic effect on the retina.[40,44] Electroretinographic studies demonstrate a rapid and direct effect on the retina (decreased potentials) within minutes after doses of

TABLE 58–1. Common Adult Doses of Antimalarials Used Worldwide

Drug	Prophylactic Dose	Upper Dose Range, Treatment[a]
Amodiaquine	Not used	10 mg of base/kg/d × 3 days
Artemether/lumefantrine	Not used	80 mg artomether + 480 mg lumefantrine bid × 3 days
Artesunate/amodiaquine	Not used	200 mg arteunate + 612 mg amodiaquine × 3 days
Artesunate/mefloquine	Not used	200 mg artesunate × 3 days, 1000 mg mefloquine on day 2, 500 mg mefloquine on day 3
Artesunate/pyrimethamine/sulfadozine	Not used	200 mg artesunate × 3 days, 75 mg pyrimethamine + 1500 mg sulfadoxine as single dose
Chloroquine phosphate (Aralen)	500 mg/wk as single dose	1000 mg STAT then 500 mg at 6 h, 24 h, and 48 h
Doxycycline (Vibramycin)	100 mg/day	100 mg bid[d]
Halofantrine	Not used	500 mg q6h × 3 doses, repeat in 7 days
Hydroxychloroquine sulfate (Plaquenil)	400 mg/wk as single dose	Rarely used
Mefloquine (Lariam)	250 mg/wk as single dose	750 mg STAT, then 500 mg 8 h later
Primaquine phosphate	30 mg of base/d × 14 days[c]	30 mg of base/d × 14 days
Proguanil/atovaquone (Malarone)	100 mg proguanil + 250 mg atovaquone once per day	400 mg proguanil 1000 mg atovaquone per day × 3 days
Proguanil/chloroquine	200 mg proguanil + 100 mg chloroquine once per day	Not used
Pyrimethamine/sulfadoxine (Fansidar)	Not used	75 mg pyrimethamine + 1500 mg sulfadoxine as single dose
Quinine sulfate (Qualaquin)	Not used	650 mg tid × 7 days[b]

[a] Choice, duration, and dosage may vary with malarial species and frequency of drug resistance in the geographic area.

[b] Usually with doxycycline, tetracycline, or clindamycin for chloroquine-resistant cases.

[c] After leaving *Plasmodium vivax* or *Plasmodium ovale* area.

[d] With quinine sulfate for chloroquine-resistant cases.

quinine.[40] These early retinographic changes, as well as histologic lesions in photoreceptor and ganglion cell layers, provide evidence of direct damage.[40] Changes in the electrooculogram suggest changes in the retinal pigment epithelium, and parallel changes in visual acuity. In contrast, no electrophysiologic, angiographic, or morphologic experimental evidence for retinal ischemia has been found.[40,44] Quinine may also antagonize cholinergic neurotransmission in the inner synaptic layer.

Quinine has direct irritant effects on the gastrointestinal (GI) tract and stimulates the center in the brainstem responsible for nausea and emesis.[114]

Clinical Manifestations Quinine overdose typically leads to GI complaints, tinnitus, and visual symptoms within hours, but the time course varies with the formulation ingested, coingestants, patient characteristics, and other case-specific details. Significant overdose is heralded by cardiovascular and central nervous system toxicity. Death can occur within hours to days, usually from a combination of shock, ventricular dysrhythmias, respiratory arrest, or renal failure.

Patients receiving even therapeutic doses often experience a syndrome known as "cinchonism," which typically includes GI complaints, headache, vasodilation, tinnitus, and decreased hearing acuity.[73,114] Vertigo, syncope, dystonia, tachycardia, diarrhea, and abdominal pain are also described.[47,63,81,114]

Quinine toxicity is closely correlated with total serum concentrations, but only the non-protein-bound portion is likely responsible for toxic effects. However, since free and total quinine concentrations vary widely from person to person,[35] a single quinine concentration may not always correlate with clinical toxicity. In general, serum concentrations of greater than 5 µg/mL may cause cinchonism, greater than 10 µg/mL

visual impairment, greater than 15 µg/mL cardiac dysrhythmias, and greater than 22 µg/mL death.[2] Similar concentrations in individuals who are severely ill with malaria do not necessarily result in as severe toxicity because of the increase α_1-acid glycoprotein and consequent reduction in free fraction of quinine present.[98,103]

The margin between therapeutic and toxic dosing of quinine is very small. It is not surprising that patients taking therapeutic doses frequently develop toxicity since the recommended range of serum quinine concentrations for treatment of falciparum malaria is 5 to 15 µg/mL, well above the concentration reported to cause cinchonism.

The average oral lethal dose of quinine is 8 g, although a dose as small as 1.5 g has been reported to cause death.[36,47] Delirium, coma, and seizures are less common, usually occurring only after severe overdoses.[14]

Cardiovascular manifestations of quinine use are related to myocardial drug concentrations.[11] They manifest on the electrocardiogram (ECG) as prolongation of the PR interval; prolongation of the QRS complex, QT interval, and ST depression with or without T-wave inversion also occurs.[11] Patients may develop complete heart block or dysrhythmias.[11] Patients on high doses of quinine must be monitored for torsades de pointes, ventricular tachycardia, and ventricular fibrillation. Quinine toxicity can also result in significant hypotension.

Although mild hyperinsulinemia may occur, hypoglycemia is not commonly described in cases of oral quinine overdose.[14,18,38,59,102,122,126] Hypoglycemia with elevated serum insulin concentrations following therapeutic dosing was seen in case reports complicated by severe congestive heart failure and significant ethanol consumption. Hypoglycemia was also noted in a healthy patient following overdose.[59,121]

TABLE 58–2. Pharmacokinetic Properties of Antimalarials

Antimalarial	Bioavailability (%)	Time to Peak Hours (oral)	Protein Bound (%)	Volume of Distribution (L/kg)	Half-Life	Urinary Excretion (%)	Comments
Artemisinin	Limited	–	Large	–	2–5 h	–	Metabolism largely through cytochrome p450 system.
Chloroquine	80	2–5	50-65	>100	40–55 d	55	–
Dapsone	90	3–6	70–80	0.5–1	21–30 h	20	–
Halofantrine	Low, varies	4–7	–	>100	1–6 d	–	Active metabolite.
Mefloquine	>85	8–24	98	15–40	15–27 d	<1	Hepatic metabolism. Inactive metabolite.
Primaquine	74	1–3	–	2.9	5–7 h	4	Metabolites primarily responsible for therapeutic and toxic effects.
Pyrimethamine	>95	2–6	87	3	3–4 d	16-32	–
Quinine	76	1–3	93	1.8–4.6	9–15 h	20	Protein binding increased in alkaline environments. Urinary excretion increased with acidic urine.

–, poorly studied or unknown.

Eighth-nerve dysfunction results in tinnitus and deafness. The decreased acuity is not usually clinically apparent, although the patient recognizes tinnitus.[95] These findings usually resolve within 48 to 72 hours, and permanent hearing impairment is unlikely.

Ophthalmic presentations include blurred vision, visual field constriction, tunnel vision, diplopia, altered color perception, mydriasis, photophobia, scotomata, and sometimes complete blindness.[14,32,40] Onset of blindness is invariably delayed and usually follows the onset of other manifestations by at least 6 hours. The pupillary dilation that occurs is usually nonreactive and correlates with the severity of visual loss. Funduscopic examination may be normal, but usually demonstrates extreme arteriolar constriction associated with optic disc and retinal edema. Normal arteriolar caliber may be initially present, but funduscopic manifestations such as vessel attenuation and disc pallor may develop as clinical improvement occurs. Improvement in vision can occur rapidly, but is usually slow, occurring over a period of months after a severe exposure. Initially, improvement occurs centrally and is followed later by improvement in peripheral vision. The pupils may remain dilated even after return to normal vision.[36] Patients with the greatest exposure may develop optic atrophy.

Hypokalemia is often described in the setting of quinine poisoning,[102] although the mechanism is unclear. An intracellular shift of potassium rather than a true potassium deficit is the predominant theory behind the hypokalemia associated with chloroquine,[68,70] and the mechanism may be similar with quinine.

A number of hypersensitivity reactions are described. These are the result of antiquinine or antiquinine-hapten antibodies cross-reacting with a variety of membrane glycoproteins.[15,51] Asthma, and dermatologic manifestations including urticaria, photosensitivity dermatitis, cutaneous vasculitis, lichen planus, and angioedema also occur.[94]

Hematologic manifestations of hypersensitivity are rare, but include thrombocytopenia (Chap. 24), agranulocytosis, microangiopathic hemolytic anemia, and disseminated intravascular coagulation (DIC), which can lead to jaundice, hemoglobinuria, and renal failure.[47,51] Hemolysis may also occur in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Immunogenic drug-platelet complex interactions can occur even after low doses of quinine, such as those in tonic drinks. This self-limited interaction has previously been termed "cocktail purpura."[73,114]

A hepatitis hypersensitivity reaction,[34] acute respiratory distress syndrome (ARDS), and a sepsis-like syndrome are also reported.[55]

Diagnostic Testing Urine thin-layer chromatography is sensitive enough to confirm the presence of quinine, even following the ingestion of tonic water.[126] Quinine immunoassay techniques are also available. Quantitative serum testing is not rapidly or widely available.

Management Patients may frequently vomit spontaneously. Emetics should not be used in the absence of vomiting since seizures, dysrhythmias, and hypotension can occur rapidly. Orogastric lavage should only be considered for patients with recent, substantial (potentially life-threatening) ingestions with no spontaneous emesis. Activated charcoal effectively adsorbs quinine and may additionally decrease serum concentrations by altering enteroenteric circulation.[3,62]

Supportive care should be initiated including oxygen, cardiac and hemodynamic monitoring, IV fluid resuscitation, and frequent ECG and blood glucose measurements.

Cardiac. Prolonged QRS should be treated with sodium bicarbonate alkalinization to achieve a serum pH of 7.45 to 7.50, as would be done in patients with cardiotoxicity associated with cyclic antidepressant overdoses (see Antidotes in Depth A5: Sodium Bicarbonate). The cardiotoxic manifestations of quinine and increased protein binding in the setting of alkalosis make the choice of serum alkalinization a logical therapeutic intervention. Sodium bicarbonate therapy has been successful in case reports,[11,38,73] but has not been specifically studied. Hypertonic sodium bicarbonate may result in or worsen existing hypokalemia, potentially exacerbating the effect of potassium channel blockade.

Potassium supplementation for quinine-induced hypokalemia is controversial since experimental data from the 1960s suggest that hypokalemia is protective against cardiotoxicity and prolongs survival.[17,68,102] Since hypokalemia can also lead to lethal dysrhythmias, supplementation for hypokalemia is presently recommended.

The QT interval should be carefully monitored for prolongation. If necessary, interventions for torsades de pointes, including magnesium

administration, potassium supplementation, and overdrive pacing, should be initiated (Chap. 22).

Class IA, IC, or III antidysrhythmics and other xenobiotics with sodium-channel- and/or potassium-channel-blocking activity should not be used to treat a quinine overdosed patient because they may exacerbate quinine-induced conduction disturbances or dysrhythmias. Type IB antidysrhythmics, such as lidocaine, have been used with reported success, but no clinical trials have been performed (Chap. 63).

Hypotension refractory to IV crystalloid boluses should be treated with vasopressors. Although not directly studied, direct-acting vasopressors such as epinephrine, norepinephrine, or phenylephrine are recommended. An intraaortic balloon pump was successfully used for the treatment of refractory hypotension in one case report.[102]

Ophthalmic. Funduscopic examination, visual field examination, and color testing may be appropriate bedside diagnostic studies. Electroretinography, electrooculogram, visual-evoked potentials, and dark adaptation may be helpful in assessing the injury, but are not practical because they require equipment that is not portable or readily available in most clinical settings. There is no specific, effective treatment for quinine retinal toxicity,[40,42] although hyperbaric oxygen (HBO) was used in three patients who recovered vision, but the role of HBO in that recovery was not established.[40,127]

Hypoglycemia. A low serum glucose concentration should be supported with an adequate infusion of dextrose. Serum potassium concentration and the QT interval should be monitored during correction and maintenance. Octreotide has been successfully used to correct quinine-induced hyperinsulinemia in adult malaria victims.[84,85] In volunteers, quinine-induced hyperinsulinemia was suppressed within 15 minutes following a 100 μg intramuscular dose of octreotide (see Antidotes in Depth A11: Octreotide).[85] Octreotide should be used for cases of refractory hypoglycemia in a fashion similar to that recommended in sulfonylurea toxicity which is 50 μg subcutaneously (SC) every 6 hours (Chap. 48).

Enhanced Elimination The effect of multiple-dose activated charcoal (MDAC) on quinine elimination was studied in an experimental human model as well as in symptomatic patients.[88] In these patients, MDAC decreased the half-life of quinine from approximately 8 hours to about 4.5 hours, and increased clearance by 56%.[88] Although numerous studies show that activated charcoal decreases quinine half-life,[9,62,88] evidence of clinical benefit is lacking. Nevertheless, because ophthalmic, central nervous system (CNS), and cardiovascular toxicity are related to serum concentration, it is prudent to reduce concentrations as quickly as practicable; thus, activated charcoal (0.5 g/kg) should be administered every 2 to 4 hours, unless otherwise contraindicated, for about four doses.

There is conflicting evidence about a benefit of urinary acidification in enhancing clearance.[9,98] But because of the increased potential for cardiotoxicity associated with acidification, this technique is never recommended.

Because quinine has a relatively large volume of distribution and is highly protein bound, hemoperfusion, hemodialysis, and exchange transfusion have only a limited effect on drug removal.[9,14,67,98,114,119] Although the blood compartment can be cleared with these techniques, total body clearance is only marginally altered. After rapid tissue distribution occurs, there is little impact on the total body burden because of the large volume of distribution and extensive protein binding.

Extracorporeal membrane oxygenation (ECMO) was used in one case of severe quinidine poisoning with bradydysrhythmias and refractory hypotension to stabilize the cardiovascular system while a quinidine-activated charcoal bezoar was removed, and the patient metabolized the remaining quinidine.[112] A similar approach should be considered for intractable quinine toxicity.

■ CHLOROQUINE, HYDROXYCHLOROQUINE, AND AMODIAQUINE
The structurally related compounds chloroquine and amodiaquine were once used extensively for malaria prophylaxis. However, with the development of resistance, they are used in fewer geographic regions. Amodiaquine is associated with a higher incidence of hepatic toxicity and agranulocytosis. In general, these xenobiotics have low toxicity when used in therapeutic doses. Because of its low toxicity, chloroquine remains the first-line drug for malaria prophylaxis and treatment in areas where *Plasmodium* remains sensitive.

Hydroxychloroquine is similar to chloroquine in therapeutic, pharmacokinetic, and toxicologic properties.[67] The side-effect profiles of the two are slightly different, favoring chloroquine use for malarial prophylaxis and hydroxychloroquine use as an antiinflammatory agent.[63,114] Hydroxychloroquine is used in the treatment of rheumatic diseases such as rheumatoid arthritis and lupus erythematosus. In animal studies, chloroquine is two to three times more toxic than hydroxychloroquine.[49]

Piperaquine is structurally similar to chloroquine but is primarily used in conjunction with artemisinin compounds as a component of an artemisinin-based combination therapy (ACT). Piperaquine is discussed in more detail in the Artemisinin and Derivatives section.

Pharmacokinetics and Toxicodynamics See Table 58–2 for the pharmacokinetic properties of chloroquine. Oral chloroquine is rapidly and completely absorbed and is ultimately sequestered in many different organs, particularly the kidney, liver, and lung, as well as erythrocytes.[13,43]

Chloroquine is slowly distributed from the blood compartment to the larger central compartment, leading to transiently high whole blood concentrations shortly after ingestion.[90,104] It is the initial high blood concentrations that are thought to be responsible for the rapid development of profound cardiorespiratory collapse, which is typical of chloroquine toxicity. These whole-blood chloroquine concentrations correlate with mortality.[26]

Pathophysiology With structural similiarity to quinine, the pathophysiologic mechanisms of chloroquine and hydroxychloroquine are also

similar. Most notably, sodium and potassium channel blockade are the proposed primary mechanisms of cardiovascular toxicity.[123]

Although less common in quinine toxicity, hypokalemia is extremely common in chloroquine overdose. The mechanism appears to be a shift of potassium from the extracellular to the intracellular space and not a true potassium deficit.[68,90,102]

Clinical Manifestations Like quinine, chloroquine has a small toxic-to-therapeutic margin. Severe chloroquine poisoning is usually associated with ingestions of 5 g or more in adults, systolic blood pressure less than 80 mm Hg, QRS duration of more than 120 milliseconds, ventricular fibrillation, hypokalemia, and serum chloroquinine concentrations exceeding 25 μmol/L (8 μg/mL).[24,92]

Symptoms usually occur within 1 to 3 hours of ingestion.[92] The range of symptoms associated with chloroquine toxicity are similar to quinine, but the frequencies of various manifestations differ and other features such as cinchonism, are uncommon. Nausea, vomiting, diarrhea, and abdominal pain occur less commonly than with quinine.[47,63] In contrast, respiratory depression is common and apnea, hypotension, and cardiovascular compromise can be precipitous.[47]

The cardiovascular effects of chloroquine and hydroxychloroquine are similar to those of quinine, including QRS prolongation, atrioventricular (AV) block, ST- and T-wave depression, increased U waves, and QT interval prolongation. Hypotension is more prominent in chloroquine toxicity than with quinine.[47]

Significant hypokalemia in chloroquine toxicity is invariably associated with cardiac manifestations.[25,47] In fact, the extent of hypokalemia is a good indicator of the severity of chloroquine overdose.[24]

Neurologic manifestations include CNS depression, dizziness, headache, and convulsions.[47] Rarely, dystonic reactions occur.[82] Transient parkinsonism has been reported following excessive dosing.[82]

Ophthalmic manifestations are infrequent in acute chloroquine toxicity and transient in nature.[47,63] More severe and irreversible vision and hearing changes are described in association with the chronic use of chloroquine and hydroxychloroquine as antiinflammatory agents.[63,75] Myopathy, neuropathy, and cardiomyopathy also occur in this context.[5,120] Dermatologic findings and hypersensitivity reactions are similar to those associated with quinine.[31] Likewise, red blood cell (RBC) oxidant stress from chloroquine may result in hemolysis in patients with G6PD deficiency (Chap. 24).

Acute hydroxychloroquine toxicity is similar to chloroquine toxicity.[49] Side effects from therapeutic doses include nausea and abdominal pain, hemolysis in G6PD-deficient patients and, rarely, retinal damage, sensorineural deafness, and hypoglycemia.[10,48,101] Hypersensitivity reactions, including myocarditis and hepatitis, are described.[37,66]

One report of amodiaquine toxicity suggests that involuntary movements, muscle stiffness, dysarthria, syncope, and seizures may occur.[47] Amodiaquine is associated with hypersensitivity hepatitis and neutropenia in prophylactic use, but not therapeutic use.[18] There is no overdose experience reported.

Management Aggressive supportive care should be initiated including oxygen, cardiac and hemodynamic monitoring, and large-bore IV access, and serial blood glucose concentrations should be obtained. Orogastric lavage could be considered for life-threatening ingestions presenting early, but there is little evidence of efficacy. Activated charcoal adsorbs chloroquine well, binding 95% to 99% when administered within 5 minutes of ingestion.[54] The frequent development of precipitous cardiovascular and CNS toxicity should be considered before initiating any type of GI decontamination.

Early aggressive management of severe chloroquine toxicity decreases mortality.[92] This includes early endotracheal intubation and mechanical ventilation. There is evidence to suggest barbiturates may *not* be the best agent for induction in chloroquine overdose. When thiopental

was used to facilitate intubation, its use immediately preceded sudden cardiac arrest in seven of 25 patients after chloroquine overdose.[26] An adequate FiO$_2$, tidal volume and ventilatory rate should be ensured.

Although theoretically any direct-acting pressor would be beneficial in the setting of hypotension not responsive to fluid resuscitation, epinephrine is the pressor that has been studied the most and is considered the vasopressor of choice. High doses of epinephrine were used in the original studies describing the benefits of early mechanical ventilation and the administration of diazepam and epinephrine in chloroquine poisoning.[92,93] The epinephrine doses used in these studies are still recommended today.[92,93] The recommended dose is 0.25 μg/kg/min, increasing by 0.25 μg/kg/min until an adequate systolic blood pressure (greater than 90 mm Hg) is achieved.[28,70,92,93] Clinicians should be mindful that high doses of epinephrine could exacerbate preexisting hypokalemia.

The use of diazepam to augment the treatment of dysrhythmias and hypotension is a unique use of this drug. Initial observations with regard to patients with mixed overdoses of chloroquine and diazepam suggested less cardiovascular toxicity and a potential benefit of high-dose diazepam.[24,68] Animal and human studies that followed also showed a potential benefit.[28,92,93] When early mechanical ventilation was combined with the administration of high-dose diazepam and epinephrine in patients severely poisoned by chloroquine, a dramatic improvement in survival compared with historical controls (91% versus 9% survival) occurred.[92] Studies in moderately poisoned patients failed to show similar benefit,[24] and a rat model failed to show an inotropic effect. Although the definitive study has yet to be done, high-dose diazepam therapy (2 mg/kg IV over 30 minutes, followed by 1 to 2 mg/kg/d for 2 to 4 days) seems warranted for serious toxicity. Diazepam or an equivalent benzodiazepine should also be used to treat seizures and for sedation.

The mechanism for a potential benefit of diazepam is unclear, but multiple theories have been postulated: (1) a central antagonistic effect, (2) anticonvulsant effect, (3) antidysrhythmic effect by an electrophysiologic action inverse to chloroquine, (4) pharmacokinetic interaction between diazepam and chloroquine, and (5) decrease in chloroquine-induced vasodilation.[68,90,92,93] (see Antidotes in Depth A24: Benzodiazepines).

The use of sodium bicarbonate for correction of QRS prolongation is also controversial. Although alkalinization would be expected to counteract the effects of sodium channel blockade, it could also exacerbate preexisting hypokalemia. Although case reports describe the successful use of sodium bicarbonate in conjunction with other agents for massive hydroxychloroquine overdose, no clinical trials have been performed.[60,130] Before using sodium bicarbonate in the setting of chloroquine toxicity clinicians should consider the overall clinical status of the patient, including the suspected degree of cardiac toxicity and severity of hypokalemia.

Hypokalemia in the setting of chloroquine toxicity correlates with the severity of the intoxication.[24,68] This hypokalemia is thought to be due to intracellular shift, not total-body potassium depletion.[25,47,49] Potassium replacement in this setting is, again, controversial since it has not been shown that potassium supplementation will improve cardiac toxicity. In fact, several reports suggest a possible protective effect of hypokalemia in acute chloroquine toxicity.[24,68,90] This should be balanced against the fact that severe hypokalemia can itself result in lethal dysrhythmias and data suggesting severe hypokalemia (less than 1.9 mEq/L) is associated with severe, life-threatening ingestion.[22,47,68,104] Hypokalemia could not be directly attributed as the cause of death in most cases, however.[24] Based on the available evidence, potassium replacement for significant hypokalemia seems warranted, but it is essential to anticipate rebound hyperkalemia as chloroquine toxicity resolves and redistribution of intracellular potassium occurs. Cases of hyperkalemia-related complications after aggressive potassium supplementation have been reported.[49,60,68]

Because chloroquine and hydroxychloroquine have high volumes of distribution and significant protein binding, enhanced elimination procedures are not beneficial.[13,47]

■ PRIMAQUINE
Pharmacokinetics and Toxicodynamics See Table 58–2 for the pharmacokinetic properties of primaquine.

Pathophysiology Primaquine blocks sodium channels both in vitro and animal models.[47,123] Significant cardiovascular toxicity has not been reported, although experience with primaquine overdose is limited primarily to case reports.

The predominant clinical toxicity of primaquine relates to its ability to cause RBC oxidant stress and resultant hemolysis or methemoglobinemia (metHb). Methemoglobinemia and hemolysis can even occur in normal individuals given high doses as well as those with the autosomal recessive disorder nicotinamide adenine dinucleotide (NADH) methemoglobin reductase deficiency.[63,111]

The major complication of primaquine in therapeutic use has been hemolysis in G6PD-deficient individuals.[29] Primaquine is contraindicated in pregnant women because of the risk of metHb or hemolysis in the fetus. Reversible bone marrow suppression can occur.

Clinical Manifestations Gastrointestinal irritation is also common and dose related.

The extent of hemolysis in G6PD-deficient individuals is dependent on the extent of enzyme activity, those with higher levels of enzyme activity having less severe hemolysis than those with less enzyme activity (see Chap. 24). Other variables include the dose of primaquine and comorbid conditions, such as infection, liver disease, and administration of other drugs with hemolytic activity.

Overdose with primaquine is rarely reported and unintentional overdoses have led to metHb requiring IV methylene blue.[111] Acute liver failure has occurred following unintentional overdose and fatal hepatotoxicity is described in animal models.[61]

Management Therapy should be directed at minimizing absorption with appropriate decontamination, and diagnosing then treating significant metHb or hemolysis. Because of structural similarities with other quinolone antimalarials and animal model evidence of sodium channel blockade, cardiovascular toxicity should be anticipated with continuous monitoring and resuscitative interventions initiated as needed.

Activated charcoal would be expected to bind primaquine well if given early (see Antidotes in Depth A2: Activated Charcoal). Methylene blue (Chap. 127 and Antidotes in Depth A41: Methylene Blue) should be administered for patients who are symptomatic with methemoglobinemia. Treatment of hemolysis necessitates avoiding further exposure to primaquine and possibly exchange transfusion in severe cases. Adequate hydration should be ensured to protect against hemoglobin-induced renal injury. Urinary alkalinization with sodium bicarbonate is controversial in this setting but may have some benefit (see Antidotes in Depth A5—Sodium Bicarbonate).

Although no clinical studies have been performed, primaquine's large volume of distribution makes it an unlikely candidate for benefit from extracorporeal removal.

■ MEFLOQUINE
Pharmacokinetics and Toxicodynamics See Table 58–2 for the pharmacokinetic properties of mefloquine.

Clinical Manifestations Common effects with prophylactic and therapeutic dosing include nausea, vomiting, and diarrhea.[78] These effects are noted particularly in the extremes of age and with high therapeutic dosing. Similar symptoms should be expected in acute overdose.[94,124]

Mefloquine has a mild cardiodepressant effect—less than that of quinine or quinidine—which is not clinically significant in prophylactic dosing or with therapeutic administration. Bradycardia is commonly reported.[22,63,78] With prophylactic use, neither the PR interval nor the QRS complex is prolonged, but QT prolongation has been reported.[31,63] Reports of torsades de pointes are rare, but the increase in QT and risk of torsades de pointes are increased when mefloquine is used concurrently with quinine, chloroquine or, most particularly, with halofantrine.[63,78,79,123] The long half-life of mefloquine means that particular care must be taken with therapeutic use of other antimalarials when breakthrough malaria occurs during mefloquine prophylaxis or within 28 days of mefloquine therapy to avoid potential drug—drug interactions. This risk may increase with acute overdose, although there is little clinical experience.

Mefloquine commonly has neuropsychiatric side effects. During prophylactic use, 10% to 40% of patients experience insomnia and bizarre or vivid dreams, and complain of dizziness, headache, fatigue, mood alteration, and vertigo.[99,117] Only 2% to 10% of these complications necessitate the traveler to seek medical advice or change normal activities.[22,46,100] Predisposing factors include a past history of neuropsychiatric disorders, recent prior exposure to mefloquine (within 2 months), previous mefloquine-related neuropsychiatric adverse effects, and previous treatment with psychotropic drugs.[111] Women appear to be more likely than men to experience neuropsychiatric adverse effects.[111,117]

The risk of serious neuropsychiatric adverse effects during prophylaxis is estimated to be 1:10,600, but is reported to be as high as 1:200 with therapeutic dosing.[29,94,111] Seizures occur rarely with prophylaxis and therapeutic use.[87,96] In many of these cases, there is a history of previous seizures, seizures in a first-degree relative, or other seizure risk factors. Other neuropsychiatric symptoms include dysphoria, "clouded" consciousness, encephalopathy, anxiety, depression, giddiness, and an agitated delirium with psychosis. Although there is a suggestion that the severity of neuropsychiatric events is dose dependant, there does not seem to be a correlation with serum or tissue concentrations.[51] In one case report, the severe neuropsychiatric manifestations of mefloquine were reversed with physostigmine, leading the authors to suggest a possible central anticholinergic etiology.[107] A self-resolving postmalaria neurologic syndrome including confusion, seizures, and/or tremor is associated with therapeutic use of mefloquine for severe malaria.[65,96]

The effect of mefloquine on the pancreatic potassium channel is much less than that of quinine, resulting in only a mild increase in insulin secretion.[30,31] Symptomatic hypoglycemia has not been reported as an effect of mefloquine alone in healthy individuals, but has occurred with concomitant use of ethanol and in a severely malnourished patient with acquired immune deficiency syndrome (AIDS).[6,31,63] In overdose, particularly when accompanied by alcohol use or starvation, hypoglycemia could be severe.

Rare events such as hypersensitivity reactions reported with prophylaxis include urticaria, alopecia, erythema multiforme, toxic epidermal necrolysis, myalgias, mouth ulcers, neutropenia, and thrombocytopenia.[69,78,99,105] It is unclear which, if any, would be significant following overdose. ARDS was linked to therapeutic dosing in one case.[115]

In therapeutic use, mefloquine is associated with an increased incidence of stillbirth compared with quinine and a group of other antimalarial medications.[80] Mefloquine was not, however, linked to an increased incidence of abortion, low birth weight, mental retardation, or congenital malformations. The implications of overdose in the absence of malaria are unknown, but fetal monitoring should be instituted.

The consequences of excessive dosing and overdose are not only severe, but also prolonged and potentially permanent. Mefloquine overdose led to acute hearing loss and gradual resolution of acute symptoms over one year in one case and persistent symptoms even after one year in another.[61] After ingesting 5.25 g of mefloquine over 6 days, a man suffered prolonged prothrombin time and weakness persisting for two months after resolution of the acute symptoms.[16] A fourth case involved coingestion of 2.5 times the usual therapeutic dose of mefloquine, chloroquine, and sulfadoxine-pyrimethamine over 3 days. The man suffered encephalopathy that had not resolved 8 months later.[20]

Management In overdose, treatment is primarily supportive with monitoring for potential adverse effects. Decontamination with activated charcoal is indicated if the patient presents soon after the ingestion. Specific monitoring for ECG abnormalities, hypoglycemia, and liver injury should be provided. Patients should also be followed for CNS and cranial nerve complications.

In two patients with renal failure who received mefloquine, prophylactic hemodialysis did not remove mefloquine.[27] Given the large volume of distribution and high degree of protein binding of mefloquine, extracorporeal elimination techniques are unlikely to be effective.

PHENANTHRENE METHANOLS

■ HALOFANTRINE
Because of erratic absorption, potential for lethal cardiotoxicity, and concern for cross-resistance with mefloquine, halofantrine is not presently recommended for malaria prophylaxis by the WHO.[111]

Lumefantrine is structurally similar to halofantrine. Since lumefantrine is primarily used as a partner drug in an ACT, it is discussed in more detail in the Artemisinin and Derivatives section.

Pharmacokinetics and Toxicodynamics See Table 58–2 for the pharmacokinetic properties of halofantrine.[19]

Clinical Manifestations The primary toxicity from therapeutic and supratherapeutic doses is prolongation of the QT interval and the risk of torsades de pointes and ventricular fibrillation.[79,113] Palpitations, hypotension, and syncope may occur. First-degree heart block is common, but bradycardia is rare.[79] Dysrhythmias are also likely in the context of combined overdose, or combined or serial therapeutic use with other xenobiotics that cause QT interval prolongation, particularly mefloquine.[52] Because the QT interval duration is directly related to serum halofantrine concentration, dysrhythmias should be expected in overdose.[22,79,111] Fifty percent of children receiving a therapeutic course of halofantrine will have a QT interval greater than 440 milliseconds.[106]

Other side effects, including nausea, vomiting, diarrhea, abdominal cramps, headache, and light-headedness, which frequently occur in therapeutic use, are also expected in overdose.[63] Less frequently described side effects include pruritus, myalgias, and rigors. Seizures, minimal liver enzyme abnormalities, and hemolysis are described.[63,72,116] Whether these manifestations are related to halofantrine or to the underlying malaria is not clear.

Management Management of halofantrine overdose should focus on decontamination, supportive care, monitoring for QT interval prolongation, and treatment of any associated dysrhythmias.

■ ARTEMISININ AND DERIVATIVES
The medicinal value of natural artemisinin, the active ingredient of *Artemisia annua* (sweet wormwood or quinghao), has been known for thousands of years. Its antimalarial properties were first recognized by Chinese herbalists in 340 AD, but the primary active component of qinghaosu, now known as artemisinin, was not isolated until 1974.[5,114] Artemisinin and its semisynthetic derivatives, artesunate, artemether, arteether, and dihydroartemisinin, are the most potent and rapidly acting of all antimalarial drugs. They were introduced in the 1980s in China for the treatment of malaria, and since then millions of doses have been used in Asia and Africa. Because of their extremely short half-lives, artemisinins are now used in combination with longer half-life drugs to delay or prevent the emergence of resistance. Artemisinin-based combination therapies (ACTs) are currently recommended by the WHO for the treatment of uncomplicated malaria,[5,128] but have not been licensed for use in the United States. Only four ACTs are currently recommended by the WHO. These include artesunate plus mefloquine, artesunate plus pyrimethamine/sulfadoxine, artesunate plus amodiaquine, and artemether plus lumefantrine.

Pharmacokinetics and Toxicodynamics See Table 58–2 for the pharmacokinetic properties of artemisinin. The efficacy and toxicity of artemisinin is thought to be a result of the ability of the trioxane molecular core to form intracellular free radicals, particularly in the presence of heme. In animals, damage to brainstem nuclei is

consistently produced following prolonged, high-dose, and parenteral administration.[111] Sustained CNS exposure from slowly absorbed or eliminated artemisinins is considered markedly more neurotoxic than intermittent brief exposure seen after oral dosing.[94] Embryonic loss has also been observed in animals.[94]

Clinical Manifestations In contrast to the experience with animals, the experience of more than 8000 human study participants shows that these drugs have a very low incidence of side effects.[94] Uncommon side effects include nausea, vomiting, abdominal pain, diarrhea, and dizziness.

Prospective studies have failed to identify adverse neurologic outcomes.[53,94] Rare reports of adverse CNS effects during therapeutic use suggest the possibility of CNS depression, seizures, or cerebellar symptoms following intentional self-poisoning. In children with cerebral malaria, a higher incidence of seizures and a delay to recovery from coma were noted in a comparison with quinine.[12] No neurologic difference was noted in long-term follow-up. In an artemether—quinine comparative trial of adults with severe malaria, recovery from coma was also prolonged in the artemether group.[45] Rare patients receiving an artemisinin derivative in two other studies experienced transient dizziness or cerebellar signs.[71,89] Most recovered within days. One patient in each study suffered prolonged symptoms, 1 month and 4 months, respectively, but both ultimately recovered.[71,89]

When serial ECGs were obtained, a small but statistically significant fall in heart rate was noted, coincident with peak drug concentrations.[71] In one therapeutic trial, 7% of adult patients receiving artemether had an asymptomatic QT interval prolongation of at least 25%.[45] Changes in the QRS are not reported.

Although uncommon, neutropenia, reticulocytopenia, anemia, eosinophilia, and elevated concentrations of aminotransferases are reported.[94]

Two of the ACT partner drugs frequently being used today have not been previously discussed: lumefantrine, in the ACT artemether-lumefantrine (AL), and piperaquine, in the ACT dihydroartemisinin-piperaquine (DP).

Lumefantirine Lumefantrine is pharmacologically related to mefloquine and halofantrine. Little toxicity of lumefantrine alone or in combination is reported.[125] Studies do not show an increase in QT or evidence of cardiac toxicity related to lumefantrine.[33,118] Cough and angioedema were described in one case.[56] As with all antimalarials there is difficulty in differentiating drug-related adverse events from those of malaria, comorbid diseases, or other ingested drugs, which confounds the study of potential complications.

lumefantrine
Piperaquine Piperaquine, a bisquinolone with a structure similar to chloroquine, was used extensively in China and Indonesia as an antimalarial until the development of piperaquine-resistant strains led to the use of better alternatives. Piperaquine has since undergone

a rediscovery as a viable combination with atremisinin derivatives in ACT DP therapy. Animal studies show piperaquine to be substantially less toxic than chloroquine, with cumulative doses of piperaquine associated with cardiovascular toxicity about fivefold higher than that for chloroquine. Hepatotoxicity occurs following chronic exposure in animals. In a human study, no significant ECG, changes in serum glucose concentration, or postural hypotension was seen following therapeutic doses of DP.

piperaquine
Management Patients with overdose should be managed with supportive measures and expectant observation including cardiovascular and CNS monitoring.

OTHER ANTIMALARIALS

■ ATOVAQUONE/PROGUANIL, PYRIMETHAMINE/SULFADOXINE, AND DAPSONE

Atovaquone

Sulfadoxine

Proguanil
Pyrimethamine

Pharmacokinetics and Toxicodynamics Proguanil, pyrimethamine, sulfadoxine, and dapsone all interfere with malarial folate metabolism at concentrations far lower than that required to produce comparable inhibition of mammalian enzymes.[114] Slow onset of action and concerns for the development of resistance have led to the use of these agents in synergistic combinations. Proguanil (chloroguanide) may be used alone, but is most often used with dapsone (Lapdap), chloroquine, or the antiparasitic atovaquone (Malarone) for prophylaxis. Atovaquone inhibits the de novo pyrimidine synthesis that is necessary for protozoal survival and replication, but is unnecessary in mammalian cells. Based on its beneficial side-effect profile, many North American physicians are switching from mefloquine to atovaquone/proguanil for routine antimalarial prophylaxis for travelers. Atovaquone and proguanil may now be the most common antimalarials used in North America. The price of this combination limits its use mainly to treatment and prevention in travelers from affluent countries.[22]

Pyrimethamine is used synergistically in combination with sulfonamides such as sulfadoxine (Fansidar) or dapsone (Maloprim), but growing malarial resistance and unfavorable toxicity profiles have limited the usefulness of these drug combinations (see Table 58–2 for pharmacokinetic profile). Neither combination is recommended for antimalarial use by the US Centers for Disease Control and Prevention (CDC).

Genetic polymorphism is described in the metabolism of proguanil and dapsone.[50,91] This may be the cause of the significant hypersensitivity reactions noted with dapsone.[91]

Clinical Manifestations The side effects of proguanil during prophylaxis include nausea, diarrhea, and mouth ulcers.[63] Because of the interference with folate metabolism, megaloblastic anemia is a rare complication. Megaloblastic bone marrow toxicity has been reported in renal failure patients.[111] Folate supplementation may be required in pregnancy and renal failure to avoid this complication.[29] Rarely, neutropenia, thrombocytopenia, rash, and alopecia are also noted.[29] In a single case report, hypersensitivity hepatitis was described.[29] When used to treat malaria, atovaquone/proguanil causes vomiting, sometimes severe, in a significant portion of patients (15% to 45%).[94] This combination is also associated with aminotransferase elevations.[94] Unintentional or deliberate overdose has caused little serious toxicity.[111]

Atovaquone alone, primarily used to treat *Pneumocystis jiroveci* in AIDS patients, is relatively well tolerated.[83] Side effects include maculopapular rash, erythema multiforme (rarely), GI complaints, and mild aminotransferase elevations. Three cases of three- to 42-fold overdose or excess dosing have been reported.[23] No symptoms occurred in one case (at three times therapeutic serum concentration). Rash occurred in another, and in the third case metHb was attributed to a simultaneous overdose of dapsone.

Overdose of pyrimethamine alone is rare. In children, it results in nausea, vomiting, the rapid onset of seizures, fever, and tachycardia.[1,47] Blindness, deafness, and mental retardation have followed.[1,47] Seizures were attributed to sulfadoxine-pyrimethamine in an overdose of 12 tablets over 2 days (usual dose is three tablets taken once).[77] It is unclear whether the chronic neurologic deficits described in case reports are due to direct toxicity of pyrimethamine on the central nervous system or to complications of toxicity such as status epilepticus.[1,47] Chronic high-dose use may be associated with a megaloblastic anemia, requiring folate replacement.[1]

The sulfonamides, including the sulfone dapsone, have a long history of causing idiosyncratic reactions, including neutropenia, thrombocytopenia, eosinophilic pneumonia, aplastic anemia, neuropathy, and hepatitis.[63,94] The rare occurrence of life-threatening erythema multiforme major and toxic epidermal necrolysis, associated with pyrimethamine-sulfadoxine prophylaxis, has limited the use of this combination for prophylaxis.

Acute ingestion of dapsone may result in nausea, vomiting, and abdominal pain.[47] Following overdose, dapsone produces RBC oxidant stress leading to metHb and, to a much lesser extent, sulfhemoglobinemia through formation of an active metabolite (Chap. 127).[21,64] The onset of hemolysis may be either immediate or delayed. Dapsone, in particular, is known for its tendency to cause prolonged metHb. Other symptoms, particularly tachycardia, dyspnea, dizziness, visual hallucinations, seizure, syncope, and coma resulting from end-organ hypoxia, can occur.[21,47] Additional effects described in overdose include hepatitis and peripheral neuropathy.[47]

Management Folate supplementation should be considered after overdose of proguanil or pyrimethamine (Antidotes in Depth A13: Leucovorin [Folinic Acid] and Folic Acid). Other efforts should include supportive care.

Following dapsone ingestion, clinically significant metHb should be treated with methylene blue and possibly cimetidine (Chap. 127 and Antidotes in Depth A41: Methylene Blue). There is no antidote for sulfhemoglobinemia, but it constitutes an insignificant portion of total hemoglobin. Both hemodialysis and multidose activated charcoal enhance elimination of dapsone during therapy.[76] Multidose activated charcoal is routinely recommended in the treatment of dapsone overdose.[64] Required support may include RBC transfusion and urinary alkalinization if hemolysis is extensive (Antidotes in Depth A5: Sodium Bicarbonate).

SUMMARY

A variety of xenobiotics are used in the prevention and treatment of malaria. The optimal choices and, consequently, the most widely available xenobiotics, change rapidly with shifting patterns of parasite resistance. Most antimalarials have significant toxicity in acute overdose. Although many toxic effects are related to quinine, even within the quinine group, the pattern of predominant symptoms is xenobiotic dependent. Effects at the low doses associated with prophylaxis and therapy include nausea, vomiting, headache, and confusion. Autoimmune-mediated idiosyncratic reactions are described with most of the antimalarials. In overdose, cardiovascular, neurologic, and hematologic symptoms predominate. Dysrhythmias are the effects that are the most life threatening, particularly with quinine derivatives and especially with chloroquine. These result from sodium channel blockade effect, potassium channel blockade, and myocardial depression. Other significant effects are coma, seizures, and neurologic injury, particularly to the special senses. Primaquine and dapsone produce significant oxidant stress resulting in metHb and often hemolysis. Little is known of the acute toxicity of the newest agent, artemisinin.

Decontamination, including the administration of activated charcoal, should be considered. Multidose activated charcoal is particularly important for quinine and dapsone ingestions. When xenobiotic-specific symptoms are anticipated and specific management strategies followed, improved outcome has resulted, particularly for chloroquine poisoning.

E.
CARDIOPULMONARY MEDICATIONS

ANTICOAGULANTS

Mark Su

Anticoagulants have numerous clinical applications, including in the treatment of coronary artery disease, cerebrovascular events, deep venous thrombosis, and pulmonary embolism. The anticoagulants are a diverse group of xenobiotics that are widely studied and constantly in the process of therapeutic evolution. Bleeding is a major complication of these xenobiotics. Knowledge of anticoagulants will be of ever-increasing utility for clinicians as their use increases.

HISTORY AND EPIDEMIOLOGY

The origins and discovery of anticoagulants are extraordinary.[2,16,73,131] The discovery of modern-day oral anticoagulants originated following investigations of a hemorrhagic disorder in Wisconsin cattle in the early 20th century that resulted from the ingestion of spoiled sweet clover silage. The hemorrhagic agent, eventually identified as bishydroxycoumarin, would be the precursor to its synthetic congener warfarin (named after the *Wisconsin Alumni Research Foundation*). This knowledge also led to the use of warfarin as a rodenticide. "Superwarfarins" were subsequently developed as selective pressure caused rats to develop genetic resistance to warfarin. These potent anticoagulants permitted either small, repetitive ingestions or single, larger ingestions to successfully function as rodenticides.

As in the case of warfarin, the origins of the anticoagulant heparin are equally fascinating. A medical student initially attempting to study ether-soluble procoagulants derived from porcine intestines serendipitously found that, over time, these apparent "procoagulants" actually prevented normal blood coagulation. The phospholipid anticoagulant responsible for this effect would later be identified as an early form of heparin. Shortly thereafter, the water-soluble mucopolysaccharide termed *heparin* (because of its abundance in the liver) was then discovered. *Unfractionated* heparin is a mixture of polysaccharide chains with varying molecular weights. Following the identification of the active pentasaccharide segment of heparin in the 1970s, multiple *low-molecular-weight* heparins were isolated and synthetic forms created.

In the late 19th century, human urine was noted to have proteolytic activity with a specificity for fibrin. A substance found to be an activator of endogenous plasminogen leading to the consumption of fibrin, fibrinogen, and other coagulation proteins was isolated and purified and given the name *urokinase*. Streptokinase, a protein produced by β-hemolytic streptococci, tissue plasminogen activator (t-PA), and other synthetic thrombolytics were later discovered. Although known

to exist for many years, ancrod (a purified derivative of snake venom) and hirudin (a product of leeches) only recently gained attention as naturally occurring antithrombotic therapeutic agents.

The diversity of these anticoagulants and fibrinolytics has led to ever-increasing use in many fields of medicine. Warfarin is the most common oral anticoagulant in use today because of its utility in patients with cerebrovascular disease, cardiac dysrhythmias, and thromboembolic disease. During the period of 2005 to 2007, the total number of cases of reported warfarin exposures to the American Association of Poison Control Centers was 10,508 with eight deaths (Chap. 135). Throughout this time, there was a general trend toward an increasing number of reports. Additionally, because the common problem of excessive warfarin effects leading to hemorrhage is poorly quantitated as an adverse drug reaction, it frequently goes unrecorded. Thus, as long as warfarin continues to be routinely prescribed, it is likely that the incidence of adverse drug events will continue. Physicians must be cognizant of the complications of warfarin and other anticoagulants, as well as their various therapeutic modalities, while balancing the potential for their risk and benefits.

PHYSIOLOGY

■ BALANCE BETWEEN COAGULATION AND ANTICOAGULATION

An understanding of the normal function of the coagulation pathways is essential to appreciate the etiology of a coagulopathy. This section summarizes the critical steps of the coagulation cascade. For additional details, the reader is referred to Chap. 24 and several reviews.[63,129,155]

Coagulation consists of a series of events that prevent blood loss and assist in the restoration of blood vessel integrity. Although the traditional understanding of the events that occur in the coagulation cascade,[48,114] as discussed below, adequately describe in vitro events, the current understanding emphasizes some distinct differences that occur in vivo.[63,129,155] Despite these differences, an understanding of the traditional model is most useful for interpreting the results of diagnostic tests of coagulation.

Within the cascade, coagulation factors exist as inert precursors and are transformed into enzymes when activated. Activation of the cascade occurs through one of two distinct pathways, the *intrinsic* and *extrinsic* systems (Fig. 59–1).[48,114] Once activated, these enzymes catalyze a series of reactions that ultimately converge and lead to the generation of thrombin and the formation of a fibrin clot.

The intrinsic pathway is activated by the complexation of factor XII (Hageman factor) with high-molecular-weight kininogen (HMWK) and prekallikrein, or vascular subendothelial collagen. This results in sequential activation of factor XII, active kallikrein, active factors IX to XI, and prothrombin (factor II) (Fig. 59–2). Prothrombin is converted to thrombin in the presence of factor V, calcium, and phospholipid. The integrity of this system is usually evaluated by determining the partial thromboplastin time (PTT).

In the extrinsic or tissue-factor-dependent pathway, a complex is formed between factor VII, calcium, and tissue factor, which is released following injury. A calcium and lipid-dependent complex is then created between factors VII and X. The factor VII–X complex subsequently converts prothrombin to thrombin, which promotes the formation of fibrin from fibrinogen (see Fig. 59–1). The integrity of this pathway is usually assessed by determining the prothrombin time (PT or international normalized ratio [INR]).

Activation of factor X provides the important link between the intrinsic and extrinsic coagulation pathways. Additional evidence that tissue factors can activate both factors IX and X suggests that there are more interrelations between the two pathways.[143] Furthermore, cell surfaces facilitate the process of clotting. Platelets are also known to interact with proteins of the coagulation cascade through surface receptors for factors V, VIII, IX, and X.[66,118,169] As a final step, factor XIII assists in the cross-linking of fibrin to form a stable thrombus.

Antithrombin III (now known simply as AT), protein C, protein S, and protein Z serve as inhibitors, maintaining the homeostasis that is required to prevent spontaneous clotting and keep blood fluid. Protein C, when aided by protein S, inactivates two plasma factors, V and VIII.[27,40,63] Protein Z is a glycoprotein molecule that forms a complex with the protein Z-dependent protease inhibitor (ZPI) which, in turn, inhibits the activated factor X (Xa)[184] AT complexes with all the serine protease coagulation factors (factor Xa, factor IXa, and contact factors, including XIIa, kallikrein, and HMWK), except factor VII.[27,63,155]

Thrombolytics such as streptokinase, urokinase, anistreplase, and recombinant tissue plasminogen activator (rt-PA) enhance the normal processes that lead to clot degradation.[129]

Thrombosis is initiated when exposed endothelium or released tissue factors leads to platelet adherence and aggregation, the formation of thrombin, and cross-linking of fibrinogen to form fibrin strands.[63,129,155] This results in a hemostatic plug or thrombus formation. Thrombus formation, in turn, leads to generation of plasmin from plasminogen, which causes fibrinolysis and eventual dissolution of the hemostatic plug.[42,43] Thus the fibrinolytic system may be thought of as a natural balance against unregulated coagulation. Thrombolytic therapy increases fibrinolytic activity by accelerating the conversion of plasminogen to plasmin, which actively degrades fibrin.[42,43] Following the administration of thrombolytics, a drug-induced coagulopathy ensues, and fibrin degradation products are elevated secondary to the rapid turnover of clot.

DEVELOPMENT OF COAGULOPATHY

Impaired coagulation results from decreased production or enhanced consumption of coagulation factors, the presence of inhibitors of coagulation, activation of the fibrinolytic system, or abnormalities in platelet number or function. Platelets are involved in the initial phases of clotting following blood vessel injury by assisting in the formation of the fibrin plug. For the purposes of this chapter, a discussion of platelet-related abnormalities is excluded. Some of this information can be found in Chap. 24.

Decreased production of coagulation factors results from congenital and acquired etiologies. Although congenital disorders of factor VIII (hemophilia), factor IX (Christmas factor), factor XI, and factor XII (Hageman factor) are all reported, their overall incidence is still quite low. Clinical conditions that result in acquired factor deficiencies are much more common and result from either a decrease in synthesis or activation. Factors II, V, VII, and X are entirely synthesized in the liver,[63,129,155] making hepatic dysfunction a common cause of acquired coagulopathy. In addition, factors II, VII, IX, and X require postsynthetic

activation by an enzyme that uses vitamin K as a cofactor,[174,179,180] such that vitamin K deficiency (from malnutrition, changes in gut flora secondary to xenobiotics, or malabsorption), or inhibition of vitamin K cycling (from warfarin, as will be described) is capable of impairing coagulation.

Excessive consumption of coagulation factors usually results from massive activation of the coagulation cascade. Massive activation occurs during severe hemorrhage or disseminated intravascular coagulation. The latter results from infection, such as sepsis, and from conditions that introduce tissue factor into the blood, such as neoplasms, snake envenomations, stagnant blood flow, diffuse endothelial injury secondary to hyperthermia, ruptured aortic aneurysm, or aortic dissection. The hallmark of a consumptive coagulopathy is a depressed concentration of fibrinogen with an elevation of fibrin-degradation products. This combination suggests the rapid turnover of fibrin in the coagulation process. In the other coagulopathic conditions, the failure to activate the coagulation cascade is associated with normal or high fibrin concentrations and low fibrin-degradation products because of limited clot formation.

Inhibitors of the coagulation cascade (circulating anticoagulants) are of two types: immunoglobulin and nonimmunoglobulin. Immunoglobulins, which are often antibodies to existing coagulation factors, may occur without obvious cause. They may be part of a systemic autoimmune disorder or as a result of repeated transfusions with exogenous factors (as occurs in hemophilia).[77,106,165] The clinical syndromes associated with antibody inhibitors are similar to those associated with deficiencies of the particular coagulation factors involved. Antibodies to factors V, VII to XI, and XIII are described.[20,165] Alternatively, nonimmunoglobulin neutralizers of coagulation occur in conditions associated with rapid white blood cell turnover.[20] These lysosomal cationic proteins are neutralizers that compete with coagulation factors for negatively charged phospholipid membrane surfaces. Although they prolong in vitro coagulation times, they are rarely responsible for clinical coagulopathy because of the excess of phospholipid surface area available in vivo.[77,106]

ORAL ANTICOAGULANTS

■ WARFARIN AND "WARFARINLIKE" ANTICOAGULANTS

Oral anticoagulants can be divided into two groups: (1) hydroxy-coumarins, including warfarin (commonly called by its trade name Coumadin), difenacoum, panwarfarin, warficide, coumachlor, coumafuryl, fumasol, prolin, ethyl biscoumacetate (Tromexan), phen-procoumon, dicumarol bishydroxycoumarin, and acenocoumarin (Sintrom); and (2) indanediones, including chlorophacinone, pindone, pivalyn, diphacinone, diphenadione, phenindione, and anisindione. Regardless of the classification, their mechanism of action involves inhibition of the vitamin K cycle. Vitamin K is a cofactor in the postribosomal synthesis of clotting factors II, VII, IX, and X (Fig. 59–2). The vitamin K–sensitive enzymatic step that occurs in the liver involves the γ-carboxylation of 10 or more glutamic acid residues at the amino terminal end of the precursor proteins, to form a unique amino acid γ-carboxyglutamate.[53,174,179,180] These amino acids chelate calcium in vivo, which allows the binding of the four vitamin K–dependent clotting factors to phospholipid membranes during activation of the coagulation cascade.[195]

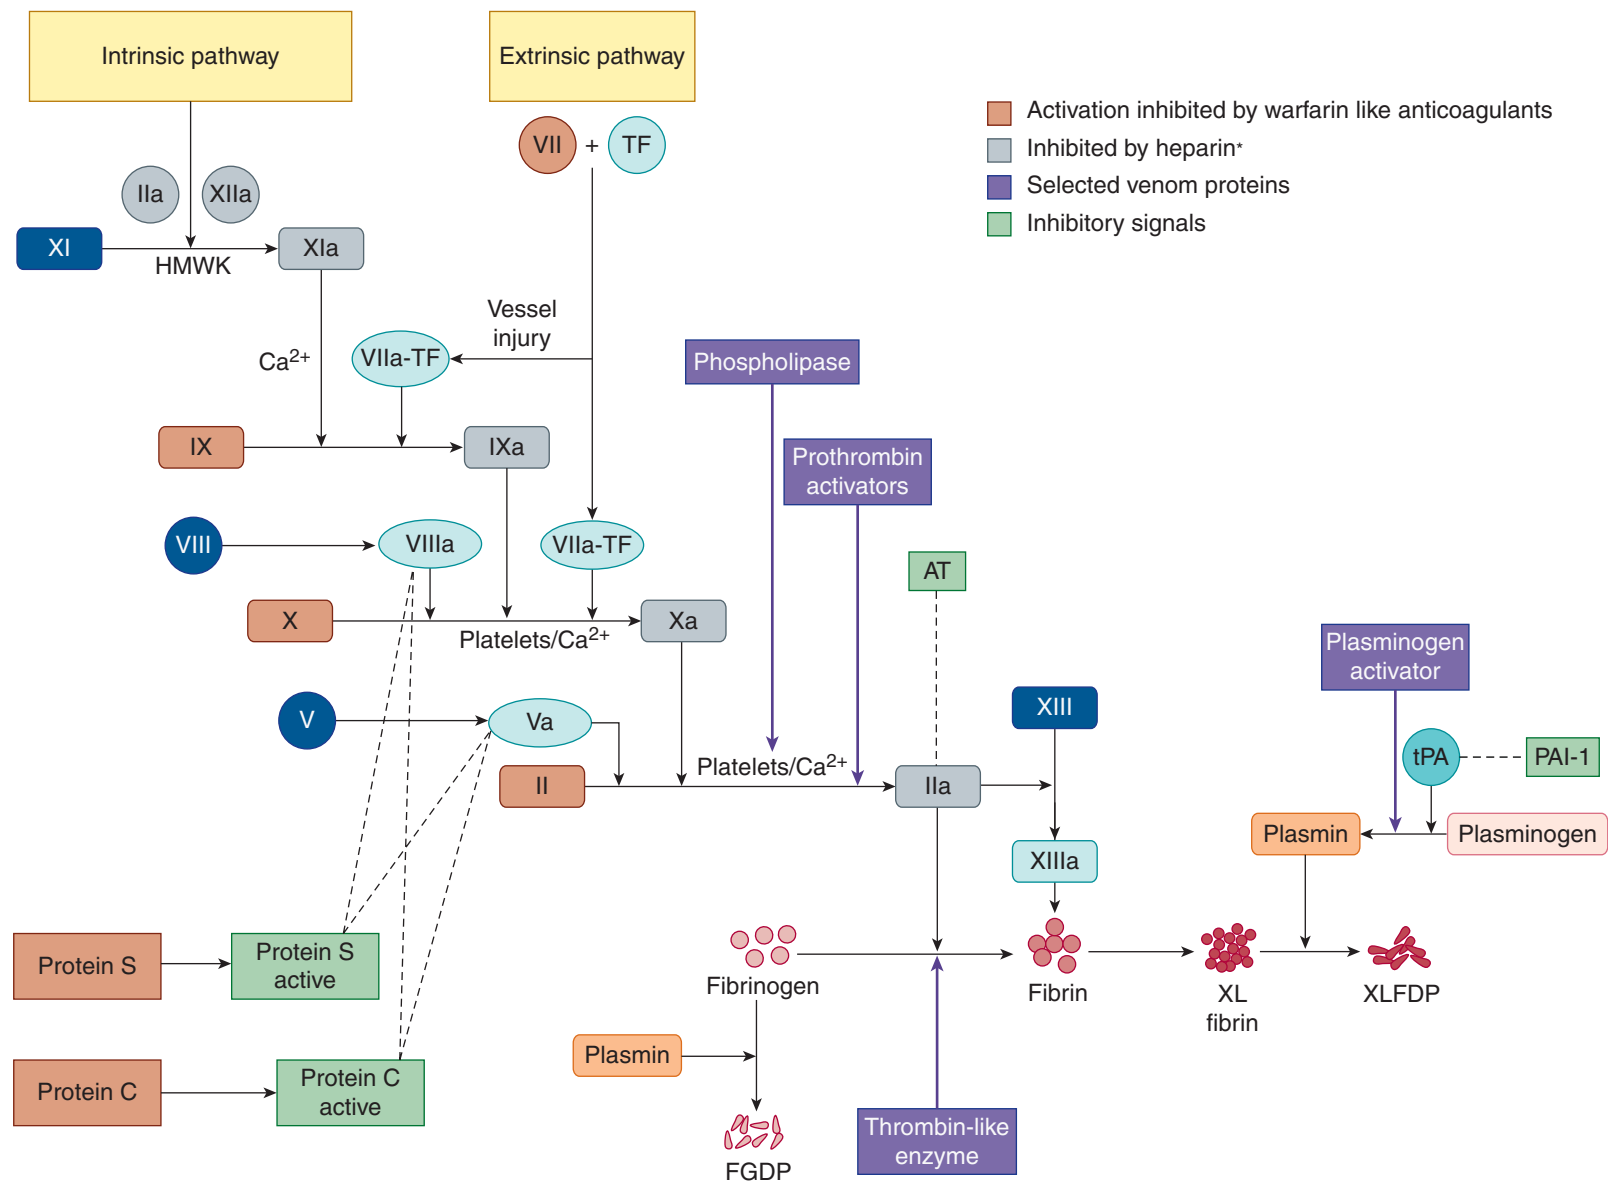
Vitamin K is inactive until it is reduced from its quinone form to a quinol (or hydroquinone) form in hepatic microsomes. This reduction of vitamin K must precede the carboxylation of the precursor factors. The carboxylation activity is coupled to an epoxidase activity for


FIGURE 59–1. A schematic overview of the coagulation and fibrinolytic pathways indicating where phospholipids on the platelet surface interact with the coagulation pathway intermediates. Arrows are not shown from platelets to phospholipids involved in the tissue factor VIIa and the factor IXa to VIIIa interactions to avoid confusion. Interactions of selected venom proteins are indicated in the purple boxes. The diagram is not complete with reference to the multiple sites of interaction of the SERPINS (serine protease inhibitors) to avoid overcrowding.[115]; XL cross-linked. FIGURE 59–2. The vitamin K cycle. Dotted lines represent pathways that can be blocked with warfarin and warfarinlike anticoagulants. The aliphatic side chain (R) of vitamin K is shown below the metabolic pathway. VKORC1=Vitamin K reductase complex 1.

TABLE 59–1. Common Xenobiotic Interactions With Warfarin Anticoagulation

Potentiation		Antagonism
Acetaminophen	Isoniazid	Antacids
Allopurinol	Ketoconazole	Barbiturates
Amiodarone	Metronidazole	Carbamazepine
Anabolic steroids	Nonsteroidal	Cholestyramine
Aspirin	antiinflammatory drugs	Colestipol
Carbenicillin	Omeprazole	Corticosteroids
Clarithromycin	Phenytoin	Griseofulvin
Cephalosporins	Propafenone	Oral contraceptives
Chloral hydrate	Propoxyphene	Phenytoin
Cimetidine	Quinidine	Rifampin
Clofibrate	Quinolones	Vitamin K
Cyclic antidepressants	Sulfonylureas	
Disulfiram	Tamoxifen	
Erythromycin	Tetracycline	
Ethanol	Thyroxine	
Fluconazole	Trimethoprim-	
fluoroquinolone	Sulfamethoxazole	
antibiotics	Vitamin E	
HMG-CoA reductase		
Inhibitors		

vitamin K, whereby vitamin K is oxidized simultaneously to vitamin K 2,3-epoxide (see Fig. 59–2).[179,195] This inactive form of the vitamin is converted back to the active form by two successive reductions.[53,116,146] In the first step, an epoxide reductase (known as vitamin K 2,3-epoxide reductase) uses reduced nicotinamide adenine dinucleotide (NADH) as a cofactor to convert vitamin K 2,3-epoxide to a quinone form.[139,179] Subsequently, the quinone is reduced to the active vitamin K quinol form (see Antidotes in Depth A16–Vitamin K₁).

Warfarin is a racemic mixture of R warfarin and S warfarin enantiomers. In rodents, S warfarin is three to six times more potent than R warfarin at producing hypoprothrombinemia.[29] In humans, S warfarin may only be about 1.5 times as potent as R warfarin.[30] Warfarin and all warfarinlike compounds inhibit the activity of vitamin K 2,3-epoxide reductase, as can be demonstrated by the observation of elevated concentrations of vitamin K 2,3-epoxide in orally anticoagulated subjects.[39,198] Additional evidence suggests that another enzyme, vitamin K quinone reductase, is also inhibited by warfarin and its related compounds (Fig. 59–2).[53,57] This reduction in the cyclic activation of vitamin K subsequently inhibits the formation of activated clotting factors.

Pharmacology of Warfarin Orally ingested warfarin is virtually completely absorbed, and peak serum concentrations occur approximately 3 hours after administration.[178] Because only the free warfarin is therapeutically active, concurrent administration of xenobiotics that alter the concentration of free warfarin, either by competing for binding to albumin or by inhibiting warfarin metabolism, may markedly influence the anticoagulant effect.[12,61,178] The pharmacologic response to warfarin is a polygenic trait with approximately 30 genes contributing to its

therapeutic effects.[101] Table 59–1 lists the xenobiotics that interfere with or potentiate warfarin's effects. Although vitamin K regeneration is altered almost immediately, the anticoagulant effect of warfarin, as well as other oral anticoagulants, is delayed until the existing stores of vitamin K are depleted and the active coagulation factors are removed from circulation. Because vitamin K turnover is rapid, this effect is largely dependent on factor half-life ($t_{1/2}$), with factor VII ($t_{1/2}$ ~5 hours) depleted most rapidly.[61] For a prolongation of the INR to occur, factor concentrations must fall to approximately 25% of normal values. Assuming complete inhibition of the vitamin K cycle, this suggests that in most patients who are not originally anticoagulated, at least 15 hours (three factor VII half-lives) are required before warfarin's effect is evident.[59] In fact, complete inhibition does not occur, and hence the onset of coagulation is even further delayed.

Because the half-life of warfarin in humans is 35 hours, its duration of action may be as long as 5 days.[29,178] On average, it takes approximately 6 days of warfarin administration to reach a steady-state anticoagulant effect.

R warfarin is metabolized by isozymes CYP1A2 and CYP3A4, and S warfarin is metabolized by CYP2C9 of the hepatic microsomal P450 enzyme system. R warfarin is metabolized by side-chain reduction to secondary alcohols that are subsequently excreted by the kidney, whereas S warfarin is metabolized by hydroxylation to 7-hydroxy warfarin, which is excreted into the bile.[178] The elimination of S warfarin is more rapid than that of R warfarin.[30]

The therapeutic dose of warfarin is established for both adults and children. Typical adult recommendations are to give a starting dose of 5 mg/d with subsequent doses based on nomograms, computer programs, and/or clinical experience.[64] Previous recommendations of

initiating with a "loading" dose appear to be unnecessary.[5] Wide variability of maintenance dosing also exists, depending on, for example, individual responsiveness, comorbid health conditions, and age. For children, the suggested starting dose of warfarin is 0.2 mg/kg, followed by continued loading over 3 days, followed by a daily maintenance dose to maintain the INR between 2 and 3.[127,152] For patients with mechanical heart valves, depending on the type of valve, an increased intensity of anticoagulation (INR 3.0 to 4.0) may be recommended.[54]

Dosing of warfarin and other vitamin K antagonists is potentially problematic in certain individuals. In one study, genetic polymorphisms of the vitamin K epoxide reductase complex 1 (VKORC1) and CYP2C9 genes appear to be the strongest predictors of interindividual variability in the anticoagulant effect of warfarin.[101] Furthermore, pharmacogenomic research with complex xenobiotics, such as warfarin, may improve the treatment of patients and predict or prevent interactions with other xenobiotics. In fact, the US Food and Drug Administration (FDA) has recently approved a commercially available test to identify variants within these genes.[97]

■ PHARMACOLOGY OF LONG-ACTING ANTICOAGULANTS

Within the coumarin group are two 4-hydroxycoumarin derivatives—difenacoum and brodifacoum differ from warfarin by their longer, higher-molecular-weight polycyclic hydrocarbon side chains (Fig. 59–3). Together with chlorophacinone, an indandione derivative, they are known as "superwarfarins," or long-acting anticoagulants.

Long-acting anticoagulants were designed to be effective rodenticides in warfarin-resistant rodents.[113] Their mechanism of action is identical to that of the traditional warfarinlike anticoagulants, as demonstrated by the measurement of increased concentrations of vitamin K 2,3-epoxide after long-acting anticoagulant administration.[28,31,32,107,145] The ability of these xenobiotics to perform as superior rodenticides is attributed to their high lipid solubility and concentration in the liver.[107,113,145] They also may saturate hepatic enzymes at very low concentrations, as demonstrated by zero-order elimination following overdose.[32] These factors make them about 100 times more potent than warfarin on a molar basis.[107,113,145] In addition, they have a longer duration of action than the traditional warfarins.[107,113,145] For example, to obtain 100% lethality in a mouse, more than 21 days of feeding with a warfarin-containing rodenticide (0.025% anticoagulant by weight of bait) is required.[113] Similar efficacy can be achieved with a single ingestion of brodifacoum (0.005% anticoagulant by weight of bait).[113]
FIGURE 59–3. Structural comparison of prototypical short-acting (warfarin) and long-acting (brodifacoum) anticoagulants.

Many animals have been poisoned with long-acting anticoagulants, either secondary to the unintentional ingestion of rodenticides or intentionally for scientific investigation. In rats, the half-life of brodifacoum is reported to be 156 hours.[9] The half-life in dogs is reported to be between 6 and 120 days.[200] Horses intentionally poisoned with brodifacoum had a half-life of 1.22 days.[23] The veterinary literature is replete with reports of fatalities and of animals that remained anticoagulated in excess of 1 month.[130,176]

Likewise, many cases of intentional overdose of long-acting anticoagulants in humans are also described in the literature. These patients' clinical courses are characterized by a severe coagulopathy that may last weeks to months, often accompanied by consequential blood loss. The most common sites of bleeding are the gastrointestinal and genitourinary tracts. Although initial parenteral vitamin K_1 doses as high as 400 mg have been required for reversal,[33] daily oral vitamin K_1 requirements may be in the range of 50 to 100 mg. Recent experience in both animals and humans suggests that parenteral vitamin K_1 therapy might not be required (see Antidotes in Depth A16: Vitamin K_1).[32,200] It should also be noted that although ingestions of these xenobiotics are the most common route of exposure and subsequent cause of toxicity, dermal absorption can occur also resulting in coagulopathy.[172]

Patients with unintentional ingestions must be distinguished from those with intentional ingestions, because the former individuals demonstrate a low likelihood of producing coagulation abnormalities and have only rare morbidity or mortality. Prolongation of the INR is unlikely with a single small ingestion of a superwarfarin rodenticide. Clinically significant anticoagulation is even rarer. In a combined pediatric case series, prolongation of the INR occurred in only eight of 142 children (5.6%) reported with single small ingestions of long-acting anticoagulants.[15,94,95,171] Only one child in this group was reported to have "abnormal prolonged bleeding," but this required no medical attention.[171] In a single case report, a 36-month-old child developed a coagulopathy manifested by epistaxis and hematuria, with anticoagulation persisting for more than 100 days after a presumed, but unwitnessed, single unintentional ingestion of brodifacoum.[182] Clinically significant coagulopathy can result, however, following small repeated ingestions. Two children reportedly became poisoned by repeated ingestions of a long-acting anticoagulant. One child presented with a neck hematoma that compromised his airway, and the other with a hemarthrosis.[69] Similarly, a 7-year-old girl required multiple hospitalizations over a 20-month period following repeated nonsuicidal ingestions of brodifacoum.[192] Finally, a 24-month-old child who presented with unexplained bruising and a PT greater than 125 seconds was the victim of brodifacoum poisoning because of a Munchausen syndrome by proxy.[8]

Most patients (usually children) are entirely asymptomatic and have a normal coagulation profile following an acute unintentional exposure. Knowing that the risk of coagulopathy is low and that it takes days to develop, most authors recommend supportive care only.[93,171] Despite the fact that significant toxicity from superwarfarins is rare, it should be recognized that the reported benign courses of pediatric exposures may be misleading. Multiple retrospective studies suggest that children with unintentional acute exposures do not require any follow-up coagulation studies.[128,132,147,166] However, this conclusion and approach to management may be an unjustified attempt to decrease the cost of "unnecessary" coagulation studies. There are clearly insufficient data to justify this conclusion, as many of these "exposed" children were never documented to have ingested long-acting anticoagulants (see Chap. 135). We recommend that clinicians continue to manage these children as possible significant exposures, and that all children be followed up with at least a single INR at least 48 hours after the exposure.

A baseline INR is usually unnecessary but may be performed if there is a suspicion of chronic ingestion.

CLINICAL MANIFESTATIONS

Typical warfarin rodenticides contain only small concentrations of anticoagulant, 0.025% (or 25 mg of warfarin per 100 g of product). Using the data previously listed, a 10-kg child would require an initial dose of 2.5 mg of warfarin (or 10 g of rodenticide). These quantities are far greater than those that occur in typical "tastes." Thus, single small unintentional ingestions of warfarin-containing rodenticides pose a minimal threat to normal patients.[93] In contrast, intentional and large unintentional ingestions of pharmaceutical-grade anticoagulants have the potential to produce a coagulopathy and bleeding. In one study describing 12 patients with surreptitious ingestion of oral anticoagulants, nine were healthcare professionals.[140] These patients presented with bruising, hematuria, hematochezia, and menorrhagia, the typical manifestations of impaired coagulation. Hemorrhage into the neck with resultant airway compromise is a rare but life-threatening complication that has occurred.[24]

Although intentional ingestions of warfarin-containing products are uncommon, adverse drug events resulting in excessive anticoagulation and bleeding frequently occur. The risk of hemorrhage during oral anticoagulant therapy depends on a myriad of factors, including the intensity of anticoagulation, patient characteristics, and comorbid conditions such as hypertension, renal insufficiency, hepatic dysfunction, malignancy, length of anticoagulant therapy, and indications for anticoagulation—cerebrovascular disease, prosthetic heart valves, atrial fibrillation, ischemic heart disease, and venous and arterial thromboembolism. Although the significance of each of these clinical conditions varies among different reports, most studies demonstrate that there is a greater incidence of bleeding complications with increasing INR,[41] increasing intensity (or variation) of coagulation, advanced age, a history of previous bleeding episodes while on therapeutic warfarin, drug interactions, impaired liver function, and dietary changes.[59,61,71,76,150,197] Clearly, the most serious complication of excessive anticoagulation is intracranial hemorrhage, which is reported to occur in as many as 2% of patients on long-term therapy.[61] This complication is associated with a fatality rate as high as 77%.[121] A recent study of patients with intracranial hemorrhage found that decreased level of consciousness and increased size of hemorrhage were predictors of poor prognosis.[203] Somewhat surprisingly, the degree of INR elevation was not associated with worse outcome.[203]

An Outpatient Bleeding Risk Index was created and shown to be more accurate than physician judgment in classifying patients according to the risk of major bleeding.[18] The index was based on independent risk factors: age 65 years or older; history of cerebrovascular accident; history of gastrointestinal bleeding; and history of recent myocardial infarction, hematocrit less than 30%, serum creatinine greater than 1.5 mg/dL, or diabetes mellitus. The sum of the number of risk factors successfully predicted major bleeding at 48 months to be 3% in low-risk (zero risk factors), 12% in intermediate risk (one to two risk factors), and 53% in high-risk (three to four risk factors) patients. Because physicians are often unable to accurately estimate the probability of bleeding, use of the Outpatient Bleeding Risk Index seems appropriate to improve awareness and treatment of these high-risk patients and was validated in at least one subsequent study.[193]

In a study of 32 patients who developed life-threatening hemorrhage while on warfarin therapy, most patients had multiple risk factors including excessive anticoagulation.[197] The gastrointestinal tract was identified as the source of bleeding in 67% of the patients.[197] Sixty-six percent of patients were given vitamin K₁, 50% were given fresh-frozen plasma (FFP), and 7% were given both therapies.[197]

LABORATORY ASSESSMENT

Established screening tests are helpful for diagnosis. Four studies—PT (INR), PTT, thrombin time, and fibrinogen concentration—are usually adequate. Prothrombin time is calculated by adding standardized thromboplastin reagent (phospholipid and tissue factor) to a sample of the patient's citrated plasma (the citrate removes calcium to prevent clotting). Calcium is then introduced and the time to clotting measured. With the exception of factor X, the PT is unaffected by the presence or absence of factors VIII to XIII, platelets, prekallikrein, and HMWK. An individual's PT was formerly expressed as a ratio (PT observed to PT control). Because this ratio is directly affected by both laboratory methodology and the source of the thromboplastin reagent used, the generated results suffered from significant variability. Thus, a standard, the INR, was developed in an attempt to limit interlaboratory variability.[78,136] The INR is derived by raising the PT ratio to a power value known as the International Sensitivity Index (ISI): (PT ratio)^{ISI}. The ISI is a measure of responsiveness of the particular thromboplastin to warfarin. Although the use of the INR does not completely eliminate variability,[80,135] it does improve the potential for standardized interpretation and limits interinstitutional variations. It should be noted that in patients taking oral anticoagulants, specifically warfarin, the INR is extremely effective at monitoring the extent of anticoagulation. However, use of the INR measurement in the setting of fulminant hepatic failure, as in the recently developed Model for End-Stage Liver Disease (MELD) score, a tool to predict the need for liver transplantation, is unwarranted.[35] In these patients the INR is extremely variable and inaccurate as a consequence of the variability in thromboplastins.[154] This problem may be mitigated in the United States because of the use of recombinant human preparations of thromboplastin, which results in greater consistency.[36]

The partial thromboplastin time is measured by adding kaolin or celite to citrated plasma in order to activate the "contact" components of the intrinsic system. This mixture is then recalcified and the time to clotting observed. Some tests use phospholipids in the reagent to activate the remaining coagulation factors, thereby giving rise to the term *activated partial thromboplastin time* (aPTT). Because the PTT and aPTT are essentially interchangeable, the term PTT is used hereafter to represent the concept. The PTT is not affected by alterations in factors VII, XIII, or platelets.

The thrombin time, determined by adding exogenous thrombin to citrated plasma, evaluates the ability to convert fibrinogen to fibrin, and is thus unaffected by abnormalities of factors II, V, VII to XIII, platelets, prekallikrein, or HMWK. Finally, either a fibrinogen concentration or a determination of fibrin degradation products will help distinguish between problems with clot formation and consumptive coagulopathy (disseminated intravascular coagulation). An evaluation of the combination of normal and abnormal results of these tests usually determines a patient's clotting abnormality (Table 59–2).

Inhibitors can be diagnosed by "mixing studies," because only a small percentage of the coagulation factors present in normal plasma are necessary to have normal clotting studies. If the patient with an abnormal PT or PTT suffers from even a severe factor deficiency, restoration of that factor activity to 50% of normal will completely normalize the PT or PTT. Thus the presence of an abnormal PT or PTT that will not correct by incubation of the patient's plasma with an equal volume of normal plasma is diagnostic of an inhibitor of coagulation. Heparin-induced anticoagulation results in an elevated PTT that corrects when mixing studies are performed. More sophisticated studies can be used to identify specific coagulation-factor deficiencies. The reader is referred to one of several standard references for a more detailed discussion of the approach to patients with abnormal coagulation studies.[156]

TABLE 59–2. Evaluation of Abnormal Coagulation Times
PT normal, PTT prolonged, bleeding
Deficiencies of factors VIII, IX, XI
von Willebrand disease
PT normal, PTT prolonged, no bleeding
Deficiencies of factor XII, prekallikrein, high-molecular-weight kininogen inhibitor syndrome
PT prolonged, PTT normal
Deficiency of factor VII
Warfarin therapy (early)
Vitamin K deficiency (mild)
Liver disease (mild)
PT and PTT prolonged, thrombin time normal, fibrinogen normal
Deficiencies of factors II, V, IX; vitamin K deficiency (severe)
Warfarin therapy (late)
PT and PTT prolonged, thrombin time abnormal, fibrinogen normal
Heparin effect
Dysfibrinogenemia
PT and PTT prolonged, thrombin time abnormal, fibrinogen abnormal
Liver disease
Disseminated intravascular coagulation
Fibrinolytic therapy
Crotaline envenomation

PT, prothrombin time; PTT, partial thromboplastin time.

Although warfarin concentrations may be useful to confirm the diagnosis in unknown cases and to study drug kinetics,[72,138] the routine use of simple and inexpensive measures such as INR determination seems more appropriate.

■ LABORATORY EVALUATION OF LONG-ACTING ANTICOAGULANTS

For patients who have ingested long-acting anticoagulants and who are considered likely to develop a coagulopathy, baseline coagulation studies are not usually helpful, but they may provide information about chronic exposures. If the history is reliable and the patient is healthy, baseline studies can be avoided. A single INR at 48 hours should identify all patients at risk of coagulopathy.[171] Depending on the social situation, these studies can be obtained while the patient remains in the home setting.

In contrast, all patients with intentional ingestion of long-acting anticoagulants should be presumed to be at risk for a severe coagulopathy. In fact, most patients do not seek medical care until bruising or bleeding is evident.[11,32,33,38,56,82,95,100,133,181] These events often occur many days after ingestion, which obviates the need for gastric decontamination unless there is a suggestion of repetitive ingestion. These patients should be managed as described below.

For patients who have suspected long-acting anticoagulant overdose, daily or twice-daily INR evaluations for 2 days should be adequate to identify most patients at risk for coagulopathy. Early detection through coagulation factor analysis may be preferred,[72,82] however, and concentrations of long-acting anticoagulants can now be measured.[102,138]

GENERAL MANAGEMENT AND ANTIDOTAL TREATMENT

Gastrointestinal decontamination should be performed on patients who are believed to have potentially significant life-threatening ingestions unless they already present with significant bleeding. For patients who present after a few hours of ingestion, gastric emptying is not indicated (see Chap. 7). Although convincing data on the efficacy of either single- or multiple-dose activated charcoal (AC; possible enterohepatic circulation) are lacking, at least a single dose of AC should be administered unless it is contraindicated. Oral cholestyramine can also be used to enhance warfarin elimination,[151] but no studies are available that compare these two therapies or evaluate the role of combined activated charcoal and cholestyramine therapy. Although in animal models phenobarbital also enhances elimination, it is relatively contraindicated in humans because of the decreased ability to reliably monitor the mental status of a patient who has the possibility of spontaneous intracranial hemorrhage and subsequent increased risk of falling. In addition to general supportive measures, the patient should be placed in a supervised medical and psychiatric environment that offers protection against external or self-induced trauma, and permits observation for the onset of coagulopathy.

Blood transfusion is required for any patient with a history of blood loss or active bleeding who is hemodynamically unstable, has impaired oxygen transport, or is expected to become unstable. Although a transfusion of packed red blood cells is ideal for replacing lost blood, it cannot correct a coagulopathy, and thus patients will continue to bleed. Whole blood contains both the cellular elements the patient is losing and the necessary coagulation factors to reverse the coagulopathy. Transfusion of whole blood may be considered in severe cases because whole blood contains many components, including platelets, white blood cells, and non–vitamin-K-dependent factors. However, because whole blood contains only relatively small amounts of vitamin K–dependent factors, selective use of specific blood products is generally preferred. These products include packed red blood cells, FFP, cryoprecipitate, or other factor concentrates, such as factor IX complex (Konyne 80), recombinant factor VIIa (rFVIIa), and prothrombin complex concentrate.

Life-threatening hemorrhage secondary to oral anticoagulant toxicity should be immediately reversed with FFP, followed by vitamin K_1. FFP is rich in active vitamin K–dependent coagulation factors and will reverse oral anticoagulant-induced coagulopathy in most patients. In general, approximately 15 mL/kg of FFP should be adequate to reverse any coagulopathy.[47] However, the specific factor quantities and volume of each unit may be varied, leading to an unpredictable response.[117] A study comparing the efficacy of FFP and various clotting factor concentrates (prothrombin complex concentrate, factor VII concentrate, and Prothromplex T [factors II, VII, IX, and X]) in rapid reversal of anticoagulation, showed that despite significant reduction in the INR, FFP had an extremely varied effect on factor IX repletion. These clotting factor concentrates not only significantly decreased the INR, but completely corrected it, and factor IX replacement was much more consistent.[117] Additionally, multiple FFP transfusions may also be required because of the rapid degradation of coagulation factors in the absence of vitamin K. Administration of FFP to patients with intracerebral hemorrhage may also result in volume overload.[1] Prothrombin complex concentrates (PCCs) are likely to produce complete INR reversal faster than FFP and appear to be associated with fewer adverse effects.[50] One group in the United Kingdom reports success with its use for the reversal of oral anticoagulation.[92] Consequently, prothrombin complex concentrates may be preferable to FFP if readily available.

Preliminary data using rVIIa demonstrates it to be a useful pharmacologic therapy for bleeding secondary to warfarin-induced excessive anticoagulation.[51,126] There is also a single case report demonstrating efficacy at reversing severe bleeding caused by enoxaparin,[86] and a recent case series showing beneficial effects in four patients with superwarfarin toxicity.[204] Since a possible complication of its use may be thrombosis, further experience with rVIIa is necessary to determine its safety and efficacy in anticoagulant-induced hemorrhage. It should also be noted that if rVIIa is used, assays based on PT may be inaccurate and should be avoided when administering rVIIa.[96]

Several issues influence the decision to administer vitamin K_1 to a patient with a suspected overdose of a warfarinlike anticoagulant. Answers to the following questions should always be considered. Does the ingestion involve a warfarin-containing rodenticide or a pharmaceutical preparation? Is the ingestion unintentional or intentional? Does the patient require maintenance of therapeutic anticoagulation? Moreover, although vitamin K_1 administration is required to reverse the blockade of coagulation factor activation, it cannot be relied on for the patient with acute and consequential hemorrhage (see Antidotes in Depth A16: Vitamin K_1). Treatment with vitamin K_1 takes several hours to activate enough factors to reverse the patient's coagulopathy,[117,146] and this delay may be potentially fatal.

Repetitive, large doses of vitamin K_1 (on the order of 60 mg/d) may be required in some patients.[72,140] If complete reversal of INR prolongation occurs or is desirable (as in most cases of life-threatening bleeding), and the patient's underlying medical condition still requires some degree of anticoagulation, they can then receive anticoagulation with heparin once the bleeding is controlled and they are otherwise stable. Heparin anticoagulation was used without apparent bleeding complications in 25% of patients in one cross-sectional study.[197]

Vitamin K_1 is preferable over the other forms of vitamin K; the other forms are ineffective[90,133,139,183] and are potentially toxic.[10] (Vitamins K_3 [menadione] and K_4 [menadiol sodium diphosphate] can cause oxidative stress on neonatal erythrocytes and produce hemolysis, hyperbilirubinemia, and kernicterus.) Parenteral administration of vitamin K_1 (phytonadione) is traditionally preferred as initial therapy by many authors, but success can also be achieved with early oral therapy, especially when the coagulopathy is not severe.[32] In most cases, the patient can be switched to oral vitamin K_1 for long-term care. Vitamin K_1 can be administered intramuscularly, subcutaneously, intradermally, or intravenously. Although intravenous therapy has the most rapid onset of action of all routes of delivery, its use as the sole therapeutic agent is still associated with a delay of several hours[116,146] and carries the added risk of anaphylactoid reactions.[153] The use of low doses and slow rate of administration reduces this risk[168] (see Antidotes in Depth A16–Vitamin K_1). In cases where oral administration is undesirable, for example, with significant gastrointestinal hemorrhage, the subcutaneous route may be used, realizing that absorption may be erratic. Furthermore, if a patient is anticoagulated or overanticoagulated, administration of vitamin K_1 by the intramuscular route may result in a large hematoma. Caution should be exercised if this route of administration is chosen.

For patients with non–life-threatening hemorrhage, the clinician must consider whether anticoagulation is required for long-term care. In patients not requiring chronic anticoagulation, even small elevations of the INR may be treated with vitamin K_1 alone to prevent deterioration in coagulation status and reduce the risk of bleeding. Because in most cases of warfarin ingestion coagulopathy persists only for several days, there may be a rationale for prophylactic vitamin K_1 administration in known warfarinlike anticoagulant ingestions in patients not requiring anticoagulation. In contrast to ingestions of warfarin, prophylactic vitamin K_1 should never be given to asymptomatic patients

with unintentional ingestions of long-acting anticoagulants because (1) if the patient develops a coagulopathy, it will last for weeks, and the one or two doses of vitamin K_1 given will not prevent complications; (2) a gradual decline in coagulation factors occurs over the first day of anticoagulation, so no one would be expected to develop a life-threatening coagulopathy in 1 or 2 days; and (3) after vitamin K_1 is administered, the onset of an INR abnormality will be delayed, which could impair the clinician's ability to diagnose any coagulation abnormality, possibly requiring the patient to undergo an unnecessarily prolonged observation period.

For patients requiring chronic anticoagulation, the American College of Chest Physicians has issued guidelines for the management of patients with elevated INRs (Table 59–3). Moreover, the use of a regression formula may assist in calculating the amount of oral vitamin K_1 necessary to partially correct the INR, without completely discontinuing the oral anticoagulant. Although it remains unvalidated, it would be extremely useful prior to minor surgery or dental procedures in patients requiring chronic anticoagulation, while theoretically decreasing the likelihood of thromboembolism.[194] It should also be noted that low-dose vitamin K may be safely administered to patients with mildly elevated INRs (4 to 10) to decrease the INR more

TABLE 59–3. Recommendations for Management of Elevated INRs or Bleeding in Patients Receiving Vitamin K Antagonists[5]

INR	Recommendations[a]
<5.0; no significant bleeding	Lower dose or omit next dose of warfarin
>5.0 but <9.0; no significant bleeding	Omit warfarin for next one or two doses. Alternatively, omit next dose and give oral vitamin K_1 (1-2.5 mg) especially if at increased risk of bleeding. If more rapid reversal is necessary, give oral vitamin K_1 (≤5 mg) and wait 24 hours. Give additional vitamin K_1 orally (1-2 mg) as needed.
>9.0; no significant bleeding	Hold warfarin therapy and give a higher dose of oral vitamin K_1 (2.5-5 mg) and wait 24 hours. Give additional vitamin K_1 if necessary.
Serious bleeding at any INR concentration or life-threatening bleeding	Hold warfarin therapy and give FFP, PCC, or rVIIa[b] supplemented with vitamin K_1 (10 mg by slow parenteral[c] infusion). Vitamin K_1 administration may need to be repeated q12h.
Administration of vitamin K	Patients with mildly to moderately elevated INRs without bleeding should be given vitamin K orally rather than subcutaneously.

FFP, fresh-frozen plasma; INR, international normalized ratio; PCC, prothrombin complex concentrate; rVIIa, recombinant factor VIIa.

[a] If continued warfarin therapy is indicated after high doses of vitamin K_1, then anticoagulation with heparin or low-molecular-weight heparin can be concomitantly given. INR values greater than 4.5 are also less reliable than values at or near the therapeutic range.

[b] rVIIa may cause thrombosis and we do not advocate its routine use at this time.

[c] Although parenteral infusion of vitamin K_1 is recommended, we urge caution with this route of administration because there may not be an appreciable difference in onset of therapeutic effect and, although rare, it may cause severe anaphylactoid reactions.

rapidly; however, one study did not demonstrate decreased bleeding in the treatment group.[46] Furthermore, simply omitting warfarin doses may be adequate for the patient without active hemorrhage who has an INR between 4 and 9.[46]

It is often unclear why patients with consistent therapeutic dosing have seemingly random elevations in their INR. A recent case-control study identified the following risk factors associated with overcoagulation from vitamin K antagonists: previous medical history of increased INR levels, antibiotic therapy, fever and concomitant use of amiodarone and proton pump inhibitors.[34] Clinicians should pay particular attention to patients with these conditions and close monitoring of coagulation profiles should be performed.[34]

■ TREATMENT OF LONG-ACTING ANTICOAGULANT OVERDOSES

Treatment of a patient with a long-acting anticoagulant overdose is essentially the same as the treatment of oral anticoagulant toxicity with certain exceptions.

Long-acting anticoagulants are metabolized by the hepatic mixed-function oxidase system (cytochrome P450 [CYP]).[9,139] In a rat model, the duration of coagulopathy was shortened by administering phenobarbital, a CYP3A4 inducer.[9] Although a phenobarbital effect has never been systematically studied in humans, this approach was used by several authors in isolated human cases of long-acting anticoagulant toxicity.[33,90,110,182,192] Although these anecdotal reports suggest some improvement with phenobarbital therapy, the risks of producing sedation in a patient who might be prone to bleeding complications appear consequential.

Patients with long-acting anticoagulant overdose should be followed until their coagulation studies remain normal while off therapy for several days. This usually requires daily or even twice-daily INR measurements until the INR is at the lower limit of the therapeutic range. Monitoring of serial INR measurements should allow for a gradual decrease in vitamin K_1 requirement over time. Periodic coagulation factor analysis, however, may provide an early clue to the resolution of toxicity.[82] The patient may require weeks to months of close observation for both psychiatric and medical management. Emphasis has been placed on determining a critical superwarfarin concentration below which anticoagulation does not occur.[33] In one case report, brodifacoum was observed to follow zero-order elimination kinetics.[32] If this type of toxicokinetics is consistent in the analysis of other long-acting anticoagulants, these laboratory measurements may prove more reliable than the current empiric end points of therapy.

■ OTHER ORAL ANTICOAGULANTS

Because of the potential therapeutic limitations of warfarin (eg, dosing, risk of hemorrhage, narrow therapeutic window, etc) novel oral anticoagulants have been developed with directed activity against specific clotting factors. Ximelagatran was one of the first direct thrombin inhibitors that appeared to be as effective as warfarin in the treatment of stroke prevention, nonvalvular atrial fibrillation, and deep venous thrombosis, and was shown to be more effective than aspirin alone for patients who have had a recent myocardial infarction.[81] Ximelagatran had many advantages over warfarin, including rapidity of onset, fixed dosing, stable absorption, decreased risk of drug interactions, and lack of necessity for therapeutic monitoring.[81] However, because of its major side effect of heptatotoxicity, it has been removed from the world market by its manufacturer. Since then, new anticoagulants including factor Xa inhibitors (eg, rivaroxaban, apixaban) and direct thrombin inhibitors (eg, argatroban, dabigatran) are gaining in popularity for their therapeutic effects.[173] Argatroban binds noncovalently

to the active site of thrombin to function as a competitive inhibitor.[79] It is metabolized by CYP3A4/5 in the liver and is particularly useful in patients with renal impairment.[79] These medications show tremendous promise and may revolutionize the treatment of thromboembolic disease. Limited data are currently available regarding toxicity of these agents; however, overdose of argatroban was successfully treated with FFP in one recent case report.[201]

PARENTERAL ANTICOAGULANTS

■ HEPARIN

Conventional or unfractionated heparin is a heterogeneous group of molecules within the class of glycosaminoglycans.[89] The heparin precursor molecule is composed of long chains of mucopolysaccharides, a polypeptide, and carbohydrates. The main carbohydrate components of heparin molecules include uronic acids and amino sugars in polysaccharide chains. Heparin for pharmaceutical use is extracted from bovine lung tissue and porcine intestines.[163]

Heparin inhibits thrombosis by accelerating the binding of AT to thrombin (factor II) and other serine proteases involved in coagulation.[115,157] Thus, factors IX to XII, kallikrein, and thrombin are inhibited. Heparin also affects plasminogen activator inhibitor, protein C inhibitor, and other components of coagulation. Heparin's therapeutic effect is usually measured through the activated PTT. The activated blood coagulation time (ACT) may be more useful for monitoring large therapeutic doses or in the overdose situation.[103]

Low-molecular-weight heparins (LMWHs) are 4000- to 6000-dalton fractions obtained from conventional (unfractionated) heparin.[62] As such, they share many of the pharmacologic and toxicologic properties of conventional heparin.[26] The various LMWHs (eg, fraxiparine, enoxaparin, dalteparin) are prepared by different methods of depolymerization of heparin; consequently, they each differ to a certain extent regarding their pharmacokinetic properties and anticoagulant profiles. The major differences between LMWHs and conventional heparin are greater bioavailability, longer half-life, more predictable anticoagulation with fixed dosing, targeted activity against activated factor X, and less targeted activity against activated factor II.[26,62] As a result of this targeted factor X activity, LMWHs have minimal effect on the activated PTT, thereby eliminating either the need for, or the usefulness of, monitoring. They are therefore administered on a fixed-dose schedule. However, in certain instances (eg, patients with impaired renal function, pregnancy, etc), monitoring of anti–factor Xa activity may be performed to assess adequacy of anticoagulation and prevent risk of bleeding.[75] Controversy exists as to whether such testing is clinically necessary.[25]

LMWHs have been investigated for prevention of thromboembolic disease after hip surgery and trauma, in patients with stroke or deep venous thrombosis, in pregnancy, and in other conditions where anticoagulation with heparin would otherwise be indicated (eg, at the onset of oral anticoagulation therapy). Although these xenobiotics are presumed to have a minimal risk in pregnancy[124] because they do not cross the placenta,[60,177] they are not yet approved for treatment or prophylaxis of thromboembolic disease in pregnancy. Most studies demonstrate a lower incidence of embolization; however, there is still a trend toward increased bleeding.[17,70,109]

■ PHARMACOLOGY

Because of the large size of heparin and negative charge it is unable to cross cellular membranes. These factors prevent oral administration, and

heparin must be administered by either subcutaneous injection or continuous intravenous infusion. Following parenteral administration, heparin remains in the intravascular compartment, in part bound to globulins, fibrinogen, and low-density lipoproteins, resulting in a volume of distribution of 0.06 L/kg in humans.[55,141] Because of its rapid metabolism in the liver by a heparinase, heparin has a short duration of effect.[115] Although the half-life of elimination is dose dependent and ranges from 1 to 2.5 hours,[115,122,141] the duration of anticoagulant effect is usually reported as 1 to 3 hours.[115] Dosing errors or drug interactions with thrombolytic agents, antiplatelet drugs, or nonsteroidal antiinflammatory drugs may increase the risk of hemorrhage.[76] LMWHs are nearly 90% bioavailable following subcutaneous administration and have an elimination half-life of 3 to 6 hours.[79] Anti–factor Xa activity peaks between 3 and 5 hours after dosing.[79] LMWHs are renally eliminated and patients with severe renal insufficiency (creatinine clearance less than 30 mL/min) or end-stage renal disease are at increased risk of toxicity.[187]

■ CLINICAL MANIFESTATIONS

Intentional overdoses with heparin are rare.[120] Most reported cases involve unintentional poisoning in hospitalized patients.[65,67,120,144,162] These cases have involved the administration of large amounts of heparin as a consequence of misidentification of heparin vials, during the process of flushing intravenous lines, and secondary to intravenous pump malfunction. Significant bleeding complications occurred in several cases, including one fatality.[65]

Similar adverse effects to unfractionated heparins are also reported with LMWHs and include epidural/spinal hematoma, intrahepatic hemorrhage,[84] abdominal wall hematomas,[6] psoas hematoma after lumbar plexus block,[98] and intracranial hemorrhage in patients with malignancy in the brain.[52] These complications were all reported in patients who received the LMWH enoxaparin.

■ EVALUATION AND TREATMENT

After stabilization of the airway and breathing, and circulation are assured, the physician should be prepared to replace blood loss and reverse the coagulopathy, if indicated. Because of the relatively short duration of action of heparin, observation alone might be indicated if significant bleeding has not occurred. For the patient requiring anticoagulation, serial PTT determinations will indicate when it is safe to resume therapy. If significant bleeding occurs, either removal of the heparin or reversal of its anticoagulant effect is indicated. Because heparin has a very small volume of distribution, it can be effectively removed by exchange transfusion.[162] Although this technique has been used successfully in neonates, it is not generally applicable to older children and adults.

When severe bleeding occurs, heparin may be effectively neutralized by protamine sulfate.[3] Protamine is a low-molecular-weight protein found in the sperm and testes of salmon, which forms ionic bonds with heparin and renders it devoid of anticoagulant activity.[115] One milligram of protamine sulfate injected intravenously neutralizes 100 Units of heparin.[115] The dose of protamine should be calculated from the dose of heparin administered if known and assuming heparin's approximate half-life to be 60 to 90 minutes; the amount of protamine should not exceed the amount of heparin expected to be found intravascularly at the time of infusion. As with other foreign proteins, protamine administration is associated with numerous adverse effects such as hypotension, bradycardia, and allergic reactions. Because approximately 0.2% of patients receiving protamine experience anaphylaxis, a complication that carries a 30% mortality rate, most authors commonly recommend that protamine be reserved for patients with life-threatening hemorrhage (see Antidotes in Depth

A17–Protamine).[83] It should also be noted that excess protamine administration may result in paradoxical anticoagulation.

Because of the severe adverse effects associated with protamine, research has focused on safer methods to reverse heparin anticoagulation. These agents include heparinase,[125] synthetic protamine variants,[188,189] and platelet factor 4, but these therapies are not widely available.

If life-threatening bleeding occurs following LMWH administration, patients should be treated with protamine. In a case report of a 10-fold dosing error of enoxaparin, protamine effectively reversed the anticoagulant effects.[199] Current recommendations are to administer 1 mg protamine per 100 anti–factor Xa units where 1 mg enoxaparin equals 100 anti–factor Xa units if within 8 hours of the LMWH.[79] A second dose of 0.5 mg protamine should be administered per 100 anti–factor Xa units if bleeding continues.[79] If more than 8 hours has elapsed, then a smaller dose of protamine can be administered. The appropriate dosages for protamine are described in detail in the Antidotes in Depth A17: Protamine. The newer experimental protamine variants appear to be effective against LMWHs but are not yet available.[188,189] Interestingly, there is one case report of recombinant activated factor VII reversing the effects of LMWH in the setting of postoperative renal failure.[134]

NONBLEEDING COMPLICATIONS OF ANTICOAGULANTS

Warfarin therapy is associated with three nonhemorrhagic lesions of the skin: urticaria,[161] purple toe syndrome,[58] and warfarin skin necrosis.[44,99,104,123,186] Although warfarin skin necrosis was once thought to be a rare and idiosyncratic reaction,[99,104] more recent evidence suggests a link between this disorder and protein C deficiency.[104,186] Protein C activation is also dependent on vitamin K.[40] Patients who are homozygotes for protein C deficiency have an increased incidence of thrombosis and embolic events, such that they often require long-term anticoagulant therapy.[40] Because the half-life of protein C is shorter than that of many of the vitamin K–dependent coagulation factors, protein C concentrations fall rapidly during the first hours of warfarin therapy. In the protein C–deficient patient, protein C concentrations fall dramatically prior to a reduction in coagulation factors. This results in an imbalance that actually favors coagulation, and skin necrosis results due to microvascular thrombosis in dermal vessels.[123,186] Although warfarin skin necrosis is more common in patients with protein C deficiency, this disorder is also described in patients with protein S and AT deficiencies.[44] Unfortunately, these deficiencies are neither necessary nor sufficient to account for the incidence of warfarin necrosis.[44] If necrosis occurs, warfarin should be discontinued and heparin should be initiated to decrease thrombosis of postcapillary venules. Some patients may also require surgical débridement.[158] The purple toe syndrome, in contrast to warfarin-induced skin necrosis, is presumed to result from small atheroemboli that are no longer adherent to their plaques by clot (see Fig. 29–7).

An additional major nonhemorrhagic complication of warfarin therapy relates to its use in pregnant women. Most warfarin-induced fetal abnormalities occur during weeks 6 to 12 of gestation, but central nervous system (CNS) and ocular abnormalities can develop at any time during gestation (see Chap. 30 for further details).[74,175]

Heparin therapy is associated with a transient and mild thrombocytopenia called heparin-induced thrombocytopenia (HIT) that occurs in approximately 25% of patients during the first few days of therapy.[191] Although this syndrome results from heparin-induced platelet aggregation, a more severe form of thrombocytopenia, heparin-induced thrombocytopenia and thrombosis syndrome (HITT; formerly known

as HIT-2 or the white clot syndrome), occurs in 1% to 5% of patients between days 7 and 14 of therapy.[116] In patients who were previously treated with heparin, these events can occur earlier than 7 days. Heparin stimulates platelets to release platelet factor 4, which subsequently complexes with heparin to provoke an IgG response. These antibodies against the heparin–platelet factor 4 complex activate platelets, which may lead to platelet–fibrin thrombotic events.[7,202] Patients may present with either hemorrhagic or thromboembolic complications. LMWH may also be associated with thrombocytopenia (isolated HIT), and less frequently with HITT.[190] Consequently, once HITT occurs, LMWH is contraindicated.[190] Treatment of HIT includes discontinuation of heparin or LMWH and immediate use of alternative anticoagulant such as danaparoid, lepirudine, or argatroban.[37] (Danaparoid is currently unavailable in the United States.[79]) In addition to HIT and HITT, necrotizing skin lesions[149] and hyperkalemia from aldosterone suppression[142] also rarely occur in patients receiving heparin therapy. These patients should not receive heparin or LMWH again, not even in low doses to keep veins open.

Some additional complications of heparin use include osteoporosis, which mostly occurs in patients on long-term therapy with unfractionated heparin.[85] A small percentage of these patients may develop bone fractures if treated continuously for more than 3 months. Data for LMWHs are limited and the incidence of osteoporosis may be less compared with unfractionated heparin.[85] In 2008, an outbreak of adverse events was linked to heparin contaminated with oversulfated chondroitin sulfate.[111] The contaminated heparin, which was found in at least 10 countries, originated in China.[22] Many patients developed anaphylactoid-type reactions with at least 100 reported deaths.[111]

■ HIRUDIN

Hirudin, a 65-amino-acid polypeptide produced by the salivary glands of the medicinal leech (*Hirudo medicinalis*), irreversibly blocks thrombin without the need for AT.[164] Unlike heparin, the small size of hirudin allows it to enter clots and inhibit clot-bound thrombin, offering the distinct advantage of restricting further thrombus formation. Hirudin demonstrates enhanced bioavailability and a longer half-life than unfractionated heparin. In addition, there are no known natural inhibitors of hirudin, such as platelet factor 4. Desirudin is a recombinant hirudin that is used in acute coronary syndrome, in the prevention of thromboembolic disease, and in patients with heparin-induced thrombocytopenia.[21,160,164] Both of these xenobiotics appear to be at least as effective as unfractionated heparin, and without increased bleeding or thrombocytopenia. However, in the Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) IIb study of patients with unstable angina/non–Q wave myocardial infarction, there was an increase in the number of blood transfusions in patients who received desirudin as compared with those who received heparin.[4]

FIBRINOLYTICS

■ THROMBOLYTICS

The fibrinolytic system is designed to remove unwanted clots, while leaving those clots protecting sites of vascular injury intact. Plasminogen exists as a proenzyme and is converted to the active form, plasmin, by various plasminogen activators.[42,43] t-PA is released from the endothelium and is under the inhibitory control of two inactivators known as tissue plasminogen activator inhibitors 1 and 2 (t-PAI-1 and t-PAI-2).[42,43,116,129] Plasmin's actions are nonspecific in that it degrades not only fibrin clots but also some plasma proteins and coagulation factors.[116] Inhibition of plasmin occurs through α_2-antiplasmin.

With their diverse indications in acute myocardial infarction, unstable angina, arterial and venous thrombosis and embolism, and cerebrovascular disease, the thrombolytic agents (streptokinase, urokinase, alteplase, and anistreplase) are commonly used.[14] The reader is referred to a number of reviews for specific indications and dosing regimens.[45,105,116,148,170,196] Although all xenobiotics enhance fibrinolysis, they differ in their specific sites of action and durations of effect. t-PA is specific for clot (it does not increase fibrinolysis in the absence of a thrombus), whereas streptokinase, urokinase, and anistreplase are not clot specific. t-PA has the shortest half-life and duration of effect (5 minutes and 2 hours, respectively), and anistreplase the longest (90 minutes and 18 hours, respectively).[148,170] Streptokinase has the additional risk of severe allergic reaction on rechallenge, limiting its use to once in a lifetime.

Newer thrombolytic drugs such a reteplase, and some non–commercially available agents, including monteplase, lanoteplase, pamiteplase, and desmoteplase, are being evaluated for therapeutic use.[112] These fibrinolytics have a longer half-life and may be administered via single or repeated bolus injections. They also have increased fibrin selectivity, but no improvement in mortality is demonstrated when compared to t-PA.[91] Although the incidence of bleeding requiring transfusion may be as high as 7.7% following high-dose (150 mg) t-PA and 4.4% following low-dose t-PA,[45] the incidence of intracranial hemorrhage with t-PA appears to be similar to the newer agents (monteplase, tenecteplase, reteplase, and lanoteplase).[185] The addition of heparin to the thrombolytic regimen increases the risk of bleeding. Reviews of multiple trials suggest that life-threatening events such as intracranial hemorrhage occur in 0.30% to 0.58% of patients receiving anistreplase, 0.42% to 0.73% of patients receiving alteplase, and 0.08% to 0.30% of patients receiving streptokinase.[196] Regardless of the thrombolytic agent used the frequency of bleeding events is similar even with the newer agents, with the exception that lanoteplase may have a decreased incidence of significant bleeding.[49] Supportive care is indicated for patients with minor bleeding complications; however, for patients with significant bleeding, fibrinogen and coagulation factor replacement with cryoprecipitate and FFP should be administered.[159]

■ SNAKE VENOMS

A detailed discussion of snake envenomations is found in Chap. 121; only a few specific issues are discussed here. Snake venoms may be composed of a vast number of complex proteins and peptides that interact with components of the human hemostatic system. In general, their functions may be thought of as being procoagulant, anticoagulant, fibrinolytic, vessel wall interactive, platelet active, or as protein inactivators. Additionally, they may more specifically also be classified based on their specific biologic activity; some of the various mechanisms include individual factor activation, inhibition of protein C and thrombin, fibrinogen degradation, platelet aggregation, and inhibition of serine protease inhibitors (SERPINS). Currently, there are more than 100 different snake venoms that affect the hemostatic system[87,88]; Fig. 59–2 is an overview of their multiple interactions with the coagulation and fibrinolytic systems.[119]

Some of these venom proteins are being used as therapeutic agents for human diseases. Ancrod, a purified derivative of the Malayan pit viper, *Calloselasma rhodostoma* (formerly known as *Agkistrodon rhodostoma*), is therapeutically used because of its defibrinogenating property.[13] The mechanism of action of ancrod and other similar agents is to link fibrinogen end to end and subsequently prevent cross-linking. It has been investigated in the treatment of deep vein thrombosis, myocardial infarction, pulmonary embolus, acute cerebrovascular thrombosis, HIT, and warfarin-related vascular complications. In a multicenter study of 500 patients with acute or

progressing ischemic neurologic events, ancrod showed a favorable benefit-to-risk ratio compared with placebo.[167] As expected, an increased risk of hemorrhage is observed; however, the risk appears to be less than that with thrombolytic agents.[167] Monitoring of fibrinogen levels is essential to avoid potential complications, as no specific antidote exists. For envenomation of other snake venoms (such as from the Crotalinae family) that induce hemorrhage, antivenin treatment may be required.

■ PENTASACCHARIDES

Pentasaccharides are recently developed synthetic anticoagulants that possess activity exclusively against factor Xa and are used for the prevention and treatment of venous thromboembolic disorders. Although other agents are currently being studied, fondaparinux is the only pentasaccharide currently available for clinical use.[108] The pentasaccharides have long half-lives and have no reliable antidote if bleeding occurs; they do not bind to protamine.[79] They are also contraindicated in patients with renal failure (CrCl less than 30 mL/min).[79] No controlled trials are available yet, but rVIIa may be effective, as demonstrated in one study of healthy volunteers.[19]

■ ANTICOAGULANT APTAMERS

Aptamer anticoagulants are small nucleic acid molecules that are currently under development to target specific blood coagulation proteins.[137] They are direct protein inhibitors and function similarly to monoclonal antibodies.[137] Specific aptamers that are currently being studied include the anti–factor IX aptamer, the anti–activated protein C aptamer, and the anti–factor VIIa aptamer.[68] These xenobiotics may have clinical utility in the future as their anticoagulant effects appear to be easier to control, and consequently safer, compared with the anticoagulants currently most used.

SUMMARY

The ever-increasing frequency of anticoagulant therapeutic use is associated with complications and adverse outcomes. A complete understanding of the normal mechanisms of coagulation, anticoagulation, and thrombolysis, combined with an understanding of the pharmacology of the agent and the patient's clinical needs, will allow the clinician to better choose among the complex therapies currently available. Supportive care is often adequate for certain complications associated with these therapies; however, occasionally, more aggressive interventions and specific antidotes are necessary depending on the particular agent and medical condition of the patient.

ANTIDOTES IN DEPTH (A16)

VITAMIN K₁

Mary Ann Howland
Vitamin K₁ (phytonadione) is the commercial preparation of the natural form of vitamin K (phylloquinone) that is indicated for the reversal of elevated prothrombin times (PTs) and international normalized ratios (INRs) in patients with xenobiotic-induced vitamin K deficiency. Acquired vitamin K deficiency is typically induced following the therapeutic administration of warfarin, or following the overdose of warfarin or the long-acting anticoagulant rodenticides (LAARs), such as brodifacoum. The optimal dosage regimen of vitamin K₁ to treat patients who develop an elevated INR while receiving warfarin has been reviewed and a revised guideline regarding the dose and route of administration published.[1,7] Oral administration of vitamin K₁ is used safely and successfully. Because intravenous administration of vitamin K₁ may be associated with anaphylactoid reactions, it should be avoided unless serious or life-threatening bleeding is present. Subcutaneous administration should only be considered when a patient is unable to tolerate oral vitamin K therapy yet is not clinically compromised enough to necessitate intravenous vitamin K₁.[7]

HISTORY

It was noted in 1929 that chickens fed a poor diet developed spontaneous bleeding. In 1935, Dam and coworkers discovered that incorporating a fat-soluble substance defined as a "koagulation factor," into the diet could correct the bleeding. Hence the name vitamin K was developed.[20,30,35]

CHEMISTRY

Vitamin K is an essential fat-soluble vitamin encompassing at least two distinct natural forms. Vitamin K₁ (phytonadione, phylloquinone) is the only form synthesized by plants and algae. Vitamin K₂ (menaquinones) is actually a series of compounds with the same 2-methyl-1, 4-naphthoquinone ring structure as phylloquinone, but with a variable number (1-13) of repeating 5-carbon units on the side chain. Bacteria synthesize vitamin K₂ (menaquinones). Most of the vitamin K ingested in the diet is phylloquinone (vitamin K₁).

DAILY REQUIREMENT

The human daily requirement for vitamin K is small; the Food and Nutrition Board set the recommended daily allowance at 1 µg/kg/d of phylloquinone for adults, although 10 times that amount is required for infants to maintain normal hemostasis.[29] Extrahepatic enzymatic reactions that are vitamin K dependent relate to carboxylation of proteins in the bone, kidney, placenta, lung, pancreas, and spleen, and include the synthesis of osteocalcin, matrix Gla protein, plaque Gla protein, and one or more renal Gla proteins.[29,30,34] Variations in an individual's dietary vitamin K intake while receiving therapeutic oral anticoagulation can significantly result in either over- or under-anticoagulation.[1,13]

PHARMACOKINETICS OF DIETARY VITAMIN K

Dietary vitamin K in the forms of phylloquinone and menaquinones is solubilized in the presence of the bile salts, free fatty acids, and monoglycerides, which enhance absorption. Vitamin K is incorporated into chylomicrons, entering the circulation through the lymphatic system in transit to the liver.[30] In the plasma, vitamin K is primarily in the phylloquinone form, whereas liver stores are 90% menaquinones and 10% phylloquinone.[30] Within 3 days of a low vitamin K diet, a group of surgical patients showed a fourfold decrease of liver vitamin K concentrations.[33] Rats given a vitamin K—deficient diet develop severe bleeding within 2 to 3 weeks.

PHARMACOLOGY

Activation of coagulation factors II, VII, IX, and X, and proteins S and C and Z require γ-carboxylation of the glutamate residues in a vitamin K—dependent process. Only the reduced (K_1H_2, hydroquinone) form of vitamin K manifests biologic activity. During the carboxylation step, the active reduced vitamin K₁ is converted to an epoxide. This 2,3-epoxide is reduced and recycled to the active K_1H_2 in a process that is inhibited by warfarin (Fig. 59-3). For further details, the reader is referred to an in-depth model of the chemical basis of this reaction.[9,39] The phytonadione form of vitamin K can be activated to the reduced, vitamin K_1H_2 form directly by nicotinamide adenine dinucleotide (phosphate) (NAD(P)H)-dehydrogenase (DT-diaphorase)—dependent pathway that is relatively insensitive to warfarin, while the vitamin K 2,3-epoxide form cannot be activated through this pathway.[30,34,35,36]

VITAMIN K DEFICIENCY AND MONITORING

Vitamin K deficiency can result from inadequate intake, malabsorption, or interference with the vitamin K cycle. Malnourishment and any condition in which bile salts or fatty acids are inadequate, such as extrahepatic cholestasis or severe pancreatic insufficiency, can lead to vitamin K deficiency. Additionally, multifactorial etiologies place newborns at risk for hemorrhage. Phylloquinone does not readily cross the placenta, and breast milk contains less phylloquinone than vitamin K—fortified formula. Fetal hepatic stores of phylloquinone

are low and therapy such as maternal anticonvulsant therapy may lead to increased vitamin K metabolism.[30,34] Although menaquinones are produced in the colon by bacteria, it is unlikely that enteric production contributes significantly to vitamin K stores or that eradication of the bacteria with antibiotics, without a coexistent dietary deficiency of vitamin K, results in deficiency.[30] Determination of vitamin K deficiency is usually established on the basis of a prolonged PT or INR, which are surrogate markers of specific coagulation factors. Measurement of the vitamin K—dependent factors, II, VII, IX, and X, appears to be an effective way to determine the adequacy of vitamin K$_1$ dosing.[16] Serial measurements of factor VII, the factor with the shortest half-life, allows for the early detection of inadequate vitamin K in the diet or a therapeutic regimen.[6] Direct measurement of serum vitamin K concentrations is done by high-performance liquid chromatography (HPLC) analysis. The human serum vitamin K concentration required for adequate production of activated clotting factors in the presence of LAARs is still unclear. A single study in a patient who overdosed on brodifacoum suggested that a serum vitamin K concentration of 0.2 to 0.4 µg/mL was sufficient, to achieve a normal coagulation profile. Prior studies suggested 1.0 µg/mL was necessary in rabbits.[6,25]

MECHANISM OF ACTION FOR XENOBIOTIC-INDUCED VITAMIN K DEFICIENCY

Oral anticoagulants are vitamin K antagonists that interfere with the vitamin K cycle, causing the accumulation of vitamin K 2,3-epoxide, an inactive metabolite. Warfarin is a strong irreversible inhibitor of the vitamin K 2,3 epoxide reductase, which regenerates vitamin K into its active (K$_1$H$_2$, hydroquinone) form.[3] The superwarfarins are even more potent vitamin K reductase inhibitors. Without exogenous interference, vitamin K is recycled and only 1 µg/kg/d is required in adults to maintain adequate coagulation. NAD(P)H-dehydrogenases (DT-diaphorases) are warfarin-insensitive enzymes capable of reducing vitamin K$_1$ to its active hydroquinone form, but it is incapable of regenerating vitamin K from vitamin K 2,3-epoxide following carboxylation of the coagulation factor (Fig. 59-3).[3] Thus, in the presence of warfarin or superwarfarin, additional vitamin K$_1$ must be administered to supply this active cofactor for each and every carboxylation step, as it can no longer be recycled.[6] The minimum vitamin K$_1$ requirement in the presence of a LAAR is unknown. Other compounds have varying degrees of vitamin K antagonistic activity and include the *N*-methyl-thiotetrazole side-chain-containing antibiotics such as moxalactam and cefamandole (Chap. 56), as well as salicylates (Chap. 35).[30]

AVAILABILITY OF DIFFERENT FORMS OF VITAMIN K

Vitamin K$_1$ (phytonadione) is the only vitamin K preparation that should be used to reverse anticoagulant-induced vitamin K deficiency or to treat infants or pregnant women. In addition, patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency have an increased risk of hemolysis with other vitamin K preparations. Vitamin K$_1$ is superior to the other previously commercially available vitamin K preparations because it is more active, thus requiring comparatively smaller doses, because it works more rapidly (6 vs. 12 hours), and because it has fewer associated risks.[14,32]

Vitamins K$_3$ (menadione) and K$_4$ (menadiol sodium diphosphate) (no longer FDA approved in the US) can produce hemolysis, hyperbilirubinemia, and kernicterus in neonates, and hemolysis in G6PD-deficient patients. The only advantage that menadione and menadiol sodium diphosphate have is that these preparations are absorbed directly from the intestine by a passive process that does not require the presence of bile salts. Theoretically, they are advantageous for patients with cholestasis or severe pancreatic insufficiency. However, they are neither interchangeable with vitamin K$_1$, nor a substitute for vitamin K$_1$, when anticoagulants such as warfarin or LAAR are responsible for coagulation deficits. Therefore, for a patient deficient in bile salts who requires vitamin K$_1$, exogenous bile salts, such as ox bile extract 300 mg or dehydrocholic acid 500 mg, should be given with each dose of oral vitamin K$_1$.[26]

PHARMACOKINETICS AND PHARMACODYNAMICS OF ADMINISTERED VITAMIN K$_1$

There are only a limited number of pharmacokinetic studies of vitamin K$_1$.[6,15,25,40] One study evaluated the pharmacokinetics of vitamin K$_1$ in healthy volunteers, brodifacoum-anticoagulated rabbits, and a patient poisoned with brodifacoum.[25] In the volunteers and the poisoned patient, a 10-mg intravenous (IV) dose of vitamin K$_1$ had a half-life of 1.7 hours. After oral administration of doses of 10 and 50 mg of vitamin K$_1$, peak concentrations of 100 to 400 ng/mL and 200 to 2000 ng/mL, respectively, occurred at 3 to 5 hours. Bioavailability varied significantly between patients (10% to 65%) for both doses, and in individual patients with the 50-mg dose. Oral vitamin K$_1$ is absorbed in an energy-dependent saturable process in the proximal small intestine, and this likely contributes to the variability.[25] In maximally brodifacoum-anticoagulated rabbits, IV vitamin K$_1$ (10 mg/kg) increased prothrombin complex activity (PCA) from 14% to 50% by 4 hours, and to 100% by 9 hours, after which it declined with a half-life of 6 hours.[25] High doses of oral vitamin K$_1$ were effectively used to treat a patient anticoagulated with brodifacoum.[6]

The pharmacokinetics of oral and intramuscular (IM) vitamin K$_1$ were compared in eight healthy female volunteers. Baseline serum vitamin K concentrations were 0.23 ng/mL. Following the oral administration of 5 mg of vitamin K, peak serum concentrations of 90 ng/mL were achieved between 4 and 6 hours. These concentrations dropped to a steady state of 3.8 ng/mL, and exhibited a half-life of about 4 hours.

The pharmacokinetics were distinctly different and quite variable after IM administration. IM administration of 5 mg of vitamin K resulted in peak serum concentrations of only 50 ng/mL with delays from 2 to 30 hours following administration and with the maintenance of a plateau for about 30 hours.[15] Consequently, IM administration is not recommended; either oral or IV is more appropriate and the route will be defined by the severity of bleeding. Only in the case of acute gastrointestinal disease in a patient without life-threatening over-anticoagulation is the subcutaneous route an appropriate alternative to the oral route (see Table 59-3).

ROUTES OF ADMINISTRATION AND ADVERSE EFFECTS

Although vitamin K$_1$ can be administered orally, subcutaneously, intramuscularly, or intravenously, the oral route is preferred for maintenance therapy. When administered orally, vitamin K$_1$ is virtually free of adverse effects, except for overcorrection of the INR for a patient who requires maintenance anticoagulation. The preparations available for IV administration are rarely associated with anaphylactoid reactions. Because of the lipid solubility of vitamin K these preparations are not available in solution, but rather as an aqueous colloidal

suspension of a polyoxyethylated fatty acid derivative, dextrose, and benzyl alcohol. IV administration has resulted in death secondary to anaphylactoid reactions, probably as a result of the colloidal formulation of the preparation.[4,8,21] Numerous anaphylactoid reactions are reported, even when the preparation is properly diluted and administered slowly.[12,24,38] Rarely non-IV routes of administration may also result in an anaphylactoid reaction.[12] New liposomal preparations are under development, which may become safer alternatives.

ONSET OF EFFECT

The time necessary for the INR to return to a safe or normal range is variable and dependent on the rate of absorption of vitamin K_1, the serum concentration achieved, and the time necessary for the synthesis of activated clotting factors. A decrease in the INR can often occur within several hours, although it may take 8 to 24 hours to reach target values.[5,11,22,27] Maintenance of a normal INR depends on the half-life of the vitamin K_1, maintenance of an effective serum concentration, and the half-life of the anticoagulant involved. The IV route is unpredictably faster than the oral route in restoring the INR to a safe range.[15,19] A comparison of oral versus IV vitamin K_1 therapy for excessive anticoagulation, without major bleeding, demonstrated that individuals with INRs of 6 to 10 had similarly improved INRs at 24 hours and that the IV group was more often overcorrected to an INR of less than two.[19]

DOSING AND ADMINISTRATION

The optimal dosage regimen for vitamin K_1 remains unclear. Variables include the vitamin K_1 pharmacokinetics and the amount and type of anticoagulant ingested.[28] Reported cases of LAAR poisoning have required as much as 50 to 250 mg of vitamin K_1 daily for weeks to months.[2,6,10,17,18,31,37] A reasonable starting approach for a patient who has overdosed on LAAR is 25 to 50 mg of vitamin K_1 orally three to four times a day for 1 to 2 days. The INR should be monitored and the vitamin K_1 dose adjusted accordingly. Once the INR is less than 2, a downward titration in the dose of vitamin K_1 can be made on the basis of factor VII analysis. For an ingestion of brodifacoum, serial serum concentrations of brodifacoum may be helpful in determining the ultimate duration of treatment.[6,23]

The management of patients with elevated INRs secondary to excessive warfarin is described in Table 59-3. IV administration of vitamin K_1 should be reserved for life-threatening bleeding and serious bleeding at any elevation of INR.[1] Under these circumstances, patients may be supplemented with prothrombin complex concentrate, fresh-frozen plasma (FFP), or recombinant factor VIIa based on a risk to benefit analysis. A starting dose of 10 mg of vitamin K_1 is recommended. To minimize the risk of an anaphylactoid reaction, the preparation should be diluted with preservative-free 5% dextrose, 0.9% sodium chloride, or 5% dextrose in 0.9% sodium chloride, and administered slowly, at a rate not to exceed 1 mg/min in adults. Precautions should be anticipated in the event of an anaphylactoid reaction.

Because the duration of action of vitamin K_1 is short-lived, the dose must be repeated two to four times daily. The onset of the effect of vitamin K_1 is not immediate, regardless of the route of administration.

AVAILABILITY

Vitmain K_1 is available for IV and subcutaneous administration as AquaMEPHYTON and phytonadione injection emulsion in 2 mg/mL and 10 mg/mL concentrations. The preparation should be diluted with preservative-free 5% dextrose, 0.9% sodium chloride, or 5% dextrose in 0.9% sodium chloride, and administered slowly, at a rate not to exceed 1 mg/min in adults to minimize the risk of an anaphylactoid reaction. These preparations contain benzyl alcohol (0.9%) as a preservative. Oral vitamin K_1 is available as Mephyton in 5 mg tablets.

SUMMARY

Vitamin K_1 (phytonadione) is indicated for the reversal of elevated prothrombin times (PTs) and international normalized ratios (INRs) in patients with xenobiotic-induced vitamin K deficiency. IV administration is reserved for patients with serious or life-threatening bleeding. Vitamin K_1 is administered with other therapies such as prothrombin complex, recombinant factor VIIa, and FFP that have rapid onsets of action. The onset of action of vitamin K_1 is delayed for several hours regardless of the route of administration. The parenteral route of administration is rarely associated with consequential adverse events.

ANTIDOTES IN DEPTH (A17)

PROTAMINE

Mary Ann Howland

Protamine is a rapidly acting antidote that is used primarily to reverse the anticoagulant effects of unfractionated heparin (UFH). It also can partially reverse the effects of low-molecular-weight heparin (LMWH).

HISTORY

The antidotal property of protamine was recognized in the late 1930s, leading to its approval as an antidote for heparin overdose in 1968.[57] However, the largest body of literature pertaining to protamine originates from its use in neutralizing heparin following cardiopulmonary bypass and dialysis procedures.

PHARMACOLOGY

The protamines are a group of simple basic cationic proteins found in fish sperm that bind to heparin to form a stable neutral salt, rapidly inactivating heparin and reversing its anticoagulant effect.[62] Commercially available protamine sulfate is derived from the sperm of mature testes of salmon and related species. On hydrolysis, it yields basic amino acids, particularly arginine, proline, serine, and valine, but not tyrosine and tryptophan. The effects of protamine sulfate and protamine chloride appear to be comparable.[43] The molecular weight of heparins ranges from 3000 to 30,000 daltons and is composed of approximately 45 monosaccharide chains. One milligram of protamine will neutralize approximately 100 U (1 mg) of standard UFH (mean molecular weight [MW]~12,000 daltons).

In contrast to the case of heparin there is no proven method for neutralizing LMWH. Protamine neutralizes the anti-IIa activity of LMWH and a variable portion of the anti-Xa activity of LMWH.[28] Because the interaction of protamine and heparin is dependent on the MW of heparin, LMWH (mean MW 4500 daltons) has reduced protamine binding. The protamine-resistant fraction in LMWH is an ultralow-molecular-weight fraction with low sulfide charge.[15] It is suggested that 1 mg of enoxaparin equals approximately 100 antifactor-Xa units. To reverse the antithrombotic effects of LMWH within the first 8 hours following administration, the recommendation is to administer 1 mg protamine per 100 antifactor-Xa units of LMWH followed by administration of a second dose of 0.5 mg protamine per 100 anti factor-Xa units if bleeding continues.[28]

No human studies offer convincing evidence either demonstrating or disputing a beneficial effect of protamine as treatment for hemorrhage following LMWH use.[28] Case studies demonstrating both failure and success exist.[10,50,52,80] In animal studies, synthetic protamine variants were effective in reversing the anticoagulant effects of LMWH and are reported to be less toxic than protamine. These xenobiotics are not available for clinical use.[5,28,33,71,72]

■ MECHANISM OF ACTION

Heparins are large electronegative xenobiotics that are rapidly complexed by the electropositive protamine, forming an inactive salt. Heparin is an indirect anticoagulant, requiring a cofactor. This cofactor, AT, was formerly called antithrombin III.[28] Heparin alters the stereochemistry of AT, thereby catalyzing the subsequent inactivation of thrombin and other clotting factors.[24] Only about one-third of an administered dose of unfractionated heparin binds to AT, and this fraction is responsible for most of its anticoagulant effect.[3,45] LMWH has a reduced ability to inactivate thrombin as a result of lesser AT binding, but the smaller fragments of LMWH inactivate factor Xa almost as well as the larger molecules of UFH, allowing for equal efficacy.[28] Immunoelectrophoretic studies demonstrate that because of the net positive charge of protamine it has a greater affinity for heparin than AT, producing a dissociation of the heparin–AT complex in favor of a protamine–heparin complex.[59]

ADVERSE EFFECTS, RISK FACTORS, AND SAFETY ISSUES

Protamine is routinely used in the neutralization of heparin at the completion of cardiopulmonary bypass surgery. Millions of patients are exposed to protamine each year and approximately 100 deaths are reported in total with the use of protamine under these circumstances. It is largely in this setting that the adverse effects of protamine are also documented and studied.[30,31,49,58] It is often difficult to separate the adverse effects caused by protamine from those of the protamine–heparin complex or those actually related to heparin. Adverse effects associated with protamine include both rate- and non–rate-related hypotension,[12,18-21,23,35,38,65,68] anaphylaxsis[34,48] and anaphylactoid reactions,[37,53,55] bradycardia,[1] thrombocytopenia,[76] thrombogenicity,[14] leukopenia, decreased oxygen consumption,[73,75] acute lung injury,[4,70] pulmonary hypertension and pulmonary vasoconstriction,[7,27] cardiovascular collapse,[46,63] and anticoagulant effects.[2]

The mechanisms for these adverse effects are multifactorial. The significant electropositivity of protamine may be responsible for some of the adverse effects and probably directly injures a variety of organelles, including platelets.[9,77] The protamine–heparin complex activates the arachidonic acid pathway and the production of thromboxane is at least partly responsible for some of the hemodynamic changes, including pulmonary hypertension.[7,13,29,54,77] Pretreatment with indomethacin limits these effects.[13,29,54,77] Free protamine or protamine complexed with heparin can convert L-arginine to nitric oxide (formerly called endothelium-derived relaxing factor), which in turn causes vasodilation and inhibits platelet aggregation and adhesion.[60] Protamine administered in the absence of heparin, or in an amount exceeding that necessary for heparin neutralization, can act as an anticoagulant and may inhibit platelet function, resulting in weaker clot formation.[36,73] This anticoagulant effect may result from effects on factor VII and/or AT. Protamine in excess of heparin can enter the myocardium and decrease cyclic adenosine monophosphate (cAMP), causing myocardial depression.[7,67] Protamine and protamine–heparin complexes can activate the complement pathway and contribute to vasoactive

events.[7,61] Protamine stimulates mast cells in the human heart and skin to release histamine.[7] Risk factors for protamine-induced adverse reactions include prior exposure to protamine in insulin or during previous surgery with protamine reversal or a previous vasectomy, as well as an allergy to fish or a rapid rate of protamine infusion.[46,61] A prospective study reported a 0.06% incidence of anaphylactic reactions to protamine in all patients undergoing coronary artery bypass, but a 2% incidence in diabetics using neutral protamine Hagedorn (NPH) insulin.[6] A recent systematic review of the literature revealed an incidence of 1% but expressed caution in interpreting the results because of the heterogeneity of the studies.[58] The resultant elevation of histamine concentrations, the activation of complement, and elevated IgE, IgA, and IgG concentrations are also suggested as possible mechanisms for the adverse effects.[44,69,78,79] Diabetic patients receiving daily subcutaneous injections of a protamine-containing insulin (NPH) have a 40% to 50% increased risk of immune-mediated adverse reactions.[22,25,34,42,68]

Occasionally, patients manifesting a protamine allergy are incorrectly presumed to have insulin allergy.[41] In diabetic patients receiving protamine insulin injections, the presence of serum antiprotamine IgE antibody is a significant risk factor for acute protamine reactions. Only patients with previous exposure to protamine insulin injections had serum antiprotamine IgE antibodies. However, in the group without previous protamine insulin exposure, antiprotamine IgG antibody was noted as a risk factor for protamine reactions.[79] Either naturally occurring cross-reacting antibodies, or perhaps previously unrecognized protamine exposure, was responsible for the generation of these IgG antibodies.

ALTERNATIVES TO PROTAMINE FOR PATIENTS AT HIGH RISK FOR AN ADVERSE DRUG REACTION

There are limited options to replace protamine for the reversal of heparin in patients who have previously experienced anaphylaxis following protamine therapy, or in patients who are suspected of being at high risk. Clotting factors may be replaced, or exchange transfusion instituted in neonates, and protamine avoided, or protamine may be used while being prepared to treat anaphylaxis expectantly. Several alternatives under investigation include the placement of heparin removal devices in the coronary artery bypass extracorporeal circuit, as well as the use of hexadimethrine, methylene blue, platelet factor 4, and heparinase as antidotes.[6,40] Pretreatment with antihistamines and corticosteroids may be sufficient for immune-mediated mechanisms, but will probably not be beneficial for pulmonary vasoconstriction and non–immune-mediated anaphylactoid reactions.[32]

DOSING IN CARDIOPULMONARY BYPASS

Protamine is most frequently used at the conclusion of cardiopulmonary bypass operations to reverse the effects of heparin. There are many regimens used for protamine dosing, including (1) administration of an arbitrary amount of protamine (eg, greater than 2 mg/kg); (2) administration of protamine in a ratio of 0.6 to 1.5:1 times the initial heparin dose that results in an activated coagulation time (ACT) of about 480 seconds; and (3) giving protamine in a ratio of 0.75 to 2:1 times the total operative heparin dose.[81] Two additional methods of calculating the protamine dose to improve accuracy and avoid excess protamine have been proposed.[36,81] One advocates an initial protamine dose based on ACT, with subsequent doses based on the ratio of the change in thrombin time to the heparin-neutralized thrombin time. If this ratio is greater than 12 seconds, then 10-mg incremental

protamine doses should be administered.[36] The other uses a nomogram based on heparin activity in milligrams per kilograms versus ACT.[81] Both methods demonstrate efficacy with 2 mg/kg doses of protamine, about one-half of the dose previously used. With these approaches, the ACT responded to protamine within 5 minutes, decreasing in value from between 550 and 700 seconds to a control of 150 seconds. Other investigators suggest a variety of monitoring methods and dosing schemas in this setting.[16,26,47,66]

HEPARIN REBOUND AND REDOSING OF PROTAMINE

A heparin anticoagulant rebound effect is noted after cardiopulmonary bypass and is attributed to the presence of detectable circulating heparin several hours after apparently adequate heparin neutralization with protamine. The incidence of heparin rebound and the need for additional protamine range from 4% to 42% depending on the neutralization protocol.[24,51,64] It is likely that larger heparin doses may prolong the clearance of heparin, contributing to higher than expected heparin concentrations.[64] When 300 Units/kg of body weight doses of heparin were reversed with 3 mg/kg of protamine at the conclusion of cardiopulmonary bypass a 14% incidence of small but detectable concentrations of circulating heparin was noted at 2 hours, which lasted less than 1 hour in all but one case.[51] A prolonged prothrombin time and thrombocytopenia occurred without increase in hemorrhage.

DOSING CONSIDERATIONS

Approximately 1 mg of protamine will neutralize about 100 Units (1 mg) of heparin (UFH). A limited number of studies suggest incomplete neutralization by protamine of the LMWHs enoxaparin, dalteparin, and tinzaparin. Current recommendations are to administer 1 mg protamine per 100 anti–factor Xa units, where 1 mg enoxaparin equals 100 anti–factor Xa units if administered within 8 hours of the LMWH.[28] A second dose of 0.5 mg protamine should be administered per 100 anti–factor Xa units if bleeding continues.[17,28] If more than 8 hours have elapsed, then a smaller dose of protamine can be administered.

A number of tests directly measure heparin concentrations or indirectly measure the effect of heparin on the clotting cascade.[8,11,16] These tests may be helpful in determining the appropriate dose of protamine. Because excessive protamine can act as an anticoagulant, the dose chosen should always be an underestimation of that which is needed. In the case of unintentional overdose, the half-life of heparin should be considered, because half of the administered dose of heparin is eliminated within 60 to 90 minutes. In the case of an unintentional overdose without hemorrhage, the short half-life of heparin and the potential risks of protamine administration limit the need for and benefit from protamine reversal of anticoagulation. If protamine use is necessary to treat active hemorrhage, the dose must be administered very slowly intravenously either undiluted or diluted in D_5W or 0.9% NaCl over 10 to 15 minutes to limit rate-related hypotension.[39,62,74]

DOSING IN THE OVERDOSE SETTING

When a patient is believed to have received an overdose of an unknown quantity of heparin, the decision to use protamine should be determined by the presence of a prolonged activated partial thromboplastin time (aPTT) and the presence of persistent hemorrhage. The risks of protamine use, especially in those who have had a prior life-threatening reaction to protamine as well as in a diabetic receiving protamine-containing insulin,

and the risks of continued heparin anticoagulation must be evaluated. A baseline ACT, thrombin time, heparin-neutralized thrombin time, heparin activity, platelets, prothrombin time, partial thromboplastin time, hemoglobin, and hematocrit should be obtained. Because of the routine nature of heparin reversal following cardiopulmonary bypass, consultation with members of the bypass team may be helpful. An empiric dose of protamine may be suggested by the baseline ACT: (1) an ACT of 150 seconds necessitates no protamine; (2) an ACT of 200 to 300 seconds necessitates 0.6 mg/kg; and (3) an ACT of 300 to 400 seconds necessitates 1.2 mg/kg. These doses have not been tested outside the operating room. The ACT should be repeated 5 to 15 minutes following the protamine dose and in 2 to 8 hours to evaluate the potential for heparin rebound. Further dosing should be based on these values.

When the ACT is not available, 25 to 50 mg of protamine can be administered to an adult and adjusted accordingly. The initial dose should not be more than 50 mg in an adult.[62] Repeat dosing in several hours may be necessary if heparin rebound occurs. The dose should be administered slowly intravenously over 15 minutes with resuscitative equipment immediately available. Neonates should not receive protamine that has been diluted with bacteriostatic water containing benzyl alcohol.

Future interventions for bleeding following heparin may include activated factor VII. Activated factor VII therapy was recently shown to be successful in treating postoperative bleeding in a patient with renal failure who was given LMWH and aspirin.[56] Adenosine triphosphate, an experimental nucleotide, completely reversed clinical bleeding related to LMWH in a rat model.[17] Other substances or devices include hexadimethrine, heparinase, PF4, synthetic protamine variants, and extracorporeal heparin-removal devices.[24] These xenobiotics have not been approved by the Food and Drug Administration (FDA) for clinical use in this setting.[17,28]

AVAILABILITY

Protamine is available as a parenteral solution ready for injection in a concentration of 10 mg/mL in either a 5-mL or 25-mL vial containing totals of 50 mg and 250 mg, respectively.[62]

SUMMARY

Protamine is an effective, rapidly acting antidote used to reverse the anticoagulant effect of unfractionated heparin, while its ability to reverse the effects of LMWH is less clear. This antidote should only be used for a prolonged aPTT in the presence of persistent hemorrhage, since potential risks of its use include hypotension, anaphylaxis, dysrhythmias, leukopenia, thrombocytopenia, and acute lung injury.

CHAPTER 60
CALCIUM CHANNEL BLOCKERS

Francis Jerome DeRoos

Since calcium channel blockers (CCBs) were first introduced experimentally in the 1960s, their use has steadily risen to make them among the most frequently prescribed cardiovascular medications. Mirroring this widespread use, poisonings involving CCBs have also risen. The combination of sustained-release formulations to improve compliance and the potent hemodynamic effects complicates the management of patients poisoned with CCBs. The hallmarks of CCB toxicity include hypotension and bradydysrhythmias. Unfortunately, in severely poisoned patients, no therapeutic intervention is demonstrated to be consistently effective. Management decisions must be made on an individual patient basis with careful assessment of the physiologic response to each treatment.

HISTORY AND EPIDEMIOLOGY

CCBs were first introduced commercially in the United States in the late 1970s. Currently, there are 10 individual CCBs available in either immediate or sustained-release formulations (Table 60–1), plus several combination products. They are used for a variety of medical conditions, including hypertension, stable angina, dysrhythmias, migraine headache, Raynaud phenomenon, and subarachnoid hemorrhage.

In 1986, more than 1200 exposures and seven deaths related to CCBs were reported to the American Association of Poison Control Centers. In 2007, those figures increased to 10,084 exposures with 435 of moderate to major toxicity, including 17 deaths (Chap. 135). This reported rise in fatalities is most likely the result of the increased use and access to these drugs, along with the introduction of sustained-release preparations in 1988.

PHARMACOLOGY

There are many types of calcium channels, including L, N, P, T, Q, and R types, that can be found either intracellularly on the sarcoplasmic reticulum or on cell plasma membranes, particularly in neuronal and secretory tissue.[91]

All CCBs commercially available in the United States exert their physiologic effects by antagonizing L-type voltage-sensitive calcium channels and are classified into three structural groups (see Table 60–1).[50,107] Each group binds a slightly different region of the alpha$_{1c}$ subunit of the calcium channel and thus has different affinities for the various L-type calcium channels, both in the myocardium and the vascular smooth muscle.[1,28] Verapamil and diltiazem have profound inhibitory effects on the sinoatrial (SA) and atrioventricular (AV) nodal tissue, whereas the dihydropyridines as a class have little, if any, direct myocardial effects at therapeutic doses.[51,107] A fourth class of CCBs, sometimes referred to as "nonselective," includes mibefradil and bepridil, which are no longer available in the United States because of adverse drug events.

These receptor-binding differences among the CCB classes determine their potential therapeutic role. Verapamil and diltiazem are used in the management of hypertension, to reduce myocardial oxygen demand, to achieve rate control in atrial flutter and atrial fibrillation, and to abolish supraventricular reentrant tachycardias.[1] Dihydropyridines are typically used to treat diseases with increased peripheral vascular tone such as hypertension, Raynaud phenomenon, Prinzmetal angina, esophageal spasm, vascular headaches, and post-subarachnoid hemorrhage vasospasm, but not for rhythm disturbances.

PHARMACOKINETICS AND TOXICOKINETICS

All CCBs are well-absorbed orally and undergo hepatic oxidative metabolism predominantly via the CYP3A4 subgroup of the cytochrome P450 (CYP) isoenzyme system.[68] Norverapamil, formed by N-demethylation of verapamil, is the only active metabolite and retains 20% of the activity of the parent compound.[46] Diltiazem is predominantly deacetylated into minimally active deacetyldiltiazem, which is then eliminated via the biliary tract.[39] After repeated doses, as well as overdose, these hepatic enzymes become saturated, reducing the potential of the first-pass effect and increasing the quantity of active drug absorbed systemically.[116] Saturation metabolism contributes to the prolongation of the apparent half-lives reported following overdose of various CCBs.[84] All CCBs are highly protein bound.[68] Volumes of distribution are large for verapamil (5.5 L/kg) and diltiazem (5.3 L/kg), and somewhat smaller for nifedipine (0.8 L/kg). Although not well studied, the substantial protein binding and the large volumes of distribution make it unlikely that extracorporeal drug removal with hemodialysis or hemoperfusion would be of any value in overdose. Several case reports offer clinical support for this conclusion.[89,104]

One interesting aspect of the pharmacology of CCBs is their potential for drug–drug interactions. CYP3A4, which metabolizes most CCBs, is also responsible for the initial oxidation of numerous other xenobiotics. Verapamil and diltiazem specifically compete for this isoenzyme and can decrease the clearance of many drugs including carbamazepine, cisapride, quinidine, various β-hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, cyclosporine, tacrolimus, most HIV-protease inhibitors, and theophylline (see Chap. 12 Appendix).[33,78] In June 1998, mibefradil, a structurally unique CCB, was voluntarily withdrawn following several reports of serious adverse drug interactions caused in part by its potent inhibition of CYP3A4.[58] Other inhibitors of CYP3A4, such as cimetidine, fluoxetine, some antifungals, macrolide antibiotics, and even the flavinoids in grapefruit juice, raise serum concentrations of several CCBs and may result in toxicity.[32,93]

In addition to affecting CYP3A4, verapamil and diltiazem also inhibit P-glycoprotein–mediated drug transport into peripheral tissue—an inhibition that results in elevated serum concentrations of xenobiotics such as cyclosporine and digoxin that use this transport system (Chap. 12 Appendix). Unlike diltiazem and verapamil, nifedipine and the other dihydropyridines do not appear to affect the clearance of other xenobiotics via CYP3A4 or P-glycoprotein–mediated transport.[1]

PHYSIOLOGY AND PATHOPHYSIOLOGY

Calcium initiates excitation-contraction coupling and myocardial conduction (Fig. 60–1; see Chap. 22 and 23). Ca^{2+} enters the cardiac myocyte through L-type calcium channels and follows electrochemical gradients.[66] The alpha$_{1c}$ subunit is the pore-forming portion of this channel and is where all CCBs bind to prevent Ca^{2+} transport.[12,83] In myocardial cells, this Ca^{2+} influx is slower relative to the initial sodium influx that initiates cellular depolarization, and prolongs this

TABLE 60–1. Classification of Calcium Channel Blockers Available in the United States

Phenylalkylamine
    Verapamil (Calan, Isoptin, Verelan)

Benzothiazepine
    Diltiazem (Cardizem, Dilacor, Tiazac)

Dihydropyridines
    Nifedipine (Adalat, Procardia)
    Amlodipine (Norvasc)
    Clevidipine (Cleviprex)
    Felodipine (Plendil)
    Isradipine (DynaCirc)
    Nicardipine (Cardene)
    Nimodipine (Nimotop)
    Nisoldipine (Sular)

depolarization, creating the plateau phase (phase 2) of the action potential. The Ca^{2+} subsequently stimulates a receptor-operated calcium channel on the sarcoplasmic reticulum, known as the ryanodine receptor (RyR2), releasing Ca^{2+} from the vast stores of the sarcoplasmic reticulum into the cytosol.[74] This is often termed calcium-dependent calcium release. Calcium then binds troponin C, which causes a
FIGURE 60–1. Normal contraction of myocardial cells. The L-type voltage sensitive calcium channels (Ca$_v$-L) open to allow calcium ion influx during myocyte depolarization. This causes the concentration-dependent release of more calcium ions from the ryanodyne receptor (RyR) of the sarcoplasmic reticulum (SR) that ultimately produce cardiac contraction.

conformational change that displaces troponin and tropomyosin from actin, allowing actin and myosin to bind, resulting in a contraction (see Fig. 23–2).[16,24]

In addition to its role in myocardial contractility, Ca^{2+} influx is also important in myocardial conduction. Calcium influx plays an important role in the spontaneous depolarization (phase 4) of the action potential in the SA node. This Ca^{2+} influx also allows normal propagation of electrical impulses via the specialized myocardial conduction tissues, particularly the AV node.[85] After opening, the rate of recovery of these slow calcium channels, in both the SA and AV nodal tissue, determines rate of conduction.[107]

In smooth muscle, calcium influx stimulates myosin light-chain kinase activity through calmodulin.[66] The myosin light-chain kinase phosphorylates, and thus activates, myosin, which subsequently binds actin, causing a contraction to occur.[66]

The life-threatening toxicities of CCBs are manifested largely within the cardiovascular system and are an extension of their therapeutic effects. Inhibition of L-type-voltage–sensitive calcium channels is particularly significant in the myocardium and smooth muscle, which are dependant on this influx for normal function. In the myocardium, this impaired Ca^{2+} flow results in a decreased force of contraction. In addition, the delay in recovery of the slow calcium channels in the SA and AV nodal tissue results in decreased heart rate and conduction. In the vascular smooth muscle, the cytosolic Ca^{2+} concentration maintains basal tone and any decrease of Ca^{2+} influx results in relaxation and arterial vasodilation.[45]

The pharmacological differences among CCBs on the myocardium and the vascular smooth muscle is the result of their different affinities for the various L-type calcium channels.[1,28] In the myocardium, verapamil has the most marked effects, while diltiazem has less and dihydropyridines have little, if any, effect at therapeutic doses.[51] In fact, in several experimental models, nifedipine does not alter the recovery of myocardial calcium channels.[57] In addition, not only do verapamil and, to a lesser extent, diltiazem impede Ca^{2+} influx and channel recovery in the myocardium, but their blockade is potentiated as the frequency of channel opening increases.[34,75] Therefore, in a frequently contracting tissue, such as the myocardium, the blockade of verapamil and diltiazem would be augmented. In the peripheral vascular tissue, dihydropyridines have the most potent vasodilatory effects; verapamil is the next most potent, followed by diltiazem. Dihydropyridines bind the calcium channel best at less-negative membrane potentials. Because the resting potential for myocardial muscle (–90 mV) is lower than that of vascular smooth muscle (–70 mV), dihydropyridines bind preferentially in the peripheral vascular tissue.[75]

Consequently, verapamil is the most effective at decreasing heart rate, cardiac output, and blood pressure, whereas the dihydropyridines produce the greatest decrease in systemic vascular resistance. Because dihydropyridines have limited myocardial effect at therapeutic concentrations, the baroreceptor reflex remains intact and a slight increase in heart rate and cardiac output may occur. Isradipine is the only dihydropyridine whose inhibitory effect on the SA node is significant enough to blunt any reflex tachycardia.

CLINICAL MANIFESTATIONS

Myocardial depression and peripheral vasodilation occur, producing bradycardia and hypotension.[90] Myocardial conduction may be impaired, producing AV conduction abnormalities, idioventricular rhythms, and complete heart block.[8,29,41,44,63,77] Junctional escape rhythms frequently occur in patients with significant poisonings.[20,27] The negative inotropic effects may be so profound, particularly with verapamil,

that ventricular contraction may be completely inhibited.[11,27,36] Patients may initially be asymptomatic but deteriorate rapidly and develop cardiogenic shock.[95,109]

Hypotension is the most common abnormal vital sign finding following a CCB overdose.[81] The associated clinical findings represent the degree of cardiovascular compromise and hypoperfusion of the central nervous system (CNS). Early or mild symptoms include dizziness, fatigue, and lightheadedness, whereas more severely poisoned patients may manifest lethargy, syncope, altered mental status, coma, and death.[41,76] Seizures,[38,41] cerebral ischemic events,[87,92] ischemic bowel,[98,110] and renal failure,[77] occurring in the presence of CCB-induced cardiogenic shock, also are reported. Severe CNS depression is distinctly uncommon, and if respiratory depression or coma is present without severe hypotension, coingestants or other causes of altered mental status must be considered. Gastrointestinal (GI) symptoms, such as nausea and vomiting, are also uncommon.[42]

Although receptor selectivity is lost in overdose, and all CCBs can produce severe bradycardia, hypotension, and death, there are some subtle variations in presentation, depending on the xenobiotic. The CCBs with the most significant myocardial effects, verapamil and, to a lesser extent, diltiazem, are associated with more negative inotropic and chronotropic effects.[72] In a prospective, poison center–based study, AV nodal block occurred much more frequently in the setting of verapamil poisoning.[80] In contrast, nifedipine, and likely the other dihydropyridines because of their limited myocardial binding, may produce tachycardia or a "normal" heart rate initially, with bradycardia developing only in patients with more substantial ingestions.[19,112] While deaths are much more commonly associated with verapamil and diltiazem, they nevertheless occur with the dihydropyridines.

Numerous reports document hyperglycemia in patients with severe CCB poisoning.[38,41,61] Insulin release from the β-islet cells in the pancreas is dependent on calcium influx via an L-type calcium channel. In CCB overdose, this channel is blocked, reducing insulin release.[23] This may be due to dysregulation of the insulin-dependent phosphatidylinositol 3-kinase pathway.[9] The hyperglycemic effect may be exacerbated in a diabetic patient, or if glucagon is used as inotropic therapy (Chap. 48).[105]

Acute pulmonary injury is also associated with CCB poisoning.[43,49,60] Although the mechanism is unknown, precapillary vasodilation may cause an increase in transcapillary hydrostatic pressure.[43] The elevated pressure gradient results in increased pulmonary capillary transudates and, ultimately, interstitial edema.

Several factors, including the CCB involved, the dose ingested, the product formulation, and the patient's underlying cardiovascular health, may play a role in the ultimate degree of toxicity. Coingestion with other cardioactive xenobiotics, such as β-adrenergic antagonists and digoxin, may potentiate conduction abnormalities.[15,47,118]

The product formulation (immediate or regular versus sustained release) affects the onset of symptoms and duration of toxicity. With regular-release formulations, toxicity is often present within 2 to 3 hours of ingestion.[10,81] With sustained-release products, however, initial signs or symptoms may be delayed for 6 to 8 hours, and delays of up to 15 hours are reported.[10,81,97] In addition, with ingestion of sustained-release products, the apparent half-life is prolonged and toxicity may last longer than 48 hours.[3,8,27]

Comorbidity and age are two factors that negatively impact both morbidity and mortality in patients with CCB poisoning. Elderly patients, and those with underlying cardiovascular disease such as congestive heart failure, are much more sensitive to the myocardial depressant effects of CCBs.[67] Even at therapeutic doses, these individuals more frequently develop symptoms of mild hypoperfusion, such as dizziness and fatigue.[37,70] One or two tablets of any of the CCBs may produce significant poisoning in toddlers.[10,82]

DIAGNOSTIC TESTING

All patients with suspected CCB ingestions should have continuous cardiac monitoring and a 12-lead electrocardiogram (ECG) performed to assess heart rate and rhythm, as well as any conduction abnormalities. Careful assessment of the degree of hypoperfusion, if any, may include pulse oximetry and serum chemistry analysis for metabolic acidosis. Assays for various CCB serum concentrations are not routinely available and are not used to manage patients after overdose. If a patient presents with bradydysrhythmias of unclear origin, assessment of electrolytes, particularly potassium and magnesium, renal function, and a digoxin concentration, may be helpful, although careful history taking often provides the most valuable clues. If hyperkalemia is present, cardioactive steroid poisoning should be considered, particularly in the absence of renal failure. Acute lung injury can be initially assessed by auscultation, pulse oximetry, and chest radiography.

Because calcium channel blocker poisoning can impair insulin secretion from the pancreas, hyperglycemia may be detected. A recent retrospective study suggests that serum glucose concentrations correlate with the severity of the poisoning. The initial mean serum glucose concentration in patients who required vasopressors or a pacemaker, or who died, was 188 mg/dL versus 122 mg/dL in those not requiring intervention. Peak serum glucose concentrations were also significantly different.[61] This finding may become a useful early sign of severity and an indicator for when to initiate hyperinsulinemia-euglycemia therapy.

MANAGEMENT

Any patient with a suspected CCB ingestion should be immediately evaluated, even if there are no abnormal clinical findings and the initial vital signs are normal. Intravenous access should be initiated. A 12-lead ECG should be repeated at least every 1 to 2 hours for the first several hours. If the patient's condition remains normal (or normalizes), ECGs can be repeated subsequently at longer intervals. Initial treatment should begin with adequate oxygenation and airway protection (as clinically indicated), and aggressive GI decontamination. For a patient who is hypotensive with no evidence of congestive heart failure or acute lung injury, an initial fluid bolus of 10 to 20 mL/kg of crystalloid should be given, and repeated as needed.

Attempts to prevent absorption of drug from the GI tract may prevent or mitigate toxicity and is often a critical intervention. The importance of early initiation of GI decontamination even for well-appearing patients with a history of sustained-release CCB ingestion, particularly children, cannot be overemphasized. It is imperative to minimize any absorption and prevent delayed cardiovascular toxicity, which can be profound and difficult to reverse. Several reports describe patients who presented with mild signs of poisoning, in whom GI decontamination was not performed aggressively and who subsequently displayed severe toxicity. The most important measures to eliminate CCBs after an ingestion are multiple-dose activated charcoal (MDAC) and, for sustained-release CCBs, whole-bowel irrigation (WBI).

Induced emesis is contraindicated because CCB-poisoned patients can rapidly deteriorate. Orogastric lavage should be considered for all patients who present early (1 to 2 hours postingestion) after large ingestions, and for patients who are critically ill. Although the effects of orogastric lavage following overdose of a sustained-release CCB have not been specifically studied, and although most of these formulations tend to be large and poorly soluble, because of their significant danger in overdose, orogastric lavage should still be strongly considered. When performing orogastric lavage in a CCB-poisoned patient, it is important to remember that lavage may increase vagal tone and

potentially exacerbate any bradydysrhythmias.[106] Pretreatment with a therapeutic dose of atropine may prevent this.

All patients with CCB ingestions should receive 1 g/kg of activated charcoal orally. Multiple doses (0.5 g/kg) of activated charcoal (MDAC) without a cathartic should be administered to nearly all patients with either sustained-release pill ingestions or signs of continuing absorption. Although data are limited, there is no evidence that MDAC increases CCB clearance from the serum.[84] Rather, its efficacy may be a result of the continuous presence of activated charcoal throughout the GI tract, which adsorbs any active xenobiotic from its slow-release formulation. MDAC should not be administered to a patient with inadequate GI function (eg, hypotensive, no bowel sounds; see Antidotes in Depth A2–Activated Charcoal).

WBI with polyethylene glycol solution (1 to 2 L/h orally or via nasogastric tube in adults, up to 500 mL/h in children) should be initiated for patients who ingest sustained-release products.[14] Administration should be continued until the rectal effluent is clear (see Antidotes in Depth A3–Whole-Bowel Irrigation and Other Intestinal Evacuants).

There are no data to clearly support extracorporeal removal, and its use is generally limited by the hemodynamic effects of the CCBs.[86]

Pharmacotherapy should focus on maintenance or improvement of both cardiac output and peripheral vascular tone. Although atropine, calcium, insulin, glucagon, isoproterenol, dopamine, epinephrine, norepinephrine, and phosphodiesterase inhibitors, have been used with reported success in CCB-poisoned patients, no single intervention has consistently demonstrated total efficacy. Little prospective or basic research specifically evaluates effective treatment modalities.

Therapy should begin with crystalloids and atropine, but more critically poisoned patients will not respond to these initial efforts, and inotropes and vasopressors will be needed. Although it would be ideal to initiate each therapy individually and monitor the patient's hemodynamic response, in the most critically ill patients, multiple therapies should be administered simultaneously. A reasonable treatment sequence includes calcium followed by a catecholamine such as epinephrine or norepinephrine, hyperinsulinemia-euglycemia therapy, glucagon, and perhaps a phosphodiesterase inhibitor. In addition, in the event of a cardiac arrest, a 20% intravenous fat emulsion may be administered.

■ ATROPINE

Atropine is considered by many to be the drug of choice for patients with symptomatic bradycardia. In an early dog model of verapamil poisoning, atropine improved heart rate and cardiac output.[31] In one prospective study, two of eight bradycardic CCB-poisoned patients also had an improvement in heart rate with atropine therapy.[80] Clinical experience, however, demonstrates atropine to be largely ineffective in improving heart rate in severe CCB-poisoned patients.[76,95] Initial treatment with calcium might improve the efficacy of atropine.[42] Given its availability, familiarity, efficacy in mild poisonings, and safety profile, atropine should still be considered as initial therapy in patients with symptomatic bradycardia. Dosing should begin with 0.5 to 1.0 mg (0.02 mg/kg in children) minimum 0.1mg) intravenously (IV) every 2 or 3 minutes up to a maximum dose of 3 mg in all patients with symptomatic bradycardia. However, because of its limited efficacy in severely poisoned patients, treatment failures should be anticipated. In patients in whom WBI or MDAC will be used, the use of atropine must be carefully considered, weighing the potential benefits of improved heart rate, and thus cardiac output, against the anticholinergic effects, potentially decreasing GI motility.

■ CALCIUM

Pharmacologically, Ca^{2+} appears to be a logical choice to treat patients with CCB toxicity. Pretreatment with intravenous Ca^{2+}, prior to verapamil use for supraventricular tachydysrhythmias, prevents hypotension without diminishing the antidysrhythmic efficacy.[25,94] This is also observed in the overdose setting where Ca^{2+} tends to improve blood pressure more than it does the heart rate. Although the exact mechanism is unclear, boluses of Ca^{2+} increase the extracellular Ca^{2+} concentration and increase the transmembrane concentration gradient. Calcium salts are beneficial in experimental models of CCB poisoning.[31,36] In verapamil-poisoned dogs, improvement in inotropy and blood pressure was demonstrated after increasing the serum Ca^{2+} concentration by 2 mEq/L with an intravenous infusion of 10% calcium chloride ($CaCl_2$) at 3 mg/kg/min.[36]

Calcium ion reverses the negative inotropy, impaired conduction, and hypotension in humans poisoned by CCBs.[14,59,62,70] Unfortunately, this effect is often short lived and more severely poisoned patients may not improve significantly with Ca^{2+} administration.[18,21,84,89] Although some authors believe that these failures might represent inadequate dosing,[14,42,59] optimal effective dosing of Ca^{2+} is unclear. Moreover, if there is any suspicion that a cardioactive steroid such as digoxin is involved in an overdose, Ca^{2+} should be avoided until after digoxin-specific Fab is administered because of concerns that it may worsen digoxin toxicity (Chap. 64 and A 20).[13] Reasonable recommendations for poisoned adults include an initial intravenous infusion of approximately 13 to 25 mEq of Ca^{2+} (10 to 20 mL of 10% calcium chloride or 30 to 60 mL of 10% calcium gluconate) followed by either repeat boluses every 15 to 20 minutes up to three to four doses or a continuous infusion of 0.5 mEq/kg/h of Ca^{2+} (0.2 to 0.4 mL/kg/h of 10% calcium chloride or 0.6 to 1.2 mL of 10% calcium gluconate; see Antidotes in Depth A19–Glucagon).[72] Careful selection and attention to the type of calcium salt used is critical for dosing. Although there is no difference in efficacy of calcium chloride or calcium gluconate, 1 g of calcium chloride contains 13.4 mEq of Ca^{2+}, which is more than three times the 4.3 mEq found in 1 g of calcium gluconate. Consequently, to administer equal doses of Ca^{2+}, three times the volume of calcium gluconate compared with that of calcium chloride is required. The main limitation of using calcium chloride, however, is that it has significant potential for causing tissue injury if extravasated, so administration should ideally be via central venous access. If repeat dosing or continuous infusions are necessary serum Ca^{2+} and PO_4^{-3} concentrations should be closely monitored to detect developing hypercalcemia or hypophosphatemia. These concerns are not unfounded, and may in fact significantly limit Ca^{2+} therapy. Other adverse effects of intravenous Ca^{2+} include nausea, vomiting, flushing, constipation, confusion, and angina.

■ INOTROPES AND VASOPRESSORS

Catecholamines are the next line of therapy in the treatment of CCB poisoning. Numerous case reports describe the success or failure of a wide variety of vasopressors, including epinephrine (success,[18] failure[38,63]), norepinephrine (success,[41] failure[63]), dopamine (success,[3] failure[18,38,63]), isoproterenol (success,[77] failure[38]), dobutamine (success,[77] failure[21,63]), and vasopressin.[31,48,101] Experimentally, no single therapy is consistently effective. This is not surprising, given the significant variability in both the CCBs and the patients involved. Mechanistically, however, stimulation of either β_1-adrenergic receptors on the myocardium or α_1-adrenergic receptors on the peripheral vascular smooth muscle is the most logical target, but which one depends upon the etiology of the hypotension.

β-Adrenergic agonists activate adenylate cyclase via G_s protein, resulting in formation of cyclic adenosine monophosphate (cAMP), which stimulates protein kinase A to phosphorylate the α_1 subunit of various calcium channels (Fig. 60–2).[96] It is unclear whether this phosphorylation allows calcium channels to remain open longer,[19] or if
FIGURE 60–2. Myocardial toxicity of calcium channel blockers and use of antidotal therapies. Calcium channel blockers reduce calcium ion influx through the L-type calcium channel (Ca_v-L) and thus reduce contractility. Mechanisms to increase intracellular calcium include recruitment of new or dormant calcium channels by increasing cyclic adenosine monophosphate (cAMP) either by stimulating its formation by adenyl cyclase (AC) with catecholamines or glucagon (see text), or by inhibiting its degradation to 5'-monophosphate with phosphodiesterase inhibitors (PDEI) such as amrinone. Increasing the calcium concentration gradient across the cellular membrane to further its influx may improve contractility. The mechanism by which insulin therapy enhances inotropy is not fully known. PKA, protein kinase A; RyR = ryanodyne receptor.

FIGURE 60–3. Vascular toxicity of calcium channel blockers and antidotal therapies. Calcium's entry via voltage-sensitive channels (Ca_v-L) initiates a cascade of events that result in actin-myosin coupling and contraction; this is inhibited by calcium channel blockers. Mechanisms to increase intracellular calcium include activation of receptor-operated calcium channels with α_1-adrenergic agonists or increasing the calcium ion gradient across the cellular membrane to further its influx; RyR = ryanodyne receptor.

it opens dormant channels within the plasma membrane. In addition, protein kinase A also phosphorylates phospholamban, which improves calcium release from troponin after contraction.[100] In the myocardium, this multifactorial increase in intracellular calcium results in improved chronotropy, dromotropy, and inotropy.

In the peripheral vascular smooth muscle, α_1-adrenergic receptor agonists activate receptor-operated calcium channels. This opening of nonpoisoned calcium channels allows calcium influx (Fig. 60–3), which makes α_1-adrenergic agonists such as norepinephrine and phenylephrine logical choices if the hypotension is primarily the result of peripheral vasodilation, as would occur most typically with the dihydropyridine CCBs. Based on these pharmacologic mechanisms, and on experimental data epinephrine, or perhaps norepinephrine, appears to be the most an appropriate initial catecholamine to use in hypotensive CCB-poisoned patients. The significant β_1-adrenergic activity of both catecholamines combat the myocardial depressant effects, while the α_1-adrenergic agonist effects of norepinephrine (more so than epinephrine) increase peripheral vascular resistance if desired. There is some theoretical concern about using pure β-adrenergic receptor agonists, such as isoproterenol and, to a lesser extent, dobutamine, because β_2-adrenergic receptor agonist–induced peripheral vasodilation may worsen hypotension, particularly at high doses.

Dopamine is predominantly an indirect acting pressor that acts by stimulating the release of norepinephrine from the distal nerve terminal, and not by direct α- and β-adrenergic receptor stimulation. This may limit its effectiveness in severely stressed patients who may have catecholamine depletion.[109] Published clinical experience of patients with severe CCB poisonings support these concerns.[20,38,63,109]

Improvement in blood pressure may be noted with dopamine at high dosing, when it has additional direct α- and β-adrenergic effects.

The choice of a catecholamine is based on numerous factors, including the individual pharmacologic profile, the patient's underlying physiologic condition, and the physician's familiarity and comfort with the medication. If one catecholamine is unsuccessful, determining the cardiac output and systemic vascular resistance may be helpful in assessing whether the myocardial depressant or peripheral vasodilatory effects are responsible for the hypotension.[76] This knowledge will help guide the subsequent choice of pharmacologic agents.

■ GLUCAGON

Glucagon is an endogenous polypeptide hormone secreted by the pancreatic α cells in response to hypoglycemia and catecholamines. In addition, it has significant inotropic and chronotropic effects (see Antidotes in Depth A19–Glucagon).[17,99] Glucagon is a therapy of choice for β-adrenergic antagonist poisoning (Chap. 61) because of its ability to bypass the β-adrenergic receptor and activate adenylate cyclase via a G_s protein in the myocardium.[115] Thus, glucagon is unique in that it is functionally a "pure" β_1 agonist, with no peripheral vasodilatory effects. However, in CCB poisoning, because the cellular lesion is "downstream" from adenylate cyclase, glucagon offers no pharmacologic advantage over more traditional β-adrenergic agents (see Fig. 60–2).[4] There are reports of both successes[26] and failures[20,38] of glucagon in CCB-poisoned patients who failed to respond to fluids, Ca^{2+}, or dopamine and dobutamine.

Dosing for glucagon is not well established.[4] An initial dose of 3 to 5 mg IV, slowly over 1 to 2 minutes, is reasonable in adults, and if there is no hemodynamic improvement within 5 minutes, retreatment with a dose of 4 to 10 mg may be effective. The initial pediatric dose is 50 μg/kg.

Because of the short half-life of glucagon repeat doses may be useful. A maintenance infusion should be initiated once a desired effect is achieved (see Antidotes in Depth A19–Glucagon). Adverse effects include vomiting and hyperglycemia, particularly in diabetics or during continuous infusion.[105]

■ INSULIN AND GLUCOSE

Hyperinsulinemia euglycemia (HIE) therapy has become the treatment of choice for patients who are severely poisoned by CCBs.[61,69] Healthy myocardial tissue relies predominantly on free fatty acids for their metabolic needs and CCB poisoning forces them to become more carbohydrate dependent.[52,55,56] At the same time, CCBs inhibit calcium-mediated insulin secretion from the β-islet cells in the pancreas,[23,71] resulting in glucose uptake in myocardial cells becoming dependent upon concentration gradients rather than insulin-mediated active transport.[53] In addition, there is evidence that the CCB-poisoned myocardium also becomes insulin resistant possibly by dysregulation of the phosphatidylinositol 3 kinase pathway.[9,54] This may not allow normal recruitment of insulin-responsive glucose transporter proteins.[9] The combination of inhibition of insulin secretion and impaired glucose utilization may explain why severe CCB toxicity often produces significant hyperglycemia and may be a marker for the severity of poisoning (see Antidotes in Depth A18–Insulin-Euglycemia Therapy).[61]

There are now several reported cases of CCB-poisoned patients in whom adjuvant HIEG therapy successfully improved hemodynamic function mainly by improving contractility, with little effect on heart rate.[65,108,117] There are reports of the failure of this treatment,[22] but this may represent initiation of therapy in terminally ill patients with multiple organ failure.

Although the dose of insulin is not definitively established, therapy typically begins with a bolus of 1 Unit/kg of regular human insulin along with 0.5 g/kg of dextrose. If blood glucose is greater than 400 mg/dL (22.2 mmol/L), the dextrose bolus is not necessary. An infusion of regular insulin should follow the bolus starting at 0.5 Units/kg/h titrated up to 2 Units/kg/h if no improvement after 30 minutes. A continuous dextrose infusion, beginning at 0.5 g/kg/h should also be started. Glucose should be monitored every half hour for the first 4 hours and titrated to maintain euglycemia. The response to insulin is typically delayed for 15 to 60 minutes so it will usually be necessary to start a catecholamine infusion before the full effects of insulin are apparent.[35,69]

■ PHOSPHODIESTERASE INHIBITORS

Another class of therapeutics that has some demonstrated usefulness in treating CCB poisoning is the cardiac and vascular phosphodiesterase 3 inhibitors: inamrinone, milrinone, and enoximone. These agents inhibit the breakdown of cAMP by phosphodiesterase, thereby increasing intracellular cAMP concentrations. These noncatecholamine inotropic agents do not disproportionately increase myocardial oxygen demand and have been traditionally used for congestive heart failure (see Fig. 60–2).[5] This inhibition results in increased cAMP, increased intracellular calcium, and improved inotropy. Inamrinone improved myocardial contractility in two canine models of verapamil poisoning.[2,64] In addition, phosphodiesterase inhibitors have been reported to be clinically successful in patients with CCB poisoning when used in combination with another inotrope, such as isoproterenol or glucagon.[88,113,114] This "two-pronged" approach of increasing myocardial cAMP concentrations, by stimulating its formation and inhibiting its breakdown, is pharmacologically rational. However, because of the nonselective inhibition of phosphodiesterase 3 by these inhibitors, cAMP is also increased in the vascular smooth muscle. This causes smooth muscle relaxation, peripheral vasodilation and, unfortunately often, hypotension, which may severely limit its usefulness in many CCB-poisoned patients. Phosphodiesterase inhibitors should be used only as second-line agents, in combination with another inotrope and preferably in patients with hemodynamic monitoring. Dosing in the treatment of CCB-poisoned patients is not well defined, but should be based on traditional dosing for congestive heart failure. For inamrinone, the experimental data and the case reports suggest that an initial bolus of 1 mg/kg over 2 minutes followed by a continuous infusion of 5 to 20 μg/kg/min is appropriate.[2,113]

■ EXPERIMENTAL ANTIDOTES

In animal models intravenous fat emulsions (IFE) decreases the toxicity of a few lipid-soluble drugs, most notably bupivacaine. Other models suggest that IFE is an effective therapy for CCB-poisoned patients.[7,73,102,111] This mechanism is most likely pharmacokinetic in nature, in that IFE incorporates these highly cardiotoxic drugs and thus lower the free or effective serum drug concentrations.[7,111] Until more data are available, IFE should be considered adjuvant therapy for critically ill, preterminal CCB-poisoned patients (see Antidotes in Depth A21–Intravenous Fat Emulsion).

Digoxin has been experimentally evaluated in CCB poisoning since inhibiting the sodium/potassium adenosine triphosphatase (ATPase), the cardioactive steroids raise the intracellular Ca^{2+} concentration.[6] In a canine model of verapamil poisoning, digoxin, in conjunction with atropine or calcium, improved both systolic blood pressure and myocardial inotropy.[6,79] However, because digoxin requires a significant amount of time to distribute into tissue, and because limited efficacy data and no safety data have yet been collected, more work is needed before digoxin is administered to patients with CCB poisoning.

■ ADJUNCTIVE HEMODYNAMIC SUPPORT

The most severely CCB-poisoned patients may not respond to any pharmacologic intervention.[27,38] Transthoracic or intravenous cardiac pacing may be required to improve heart rate, as several case reports demonstrate.[95,109] However, in a prospective cohort of CCB poisonings, two of four patients with significant bradycardia requiring electrical pacing had no electrical capture.[80] In addition, even if electrical pacing is effective in increasing the heart rate, blood pressure often remains unchanged.[40,41]

Intraaortic balloon counterpulsation is another invasive supportive option to be considered in CCB poisoning refractory to pharmacologic therapy. Intraaortic balloon counterpulsation was used successfully to improve cardiac output and blood pressure in a patient with a mixed verapamil and atenolol overdose.[30] The synchronized inflation and deflation is dependent on regular cardiac electrical activity, so cardiac pacing is often required in addition to the intraaortic balloon. It is important to remember that CCB-poisoned patients typically have a much better prognosis than patients with severe left ventricular failure from ischemic heart disease, in whom this technology is traditionally used. Between 24 and 48 hours of assisted cardiac output allows metabolism and elimination of the CCBs and a return of baseline myocardial function.

Severely CCB-poisoned patients have also been supported for days and subsequently recovered fully with much more invasive and technologically demanding extracorporeal membrane oxygenation (ECMO) and emergent open and percutaneous cardiopulmonary bypass.[27,38,40] The major limitation of all these technologies, however, is that they are available only at tertiary care facilities.

DISPOSITION

Every patient who manifests any signs or symptoms of toxicity should be admitted to an intensive care setting. Because of the potential for delayed toxicity, despite some recommendations to the contrary,[10] any

patient ingesting sustained-release products should be admitted for 24 hours to a monitored setting, even if asymptomatic. This is particularly important for toddlers and small children in whom just one or a few tablets may produce significant toxicity.[10,38,82] All admitted patients should be treated with activated charcoal, and those with a history of sustained-release product ingestion should be treated with WBI. Only patients with a reliable history of an "immediate-release" preparation ingestion who have received adequate gastrointestinal decontamination, have serial ECGs over 6 to 8 hours that have remained unchanged, and are asymptomatic can be "medically cleared" for disposition. Patients with unintentional overdose may be discharged at this point, and those whose poisoning is intentional typically receive psychiatric evaluation.

SUMMARY

Calcium channel blockers are commonly used to treat hypertension, stable and vasospastic angina, dysrhythmias, migraine headaches, Raynaud phenomenon, and subarachnoid hemorrhage. Hallmarks of toxicity include bradydysrhythmias and hypotension, which are an extension of the pharmacologic effects of these agents. Although most patients develop symptoms of hypoperfusion, such as lightheadedness, nausea, or fatigue, within hours of a significant ingestion, sustained-release formulations may significantly delay any and all hemodynamic consequences and certainly may prolong toxicity.

Because of the significant lethality of large ingestions of sustained-release CCBs, it is imperative to make GI decontamination with WBI a high priority. Aggressive decontamination of patients with exposures to sustained-release products should begin as soon as possible and should not be delayed by waiting for signs of toxicity.[103] Once hemodynamic toxicity develops, in addition to supportive care, pharmacologic treatment with HIE and calcium salt boluses should be initiated. Traditional catecholamines are also typically needed, but their use alone may not be sufficient for the most critically poisoned patients. Other therapeutic options include the use of glucagon, phosphodiesterase inhibitors, and possibly IFE. Patients who fail to respond to all pharmaceutical interventions should be considered for extracorporeal mechanical support whenever available.

INSULIN-EUGLYCEMIA THERAPY

William Kerns

In the last decade, insulin has gained increased attention and importance in the management of a spectrum of critical illnesses including sepsis, heart failure, and cardiac drug toxicity. The benefits of insulin go well beyond simple control of hyperglycemia. In xenobiotic-induced myocardial depression the use of high-dose insulin along with sufficient glucose to maintain euglycemia can restore normal hemodynamics.

BACKGROUND

To understand the role of insulin specifically for resuscitating cardiac drug toxicity, it is useful to briefly review the altered myocardial physiology that occurs during drug-induced shock.

The hallmark of severe beta-adrenergic antagonist (BAA) and calcium channel blocker (CCB) toxicity is cardiogenic shock with bradycardia, vasodilation, and decreased contractility.[7] This is due to direct β-adrenergic receptor antagonism and calcium channel blockade. In addition to direct receptor or ion channel effects, metabolic derangements may occur that closely resemble diabetes with acidemia, hyperglycemia, and insulin deficiency.

In the nonstressed state, the heart primarily catabolizes free fatty acids for its energy needs. On the other hand, the stressed myocardium switches preference for energy substrates to carbohydrates, as demonstrated in models of both BAA and CCB toxicity.[19,35] The greater the degree of shock, the greater the demand for carbohydrates.[20] The liver responds to stress by making more glucose available via glycogenolysis. As a result, blood glucose concentrations are elevated. Hyperglycemia is noted both in animal models and in human cases of cardiac drug overdose.[4,9,22,36] Hyperglycemia is especially evident with CCB toxicity. This is because CCBs interfere with carbohydrate use by inhibiting pancreatic insulin release that is necessary to transport glucose across cell membranes. Insulin release from the islet cell requires functioning L-type or voltage-gated calcium channels similar to those found in myocardial and vascular tissue. Calcium channel blocking drugs directly inhibit pancreatic calcium channels.[6] In models of verapamil toxicity, circulating glucose increases without an associated increase in insulin.[20] There is additional evidence that CCBs interfere with phosphotidyl inositol 3-kinase–mediated glucose transport into cells.[1] As a result of diminished circulating insulin and inhibited enzymatic glucose uptake, glucose movement into cells becomes concentration dependent and may not sufficiently support the myocardial demand. Calcium channel blockers further contribute to metabolic abnormalities by inhibiting lactate oxidation.[19,23] This likely occurs through inhibition of pyruvate dehydrogenase, the enzyme responsible for conversion of pyruvate to

acetylcoenzyme A (acetyl-CoA). As a result, pyruvate is preferentially converted to lactate, rather than the acetyl-CoA that would ordinarily enter the Krebs cycle; lactate then accumulates. Lactate accumulation and acidemia are consistent manifestations of CCB toxicity.[7,23]

PROPOSED MECHANISM

Initially, insulin's ability to improve cardiac function was attributed to increased catecholamine release. However, there is evidence that this is not the mechanism. For example, β-receptor antagonism does not inhibit improved myocardial performance that followed insulin administration.[24,35] In a CCB toxic model that measured circulating hormone concentrations, insulin therapy improved function and survival without increasing catecholamines.[22] In contrast, evidence demonstrates that insulin works via altered calcium, potassium, and sodium ion homeostasis.[8,24] However, the preponderant evidence demonstrates that insulin's positive inotropic effects occur because of metabolic support of the heart during hypodynamic shock.

Insulin facilitates myocardial utilization of carbohydrate that is favored during stress. A number of studies demonstrate a direct correlation between carbohydrate metabolism and the improved indices of cardiac function that occur with insulin therapy. Despite β-adrenergic antagonism by propranolol, insulin increased myocardial glucose uptake with subsequent increased contractility.[35] In a model of verapamil toxicity, insulin increased glucose uptake with resultant improved contractility.[19] Insulin therapy also increased lactate uptake, most likely by restoring pyruvate dehydrogenase activity.[21] In this way, lactate serves as an energy source following conversion to pyruvate and then acetyl-CoA that can then enter the Krebs cycle. Insulin-mediated improved contractility appears to be a critical factor to survival from hypodynamic shock. In models of BAA and CCB toxicity, survival is directly due to improved contractility, as insulin neither affected drug-induced hypotension nor bradycardia.[19,23]

In studies comparing insulin to more traditional therapies for drug-induced cardiogenic shock such as epinephrine and glucagon, insulin improved cardiac function and work efficiency.[21] Epinephrine and glucagon did not perform as well because they promoted free fatty acid utilization. As such, epinephrine and glucagon afforded limited increases in contractility at the expense of less efficient work due to increased oxygen demand.

CLINICAL EXPERIENCE

Insulin-euglycemia therapy for drug-induced shock was first reported in 1999.[39] This case series included four patients who overdosed on verapamil and one with combined amlodipine-atenolol overdose. All failed traditional antidote therapy, but responded to rescue insulin therapy. Since the initial case series, the author's institution has treated six additional patients with rescue insulin therapy following inadequate response to standard antidotes, five of the six with good outcome. Sixty-seven cases appear in the literature that were treated at other institutions.[2,3,5,10-13,16,25-29,31,33,34,36-38] Thus, there is an aggregate of 78 cases in which insulin was used. Of these cases, 72 primarily

involved CCBs, five combined CCBs-BAAs, and one BAA. Various regimens of standard antidotes were used prior to insulin therapy and no case received insulin alone. Although no direct outcome comparisons can be made between insulin and standard therapies in these 78 cases, overall survival was 88% when insulin was included in resuscitation. Further review of these cases yields important clinical information that can be used to guide insulin therapy.

Experimental models suggest that large doses of insulin (2.5 to 10 units of regular insulin/kg/h) may be necessary to provide inotropic support.[1,18,21,23] However, humans appear to respond to less insulin. The most common doses given were 0.5 (n = 31) and 1.0 Units/kg/h (n = 19) of regular insulin in 62 patients where dose was reported. A few patients were treated with higher rates of infusion, up to 2.6 Units/kg/h in one case.[36] Sixteen patients received an insulin bolus (10 to 100 Units) prior to continuous infusion. The theoretical advantage to giving an initial insulin bolus is to rapidly saturate insulin receptors to enhance the physiological response. Interestingly, one report noted that patients receiving an insulin bolus prior to the infusion showed a better blood pressure response than patients who received only a continuous infusion.[10] Three patients received bolus insulin without continuous infusion, including a patient who inadvertently received 1000 units.[34] In this case, hemodynamics improved and there was no adverse event related to the extreme insulin dose. The mean duration of insulin infusion in 24 patients was 33 hours with a range of 0.75 to 96 hours. The need for prolonged infusion likely reflects the prolonged effects and kinetics of cardiovascular drugs typically observed following overdose.

The predominant clinical effect of insulin was increased contractility with subsequent blood pressure improvement. Contractility typically increased within 15 to 60 minutes after initiating insulin and often allowed a decrease in concurrent vasopressor requirements. The timing of increased contractility is consistent with the observed response times in animal models.[18,23] Other salutary effects were observed during insulin therapy. In two cases, blood pressure increased directly because of increased vascular resistance rather than increased cardiac function.[28,37] Two patients converted from third-degree heart block to normal sinus rhythm with increased pulse in temporal relationship to insulin.[40] Except for these two patients, insulin therapy did not significantly affect heart rate in other reports.

In four cases, authors reported a lack of response to insulin. Reasons for no response in three of these reports may include inadequate dose and excessive delay to insulin therapy.[5]

ADVERSE EVENTS

The major anticipated adverse event associated with the use of large amounts of insulin, especially in insulin-naïve patients, is hypoglycemia, defined here as blood glucose less than 60 mg/dL (3.3 mmol/L) regardless of the presence or absence of symptoms. Because of potential hypoglycemia, all experimental animals received sufficient dextrose during insulin infusion to maintain euglycemia. In the aggregate human cases, patients typically received empiric supplemental dextrose as well as frequent glucose monitoring. The mean dextrose dose was 23 g/h, but requirements varied widely from 0.5 to 75 g/h (actual data only available in 14 cases). The duration of exogenous dextrose averaged 43 hours, but like the dextrose dose, also varied significantly from patient to patient (9-100 hours). Dextrose supplementation was sometimes necessary beyond cessation of insulin. In seven of 10 cases with evaluable data, dextrose was continued an average of 10 hours after stopping insulin. Despite empiric dextrose and blood glucose monitoring (albeit not standardized), hypoglycemia occurred in some

patients. In 58 cases where authors specifically document the presence or absence of complications related to insulin therapy, there were 10 patients with hypoglycemia. In five cases, insulin therapy was stopped because of hypoglycemia.[27] These five patients were characterized as mildly hypotensive. If mildly toxic, they may have been more sensitive to insulin. In the remaining cases, euglycemia was restored and insulin treatment continued.

Another anticipated consequence of insulin treatment is lowered serum potassium concentration. Although serum concentrations may at times fall below normal laboratory ranges, this change simply reflects shifting of potassium from the extracellular to intracellular space that occurs as a result of the action of insulin. In other words, patients maintain normal total body potassium stores and do not experience true deficiency unless they have other reasons for potassium loss. In the initial case series, three patients had a nadir of potassium ranging from 2.2 to 2.8 mEq/L without sequelae.[39] There is a theoretical risk of excessive potassium replacement in the instance of lowered serum potassium, but normal total body stores, as hyperkalemia may worsen verapamil-induced myocardial depression.[15,30]

Other observed ion changes during insulin therapy include hypomagnesemia and hypophosphatemia. Similar to action on potassium, insulin causes an intracellular shift of both phosphorus and magnesium.[17,32] Insulin (0.6 Units/kg/hr) for diabetic ketoacidosis is likewise associated with a marked decline of serum magnesium and phosphorus.[14] In the initial series of drug-induced shock treated with insulin, four patients had lowered magnesium (0.4 to 0.6 mmol/L; normal 0.8 to 1.2 mmol/L) and phosphorus (0.2 to 0.5 mmol/L; normal 1 to 1.4 mmol/L) concentrations. No symptoms were attributed to lowered serum concentrations, but three patients received supplementation of both electrolytes. No other insulin-treated CCB cases address these two electrolytes.

INSULIN-EUGLYCEMIA TREATMENT GUIDELINES

Based on the experimental studies and aggregate human cases, insulin-euglycemia is most likely going to benefit patients with cardiac drug-induced myocardial depression. Insulin-euglycemia may also be considered for those patients with hypotension due to poor vascular resistance without myocardial depression that does not respond to standard vasopressor treatment. Lastly, it is reasonable to initiate empiric insulin-euglycemia if a delay to cardiac diagnostic studies is expected. The experimental evidence and human case experience is strongest for CCB toxicity. Animal studies and limited human experience also support its use for BAA intoxication.

Myocardial function can be estimated at the bedside via emergency department ultrasonography or more formally via echocardiography or placement of a pulmonary artery catheter. When decreased myocardial function is present, insulin therapy can be used by first administering a 1 Unit/kg bolus of regular human insulin along with 0.5 g/kg of dextrose. If blood glucose is greater than 400 mg/dL (22.2 mmol/L), the dextrose bolus is not necessary. An infusion of regular insulin should follow the bolus starting at 0.5 to 1 Unit/kg/h. A continuous dextrose infusion, beginning at 0.5 g/kg/h should also be started. Dextrose is best delivered as $D_{25}W$ or $D_{50}W$ via central venous access to lessen large fluid volumes that would otherwise be necessary with administration of more dilute dextrose solutions. Patients with markedly elevated blood glucose may not require dextrose support at the start of insulin therapy.

If possible, cardiac function should be reassessed every 20 to 30 minutes after starting insulin-euglycemia therapy. If cardiac function

remains depressed or there is persistent hypotension, the insulin dose can be increased. Doses up to 2.5 Units/kg/h have been used, although the maximum dose is not established in humans. The blood glucose should be monitored every 30 minutes until stable and then every 1 to 2 hours. The dextrose infusion should be titrated to keep blood glucose between 100 and 250 mg/dL (5.5 to 14 mmol/L).

The serum potassium concentration should be measured during insulin-euglycemia therapy. If it is low, especially when potassium loss is suspected, then supplementation to maintain the concentration in the "mildly hypokalemic" range (2.8 to 3.2 mEq/L) can be given. Magnesium and phosphorus can also be measured and supplemented as medically indicated. However, unless there is reason for loss of these three electrolytes, lowered serum concentrations likely reflect compartmental shifts, not depletion.

The ultimate goal of insulin-euglycemia is improvement in organ perfusion as demonstrated by increased blood pressure, improved mental status, and adequate urine output. Other markers of effective insulin-euglycemia therapy are reversal of acidemia and decreasing lactate concentrations. An increase in dextrose infusion to maintain euglycemia often accompanies hemodynamic and metabolic improvements. This is due to drug metabolism and loss of the drug-induced diabetogenic influences, and can be regarded as a favorable prognostic indicator.

CHAPTER 61
β-ADRENERGIC ANTAGONISTS

Jeffrey R. Brubacher
The pharmacology, toxicology, and poison management issues discussed in this chapter are applicable to all of the β-adrenergic antagonists. They are commonly used in the treatment of patients with cardiovascular disease, including hypertension, coronary artery disease, and tachydysrhythmias. Additional indications for β-adrenergic antagonists include congestive heart failure, migraine headaches, benign essential tremor, panic attack, stage fright, and hyperthyroidism. Ophthalmic preparations containing β-adrenergic antagonists are used in the treatment of glaucoma.[56] The diverse indications have led to complex toxicologic emergencies from intentional and unintentional overdoses as well as adverse drug reactions and drug–drug interactions. The management of patients with β-adrenergic antagonist overdoses is complicated by the lack of a routine strategy or a simple antidote. It is for these reasons that this class of xenobiotics remains intensely under study.

HISTORY

In 1948, Raymond Alquist postulated that epinephrine's cardiovascular actions of hypertension and tachycardia were best explained by the existence of two distinct sets of receptors that he generically named α and β receptors. At that time, the contemporary "antiepinephrines," such as phenoxybenzamine, reversed the hypertension but not the tachycardia associated with epinephrine. According to Alquist's theory, these drugs acted at the α-adrenergic receptors. The β-adrenergic receptors, in his schema, mediated catecholamine-induced tachycardia. The British pharmacist Sir James Black was influenced by Alquist's work and recognized the potential clinical benefit of a β-adrenergic antagonist. In 1958, Black synthesized the first β-adrenergic antagonist, pronethalol. This drug was briefly marketed as Alderlin, named after Alderly Park, the research headquarters of ICI Pharmaceuticals. Pronethalol was discontinued because it produced thymic tumors in mice. Propranolol was soon developed and marketed as Inderal (an incomplete anagram of Alderlin) in the United Kingdom in 1964[17,146] and in the United States in 1973.

Before the introduction of β-adrenergic antagonists, the management of angina was limited to medications such as nitrates that reduced preload through dilatation of the venous capacitance vessels and increased myocardial oxygen delivery by vasodilation of the coronary arteries. Propranolol gave clinicians the ability to decrease myocardial oxygen utilization. This new approach proved to decrease morbidity and mortality in patients with ischemic heart disease.[74] New drugs soon followed, and by 1979 there were ten β-adrenergic antagonists available in the United States.[37] Unfortunately it soon became apparent that these medications were dangerous when taken in overdose, and by 1979 cases of severe toxicity and death from β-adrenergic overdose were reported.[37] Today 19 β-adrenergic antagonists are approved by the Food and Drug Administration (FDA), and other β-adrenergic antagonists are available worldwide (Table 61–1).

EPIDEMIOLOGY

Intentional β-adrenergic antagonist overdose, although relatively uncommon, continues to account for a number of deaths annually. From 1985 to 1995, there were 52,156 β-adrenergic antagonist exposures reported to the American Association of Poison Control Centers (see Chap. 135). These exposures accounted for 164 deaths of which β-adrenergic antagonists were implicated as the primary cause of death in 38. The other fatalities could not be clearly ascribed to β-adrenergic antagonists because of cardioactive co-ingestants such as calcium channel blockers or other factors. Children younger than age 6 years accounted for 19,388 exposures, but no fatalities were reported in this age group. The youngest fatality reported in this series was 7 years old. It is interesting to note that more than 50% of the patients who died developed cardiac arrest after reaching healthcare personnel.[91] The number of exposures to β-adrenergic antagonists reported to the National Poison Data System (NPDS) has increased annually from 9500 in 1999 to nearly 20,000 in 2007. Each year in this period, β-adrenergic antagonist exposures resulted in 200 to 400 cases with a "major toxic effect" and 20 to more than 40 deaths. This changed in 2006, when deaths and major morbidity were only tabulated for single-substance exposures. In 2007, β-adrenergic antagonists were the sole ingestant in 61 exposures, with major morbidity and three deaths (see Chap. 135).

Compared with the other β-adrenergic antagonists, propranolol accounts for a disproportionate number of cases of self-poisoning[25,117] and deaths.[72,91] This may be explained by the fact that propranolol is frequently prescribed to patients with diagnoses such as anxiety, stress, and migraine who may be more prone to suicide attempts.[117] Propranolol is also more lethal because of its lipophilic and membrane stabilizing properties.[51,117]

TABLE 61–1. Pharmacologic Properties of the β-adrenergic Antagonists[38,51,109,154,101,165]

	Adrenergic Antagonist Activity	Partial Agonist Activity (ISA)	Membrane Stabilizing Activity	Vasodilating Property	Lipid Solubility	Protein Binding (%)	Oral Bio-availability (%)	Half-Life (h)	Metabolism	Volume of Distribution (L/kg)
Acebutolol*	β_1	Yes	Yes	No	Low	25	40	2–4	Hepatic or renal	1.2
Atenolol	β_1	No	No	No	Low	<5	40–50	5–9	Renal	1
Betaxolol (tablets and ophthalmic)	β_1	No	Yes	Yes (Calcium channel blockade)	Low	50	80–90	14–22	Hepatic or renal	NA
Bisoprolol	β_1	No	No	No	Low	30	8	9–12	Hepatic or renal	NA
Bucindolol[a]	β_1, β_2	No		Yes (β_2-agonism and α_1 blockade)	Moderate		30	8 ± 4.5	Hepatic	NA
Carteolol (ophthalmic)	β_1, β_2	Yes	No	Yes (β_2-agonism and nitric oxide mediated)	Low	30	85	5–6	Renal	NA
Carvedilol	β_1, β_2, α_1	No	Yes	Yes (α_1 blockade; calcium channel blockade)	Moderate	~98	25–35	6–10	Hepatic	115
Celiprolol[a]	α_2, β_1	No		Yes (β_2-agonism, nitric oxide mediated)	Low	22–24	30–70	5	Hepatic	NA
Esmolol	β_1	No	No	No	Low	50	NA	~8 min	RBC esterases	2
Labetalol	α_1, β_1, β_2	β_2	Low	Yes (α_1 blockade, β_2 agonism)	Moderate	50	20–33	4–8	Hepatic	9
Levobunolol (ophthalmic)	β_1, β_2	No	No	No	NA	NA	NA	6	NA	NA
Metipranolol (ophthalmic)	β_1, β_2	No	No	No	NA	NA	NA	3–4	NA	NA
Metoprolol (long-acting form available)	β_1	No	Low	No	Moderate	10	40–50	3–4	Hepatic	4
Nadolol	β_1, β_2	No	No	No	Low	20–30	30–35	10–24	Renal	2
Nebivolol[a]	β_1	No		Yes (nitric oxide mediated)	Moderate	98	12–96	8–32	Hepatic	10–40
Oxprenolol	β_1, β_2	Yes	Yes	No	Moderate	80	20–70	1–3	Hepatic	1.3
Penbutolol	β_1, β_2	Yes	No	No	High	90	~100	5	Hepatic or renal	NA
Pindolol	β_1, β_2	Yes	Low	No	Moderate	50	75–90	3–4	Hepatic or renal	2
Propranolol (long-acting form available)	β_1, β_2	No	Yes	No	High	90	30–70	3–5	Hepatic	4
Sotalol*	β_1, β_2	No	No	No	Low	0	90	9–12	Renal	2
Timolol (tablets and ophthalmic)	β_1, β_2	No	No	No	Moderate	60	75	3–5	Hepatic or renal	2

[a] Not approved by the Food and Drug Administration.

NA, information not available; ISA, intrinsic sympathomimetic activity.

* Also inhibits K channels.

PHYSIOLOGY AND PHARMACOLOGY

■ THE CARDIAC CYCLE

Normal cardiac electrical activity involves a complex series of ion fluxes that result in myocyte depolarization and repolarization. Cardiac electrical activity is coupled to myocyte contraction and relaxation respectively by increases and decreases in intracellular calcium concentrations that is closely regulated by the autonomic nervous system. In normal conditions, heart rate is determined by the rate of spontaneous discharge of specialized pacemaker cells that comprise the sinoatrial (SA) node (Fig. 61–1). Pacemaker cell depolarization is caused by either inward cation current through "pacemaker channels"[2,29] or through rhythmic release of calcium from the sarcoplasmic reticulum (SR).[99,100] β-adrenergic stimulation significantly increases the rate of pacemaker cell depolarization by phosphorylating SR proteins and by a direct phosphorylation-independent action of cyclic AMP (cAMP) at the pacemaker channels.[2,20,21,99] Depolarization of cells in the SA node initiates an electric current that spreads from cell to cell along specialized pathways to depolarize the entire heart. This depolarization, referred to as *cardiac excitation*, is linked to mechanical activity of the heart by the process of electrical–mechanical coupling described below (see Chap. 22 and 23).

Myocyte Calcium Flow and Contractility During systole, voltage sensitive slow L-type calcium channels on the myocyte membrane open in response to cell depolarization allowing calcium to flow down its concentration gradient into the myocyte (Fig. 61–2). Invaginations of the myocyte membrane (T-tubules) place L-type calcium channels in close proximation to calcium release channels (ryanodine receptors: RyR) on the SR. The local increase in calcium concentration that occurs after the opening of these L-type calcium channels (couplons) triggers the opening of the associated RyR channels, resulting in a large release of calcium from the SR, a phenomenon known as calcium-dependent calcium release.[45,167] Myocyte contraction requires synchronized release of calcium from numerous couplons throughout the myocyte. After its release from the SR, cytosolic calcium binds to troponin C and allows actin-myosin interaction and subsequent myocyte contraction. The strength of contraction is proportional to the amount of calcium release from the SR during depolarization, which depends, in part, on the magnitude of SR calcium stores. Actin–myosin interaction is also modulated by β-adrenergic–mediated troponin phosphorylation, ischemia, intracellular pH, and myofilament stretch.[11,13,15,127,153]

During diastole, several ion pumps actively remove calcium from the cytoplasm (Fig. 61–2). The most important of these are the SR calcium ATPase that pumps cytosolic calcium into the SR and the calcium–sodium transporter that exchanges one calcium ion for three sodium ions. The SR calcium ATPase is important for maintaining SR calcium stores and is modulated by β-adrenergic stimulation (see below). When calcium concentrations decrease during diastole, calcium dissociates from troponin, and relaxation occurs.[11,13,14,15,136]

FIGURE 61–1. Cardiac conduction system. (**A**) The cardiac cycle begins when pacemaker cells in the sinoatrial node depolarize spontaneously. Traditionally, this depolarization has been attributed to inward "pacemaker" currents (I_f). Recent evidence suggests that that pacemaker cell depolarization may be driven by cyclical calcium release from a "calcium clock" in the sarcoplasmic reticulum (SR) and modulated by the "pacemaker" currents (I_f). β-adrenergic stimulation increases both the frequency of the "calcium clock" by a protein kinase Cav-L = L type voltage dependent calcium channel A (PKA)–mediated effect and the magnitude of the pacemaker current secondary to a direct effect of cAMP. These effects both increase the heart rate. Cholinergic stimulation has the opposite effects and results in bradycardia. Pacemaker cells lack fast sodium channels. Pacemaker cell depolarization triggers the opening of voltage sensitive L-type calcium channels (I_{Ca}-L), and the impulse is transmitted to surrounding cells. (**B**) Coordinated sinoatrial nodal depolarization generates an impulse sufficient to open fast sodium channels in surrounding atrial tissue, and the impulse spreads along specialized pathways to depolarize the atria and ventricles.

FIGURE 61–2. Fluctuations in calcium concentrations couple myocyte depolarization with contraction and myocyte repolarization with relaxation. 1. Depolarization opens voltage-sensitive calcium channels (Ca$_v$-L) and calcium flows down its concentration gradient into the myocyte. 2. This calcium current triggers the opening of ryanodyne calcium release channels (RyR) in the sarcoplasmic reticulum (SR), and calcium pours out. The amount of calcium released is proportional to the initial inward calcium current and to the amount of calcium stored in the SR. 3. At rest, the actin-myosin interaction is prevented by troponin. When calcium binds to troponin, this inhibition is removed, actin and myosin slide relative to each other, and the cell contracts. 4. After contraction, calcium is actively pumped back into the SR primarily by a calcium ATPase (Ca-ATPase) to allow relaxation. Calcium stored in the SR is thus available for release during subsequent depolarizations. 5. Additionally, the sodium-calcium antiporter (NCX) couples the flow of three molecules of sodium in one direction to that of a single molecule of calcium in the opposite direction. This transporter is passively driven by electrochemical gradients, which usually favors the extrusion of calcium. However, the extrusion of calcium is inhibited by high intracellular sodium or extracellular calcium concentrations and by cell depolarization. Under these conditions, the pump may "run in reverse." 6. Some calcium is actively pumped from the cell by a calcium ATPase. 7. As myocyte calcium concentrations decrease, calcium is released from troponin, and the myocyte relaxes.   .

β-adrenergic Receptors and the Heart β-adrenergic receptors are divided into β_1, β_2, and β_3 subtypes. In the healthy heart, approximately 80% of human cardiac β-adrenergic receptors are β_1, and 20% are β_2. Human hearts may also contain a small number of β_3-adrenergic receptors.[23,40,126] The relative density of cardiac β_2-adrenergic receptors increases with heart failure.[23,147] β_1-adrenergic receptors mediate increased inotropy by a well-described pathway involving cAMP and protein kinases (Fig. 61–3). β_1-adrenergic receptors are coupled to G_s proteins that activate adenylate cyclase when the receptor is stimulated. This increases intracellular production of cAMP, which binds to and activates protein kinase A and other cAMP-dependent protein kinases.[81] Protein kinase A, in turn, phosphorylates important myocyte proteins, including phospholamban, the voltage-sensitive calcium channels, the SR Ca^{2+} release (RyR) channels, and troponin.[13,23,48,136,150,153] Phosphorylation of the L-type calcium channel increases contractility by increasing the influx of Ca^{2+} during each cell depolarization, triggering greater release of Ca^{2+} from the SR.[118,138,144] Phospholamban inhibits the SR calcium ATPase. Phosphorylation of phospholamban removes this inhibition and increases the activity of the sarcoplasmic calcium ATPase, resulting in increased SR Ca^{2+} stores and hence enhanced contractility.[27,150] Improved activity of the SR calcium ATPase also results in more rapid removal of cytoplasmic Ca^{2+} during diastole and aids in myocyte relaxation. Phosphorylation of the RyR channels results in more rapid release of Ca^{2+} from SR stores.[13,136,153] Troponin
FIGURE 61–3. β_1-adrenergic agonists are positive inotropes. 1. β_1-adrenergic receptors are coupled to G_s proteins, which activate adenyl cyclase when catecholamines bind to the receptor. This increases formation of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate. 2. Increased cAMP levels activate protein kinase A (PKA), which mediates the ultimate effects of β-adrenergic receptor stimulation by phosphorylating key intracellular proteins. 3. Phosphorylation of phospholamban disinhibits the sarcoplasmic reticulum (SR) calcium ATPase, resulting in increased SR calcium stores available for release during subsequent depolarizations, and phosphorylation of SR calcium release channels (RyR) enhances calcium release from the SR during contraction. 4. Phosphorylation of voltage-sensitive calcium channels increases calcium influx through these channels during systole. 5. Troponin phosphorylation improves cardiac performance by facilitating calcium unbinding during diastole. β_2 receptors are also coupled to G_s proteins and mediate positive inotropy through a cAMP mechanism (see text). Increased cAMP directly increases the heart rate (see Fig. 61–1A).

phosphorylation facilitates Ca^{2+} unbinding and thus improves cardiac performance by enhancing myocyte relaxation.[3,11,82,150] β_1-adrenergic receptors increase chronotropy by an incompletely understood mechanism that may involve phosphorylation of SR proteins, resulting in an increased rate of Ca^{2+} discharge from the SR[99,100] in addition to direct cAMP interaction with membrane-bound pacemaker channels.[2,21] Although β-adrenergic stimulation acutely improves cardiac function, chronic β-adrenergic stimulation results in a number of detrimental effects, including Ca^{2+} related increased risk of dysrhythmias, impaired excitation–contraction coupling, and possibly myocyte apoptosis.[13,23]

Cardiac β_2-adrenergic receptors also mediate increased inotropy and chronotropy; however, the mechanisms are less well understood than for β_1-adrenergic receptors. Under normal conditions, human cardiac β_2-adrenergic receptors, similar to β_1-adrenergic receptors, appear to be linked to excitatory G_s proteins so that β_2-adrenergic stimulation improves cardiac contractility, relaxation, and chronotropy through the protein kinase A pathway described above. In the failing heart, β_2-adrenergic receptors are also linked to inhibitory G_i proteins that, when stimulated by receptor binding, inhibit adenyl cyclase and reduce cAMP formation. β_2-adrenergic receptor stimulation may also improve contractility by increasing cytoplasmic pH independent of G-protein activation.[23,136,170]

Noncardiac Effects of β-Adrenergic Receptor Activation β-adrenergic agonists have important noncardiac effects. β–adrenergic receptors mediate smooth muscle relaxation in several organs. Relaxation of arteriolar smooth muscle predominately by β_2-adrenergic stimulation reduces peripheral vascular resistance and decreases blood pressure. This counteracts α-adrenergic–mediated arteriolar constriction. In the lungs, β_2-adrenergic receptors mediate bronchodilation. Third trimester uterine tone and contractions are inhibited by β_2-adrenergic agonists, and gut motility is decreased by both β_1- and β_2-adrenergic stimulation.

β-adrenergic receptors play a role in the immune system. Mast cell degranulation is inhibited by β_2-adrenergic stimulation, explaining the role of epinephrine in aborting and treating severe allergic reactions. Polymorphonuclear leukocytes demarginate in response to β-adrenergic stimulation, resulting in the increased white blood cell counts with catecholamine infusions or with increased endogenous release of epinephrine seen with pain or physiological stress.

β-adrenergic agonists also have important metabolic effects. Insulin secretion is increased by β_2-adrenergic receptor stimulation. Despite increased insulin concentrations, the net effect of β_2-adrenergic receptor stimulation is to increase glucose concentrations because of increased skeletal muscle glycogenolysis and hepatic gluconeogenesis and glycogenolysis. β_2-adrenergic receptors also cause glucagon secretion from pancreatic α cells.[73] β-adrenergic agonists act at fat cells, causing lipolysis and thermogenesis. Stimulation of adipocyte β-adrenergic receptors results in breakdown of triglycerides and release of free fatty acids. Skeletal muscle potassium uptake is increased by β_2-adrenergic stimulation, resulting in hypokalemia, explaining the role of β_2-adrenergic agonists in the treatment of hyperkalemia. Finally, renin secretion is increased by β_1-adrenergic stimulation, resulting in increased blood pressure.

■ ACTION OF β-ADRENERGIC ANTAGONISTS

β-adrenergic antagonists competitively antagonize the effects of catecholamines at β-adrenergic receptors and blunt the chronotropic and inotropic response to catecholamines. Bradycardia and hypotension may be severe in patients who take other xenobiotics that impair cardiac conduction or contractility and in those with underlying cardiac or medical conditions that make them reliant on sympathetic stimulation. In addition to slowing the rate of SA node discharge, β-adrenergic

antagonists inhibit ectopic pacemakers and slow conduction through atrial and AV nodal tissue. β-adrenergic antagonists block the detrimental effects of chronic overstimulation and have become the standard of care for patients with all stages of compensated chronic heart failure, including patients with stable New York Heart Association class III or IV disease.[1,44,169] Unfortunately, β-adrenergic antagonism may acutely exacerbate symptoms in patients with decompensated congestive heart failure.[108,159]

The antihypertensive effect of β-adrenergic antagonists is counteracted by a reflex increase in peripheral vascular resistance. This effect is augmented by the β_2-adrenergic antagonism of nonselective β-adrenergic antagonists. By causing increased peripheral vascular resistance, β_2-adrenergic antagonists may rarely worsen peripheral vascular disease.

Patients with reactive airways disease may experience severe bronchospasm after using β-adrenergic antagonists because of a loss of β_2-adrenergic–mediated bronchodilation. Catecholamines inhibit mast cell degranulation through a β_2-adrenergic mechanism. Interference with this may predispose to life-threatening effects after anaphylactic reactions in atopic individuals.[61] β_2-adrenergic antagonists impair the ability to recover from hypoglycemia and may mask the sympathetic discharge that serves to warn of hypoglycemia. This combination of effects is dangerous for diabetic patients at risk for hypoglycemic episodes.[165]

β_2-adrenergic antagonism inhibits catecholamine-mediated K^+ uptake at skeletal muscle. This may cause slight elevations in serum K^+, concentrations, especially after exercise. Although β_2-adrenergic stimulation augments insulin release, β-adrenergic antagonists seldom lower insulin concentrations and may actually cause hypoglycemia by interference with glycogenolysis and gluconeogenesis. As mentioned above, these effects are important in diabetics at risk for hypoglycemia. β-adrenergic antagonists also alter lipid metabolism. Although the release of free fatty acids from adipose tissue is inhibited, patients taking nonselective β-adrenergic antagonists typically have increased serum concentrations of triglycerides and decreases in high-density lipoproteins.[165]

PHARMACOKINETICS

The pharmacokinetic properties of the β-adrenergic antagonists depend in large part on their lipophilicity. Propranolol is the most lipid soluble, and atenolol is the most water soluble. The oral bioavailability ranges from approximately 25% for propranolol to almost 100% for pindolol and penbutolol.

The highly lipid soluble drugs cross lipid membranes rapidly and concentrate in adipose tissue. These properties allow rapid entry into the central nervous system (CNS) and typically result in large volumes of distribution. In contrast, highly water-soluble drugs cross lipid membranes slowly, distribute in total body water, and tend to have less CNS toxicity. Volumes of distribution range from about 1 L/kg for atenolol to more than 100 L/kg for carvedilol.

The highly lipid-soluble β-adrenergic antagonists are highly protein bound and are therefore poorly excreted by the kidneys. They require hepatic biotransformation before they can be eliminated and tend to accumulate in patients with liver failure. In contrast, the water-soluble β-adrenergic antagonists tend to be slowly absorbed, poorly protein bound, and renally eliminated. They tend to accumulate in patients with renal failure. Esmolol, although water soluble, is rapidly metabolized by red blood cell esterases and does not accumulate in renal failure. The half life of esmolol is about 8 minutes. Half lives of the other β-adrenergic antagonists range from about 2 hours for oxprenolol to as much as 32 hours for nebivolol. The β-adrenergic antagonists also differ in their β_1-adrenergic selectivity, intrinsic sympathomimetic activity (ISA), and vasodilatory properties[109,116,119,151,165] (see Table 61–1 and below).

■ β_1 SELECTIVITY (ACEBUTOLOL, ATENOLOL, BETAXOLOL, BISOPROLOL, CELIPROLOL, ESMOLOL, METOPROLOL, NEBIVOLOL)

β_1-selective antagonists may avoid some of the adverse effects of the nonselective antagonists. Short-term use of β_1-adrenergic selective antagonists appears to be safe in patients with mild to moderately severe reactive airways.[131] These drugs may be safer for patients with diabetes mellitus or peripheral vascular disease and may be more effective antihypertensive agents. Their β_1-adrenergic selectivity, however, is incomplete, and adverse reactions secondary to β_2-adrenergic antagonism may occur with therapeutic dosage as well as in overdose.[83,165]

■ MEMBRANE-STABILIZING EFFECTS (ACEBUTOLOL, BETAXOLOL, CARVEDILOL, OXPRENOLOL, PROPRANOLOL)

β-adrenergic antagonists that inhibit fast sodium channels (also known as type I antidysrhythmic activity) are said to possess membrane-stabilizing activity. No significant membrane stabilization occurs with therapeutic use of β-adrenergic antagonists, but this property contributes to toxicity in overdose.

■ INTRINSIC SYMPATHOMIMETIC ACTIVITY (ACEBUTOLOL, CARTEOLOL, OXPRENOLOL, PENBUTOLOL, PINDOLOL)

These antagonists act as partial agonists at β-adrenergic receptors and are said to have ISA. This property avoids the severe decrease in resting heart rate that occurs with β-adrenergic antagonism in susceptible patients, but the clinical benefit is not demonstrated in controlled trials.[35]

■ POTASSIUM CHANNEL BLOCKADE (ACEBUTOLOL, SOTALOL)

Sotalol is a nonselective β-adrenergic antagonist with low lipophilicity, no membrane stabilizing effect, and no ISA. Sotalol blocks the delayed rectifier potassium current responsible for repolarization, prolonging the action potential duration. This is manifested on the electrocardiogram (ECG) by a prolonged QT interval.[57] The prolonged QT interval predisposes to torsades de pointes, and ventricular dysrhythmias may complicate the therapeutic use of sotalol.[71] In patients taking sotalol therapeutically, torsades de pointes occurs more commonly in those who have renal failure, use other xenobiotics that prolong the QT interval, or have predisposing factors for QT prolongation such as hypokalemia, hypomagnesemia, bradycardia, or congenital QT prolongation.[26,57] Some authors suggest that QT dispersion is a better predictor of sotalol-induced torsades de pointes than QT prolongation alone. A difference between the longest and shortest QT interval on the 12-lead ECG of more than 100 msec indicates an increased risk of torsade de pointes.[26] Acebutolol also prolongs the QT interval presumably secondary to blockade of outward potassium channels.[88]

■ VASODILATION (BETAXOLOL, BUCINDOLOL, CARTEOLOL, CARVEDILOL, CELIPROLOL, LABETALOL, NEBIVOLOL)

Labetalol and the newer "third-generation" β-adrenergic antagonists (betaxolol, bucindolol, carteolol, carvedilol, celiprolol, nebivolol) are also vasodilators. Labetalol and carvedilol are nonselective β-adrenergic antagonists that also possess α-adrenergic antagonist activity. Nebivolol is a selective β_1-adrenergic antagonist that causes vasodilation by release of nitric oxide.[101] Bucindolol, carteolol, and celiprolol vasodilate because

they are agonists at the β_2-adrenergic receptors. Celiprolol and carteolol also vasodilate because of nitric oxide–mediated effects. Bucindolol and celiprolol are not FDA approved. Carteolol is currently available as an ocular preparation. Betaxolol and carvedilol also have calcium channel blocking properties that result in vasodilation (see Table 61–1). β-adrenergic antagonists with vasodilating properties may be particularly beneficial for patients with congestive heart failure.[114] These medications may also have a role in managing patients with coronary artery disease or peripheral vascular disease. Those drugs with β_2-adrenergic agonist activity may prove useful for patients with reactive airways.

β-adrenergic antagonists should not be given without appropriate α-adrenergic blockade in situations of catecholamine excess such as pheochromocytoma or cocaine use. In these conditions, β_2-adrenergic mediated vasodilation is essential to counteract α-adrenergic mediated vasoconstriction. Administration of β-adrenergic antagonists would result in an "unopposed α" adrenergic effect, causing dangerous increases in vascular resistance. Even the β-adrenergic antagonists with combined α-adrenergic antagonism may cause this problem. Labetalol, for example, is five- to 10-fold more potent as a β-adrenergic antagonist than as an α-adrenergic antagonist. Theoretically, medications with β_2-adrenergic agonist properties may avoid the "unopposed α" effect, but their availability is limited, and use in this situation has not yet been investigated.[33,42,101,154,165]

■ **OTHER PREPARATIONS (OPHTHALMIC PREPARATIONS, SUSTAINED-RELEASE PRODUCTS, COMBINED PRODUCTS)**

Therapeutic use of ophthalmic solutions containing β-adrenergic antagonists may cause systemic adverse effects such as bradycardia, high-grade atrioventricular (AV) block, heart failure, and bronchospasm.[38,104,139,165] An extended-release tablet containing a combination of the calcium channel blocker felodipine and metoprolol has been studied as an antihypertensive medication.[47] This medication (Logimax, Astra-Zeneca) is marketed in more than 35 countries worldwide but is not available in the United States or Canada. Another combined β-adrenergic antagonist and calcium channel blocker containing atenolol and nifedipine (Nif-Ten, Astra-Zeneca) is also used as an antihypertensive agent.[31]

PATHOPHYSIOLOGY

Most of the toxicity of β-adrenergic antagonists is because of their ability to competitively antagonize the action of catecholamines at cardiac β-adrenergic receptors. The peripheral effects of β-adrenergic antagonism are less prominent in overdose. β-adrenergic antagonists also appear to have toxic effects independent of their action at catecholamine receptors. In catecholamine-depleted, spontaneously beating isolated rat hearts, propranolol, timolol, and sotalol all decreased heart rate and contractility.[28] Surprisingly, these effects were similar in catecholamine-depleted and nondepleted hearts.[77] A membrane depressant effect likely contributes to the cardiac depressant effects of propranolol but not to that of timolol or sotalol. It may be concluded that β-adrenergic antagonists cause myocardial depression at least in part by an action independent of catecholamine antagonism or membrane depressant activity.[77]

Other investigators studied the role of extracellular ions and cardiac membrane potential in modulating β-adrenergic antagonist toxicity. β-adrenergic antagonists interfere with Ca^{2+} uptake into intracellular organelles. This interference with cytosolic Ca^{2+} handling may stimulate Ca^{2+} sensitive outward potassium channels and result in myocyte hyperpolarization and subsequent refractory bradycardia. Decreasing extracellular potassium or increasing extracellular Na^+ concentrations

was conjectured to counteract this effect and, in fact, partially reversed propranolol and atenolol toxicity in isolated rat hearts.[64] In another series of experiments with isolated rat hearts, calcium improved the function of rat hearts poisoned with β-adrenergic antagonists. This may have been caused by a nonspecific positive inotropic action of Ca^{2+}.[75] Although cardiovascular effects are most prominent in overdose, β-adrenergic antagonists also cause respiratory depression.[76] This effect is centrally mediated and appears to be an important cause of death in spontaneously breathing animal models of β-adrenergic antagonism toxicity.[75] Propranolol may interfere with synaptic transmission, which may explain some of the CNS effects noted in propranolol overdose.

CLINICAL MANIFESTATIONS

Symptoms of toxicity generally occur within 2 hours after immediate-release β-adrenergic antagonist overdose. Propranolol overdose, in particular, may be complicated by the rapid development of hypoglycemia, seizures, coma, and dysrhythmias. In a retrospective review of published reports of adult β-adrenergic antagonist overdose, there were 39 symptomatic patients with well-documented times from ingestion to symptom onset. Only one patient had ingested a sustained-release product. Thirty-one patients were symptomatic at 2 hours, all but one developed symptoms by 4 hours, and all of the patients developed symptoms within the first 6 hours. The authors concluded that there have been no well-documented reports of immediate-release β-adrenergic antagonist overdose resulting in toxicity delayed more than 6 hours after ingestion.[85] In 58 patients with β-adrenergic antagonist overdose, all major symptoms began within 6 hours of ingestion.[117] These observations do not apply to sotalol, which is well known to cause delayed toxicity in overdose, nor to sustained-release preparations.

Isolated β-adrenergic antagonist overdose in healthy people is often benign. In several series, one-third or more of patients reporting a β-adrenergic overdose remained asymptomatic.[32,87,151] This is partially explained by the fact that β-adrenergic antagonism is often well tolerated in healthy persons who do not rely on sympathetic stimulation to maintain cardiac output. In particular, unintentional ingestions in children rarely result in significant toxicity.[12] In fact, a recent review of published cases found a few reports of hypoglycemia but no deaths or serious cardiovascular morbidity after β-adrenergic antagonist ingestion in children younger than age 6 years.[93] This finding should be interpreted with caution because actual ingestion of a β-adrenergic antagonist was not confirmed in most cases.

β-adrenergic antagonists severely impair the heart's ability to respond to peripheral vasodilation, bradycardia, or decreased contractility caused by other toxins. Therefore, even relatively benign vasoactive xenobiotics may cause catastrophic toxicity when co-ingested with β-adrenergic antagonists. Thus, an important predictor of toxicity in β-adrenergic antagonist overdose is likely to be the presence of a cardioactive co-ingestant.[84] Isolated β-adrenergic antagonist overdose is most likely to cause symptoms in persons with congestive heart failure, sick sinus syndrome, or impaired AV conduction who rely on sympathetic stimulation to maintain heart rate or cardiac output. Nevertheless, severe toxicity and death may still occur in healthy persons who have ingested β-adrenergic antagonists alone.[37,117,145] This may be explained by an increased susceptibility of certain persons to β-adrenergic antagonism or by special properties that increase the toxicity of certain β-adrenergic antagonists (see below). In patients without a co-ingestant, toxicity is most likely to occur in those who ingest a β-adrenergic antagonist with membrane-stabilizing activity.[84]

Patients with symptomatic β-adrenergic antagonist overdose will most often be hypotensive and bradycardic. Decreased SA node function results in sinus bradycardia, sinus pauses, or sinus arrest. Impaired

AV conduction manifested as prolonged PR interval or high-grade AV block occurs rarely. Prolonged QRS and QT intervals may occur, and severe poisonings may result in asystole. Congestive heart failure often complicates β-adrenergic antagonist overdose. Delirium, coma, and seizures occur most commonly in the setting of severe hypotension but may also occur with normal blood pressure, especially with exposure to the more lipophilic agents such as propranolol.[37,117] Respiratory depression and apnea may have an additional role in toxicity.[6] In a review of reported cases, 18% of patients with propranolol toxicity and 6% of those with atenolol toxicity had a respiratory rate less than 12 breaths/min.[117] Respiratory depression after β-adrenergic antagonist overdose typically occurs in patients who are hypotensive and comatose but is also reported in awake patients.[105] Hypoglycemia may complicate β-adrenergic antagonist poisoning in children[55,93] but is uncommon in acutely poisoned adults. In a series of 15 cases of β-adrenergic antagonist overdose, none of the 13 adults were hypoglycemic, but both of the two children had symptomatic hypoglycemia.[37] Bronchospasm is relatively uncommon after β-adrenergic antagonist overdose and appears to occur only in susceptible patients. In the series mentioned above, only two of the 15 patients developed bronchospasm,[37] and in a recent review of 39 cases of symptomatic adults with β-adrenergic antagonist overdose, only one patient developed bronchospasm.[85] Clinical use of β-adrenergic antagonists slightly increases serum K^+, concentration[94] but significant hyperkalemia is rare.

β₁ SELECTIVITY

In overdose, cardioselectivity is largely lost, and deaths attributable to the β₁-adrenergic selective agents, including acebutolol,[51] atenolol,[91] betaxolol, and metoprolol,[121,145] have been reported. There have been single reports of minor toxicity after overdose with bisoprolol[154] and nebivolol.[50]

MEMBRANE-STABILIZING EFFECTS

Propranolol possesses the most membrane-stabilizing activity of this class, and propranolol poisoning is characterized by coma, seizures, hypotension, bradycardia, impaired AV conduction, and prolonged QRS interval. Ventricular tachydysrhythmias may also occur.[4,91] Hypotension may be out of proportion to bradycardia, and deaths from propranolol overdose are well reported.[37,51,91] Acebutolol, betaxolol, and oxprenolol also possess significant membrane-stabilizing activity and have caused fatalities when taken in overdose.[51,109,115]

LIPID SOLUBILITY

In overdose, the more lipophilic β-adrenergic antagonists may cause delirium, coma, and seizures even in the absence of hypotension.[37,117] Atenolol, the least lipid soluble of the β-adrenergic antagonists, appears to be one of the safer β-adrenergic antagonists when taken in overdose.[51] In fact, in one series of β-adrenergic antagonist overdoses, none of the 18 patients with atenolol overdose had seizures compared with eight of 28 patients with propranolol overdose.[117] Nevertheless, atenolol overdose may result in severe toxicity and cardiovascular death.[91,112,148]

INTRINSIC SYMPATHOMIMETIC ACTIVITY

There is little experience with overdose of these medications, but ISA would theoretically make them safer than the other β-adrenergic antagonists. Sympathetic stimulation with mild tachycardia or hypertension often predominates in patients with pindolol overdose.[37,72,116] In addition to ISA, acebutolol and oxprenolol have significant membrane-stabilizing activity, making them dangerous in overdose; deaths have been reported.[37,51,88,115] Overdose with carteolol or penbutolol has not been reported.

POTASSIUM CHANNEL BLOCKADE

In six patients with sotalol overdose, the average QT interval was 172% of normal, and five patients had ventricular dysrhythmias, including multifocal ventricular extrasystoles, ventricular tachycardia, and ventricular fibrillation.[107] Sotalol overdose may also be complicated by hypotension, bradycardia, and asystole,[5,107] and fatalities are well documented.[111]

Sotalol overdose may cause delayed and prolonged toxicity, although ECG changes appear to occur early. In a series of six patients with sotalol overdose, all had prolonged QT interval noted on the initial ECG taken 30 minutes to 4.5 hours after ingestion. The authors do not specify whether these patients were taking sotalol therapeutically before the overdose, so it is possible that the prolonged QT on the initial ECG was present before the overdose.[107] The greatest QT prolongation occurred 4 to 15 hours after ingestion, and the risk of ventricular dysrhythmias was highest between 4 and 20 hours. All four patients who developed ventricular tachycardia did so after 4 hours, and in two patients, ventricular dysrhythmias first occurred 9 hours after ingestion. One patient continued to have ventricular dysrhythmias at 48 hours, and abnormally prolonged QT intervals were noted as long as 100 hours after ingestion. In this series, the average sotalol half-life was 13 hours, and the average time until normalization of the QT interval was 82 hours.[107] Acebutolol-induced QT interval prolongation may partially explain the ventricular tachydysrhythmias that occur with severe acebutolol toxicity.[30,88,91]

VASODILATION

The vasodilatory properties of these antagonists would theoretically act in synergy with β-adrenergic antagonism to increase toxicity. Conversely, the low membrane-stabilizing effect of these drugs may make them relatively safe in overdose. Betaxolol is the sole drug in this class with membrane-stabilizing properties. Overdose with labetalol appears to be similar to that of other β-adrenergic antagonists, with hypotension and bradycardia as prominent features.[67,68] Experience with overdose of the newer vasodilating β-adrenergic antagonists is extremely limited. There have been two reports of carvedilol overdose, and clinical manifestations were similar to those caused by poisoning with conventional β-adrenergic antagonists. One patient developed hypotension and bradycardia responsive to dopamine.[46] The second patient chewed carvedilol tablets and developed a rapid onset of hypotension and bradycardia responsive to glucagon and dopamine.[18] Both patients had full recoveries. In a single case report from Germany, nebivolol overdose was complicated by bradycardia, lethargy, and hypoglycemia. The patient received standard treatment and had a benign outcome.[50] Severe toxicity and death have occurred after betaxolol[16] and celiprolol[125] poisoning. Overdoses with bucindolol or carteolol have not been reported.

OTHER PREPARATIONS

There is very little published experience with overdoses of the sustained release β-adrenergic antagonists, but it is reasonable to expect that overdose with these agents will result in both a delayed onset and prolonged duration of toxicity. Acute overdose of ophthalmic β-adrenergic antagonists has not been reported. Patients who take mixed overdoses with calcium channel blockers and β-adrenergic antagonists are difficult to manage because of synergistic toxicity.[130,137,142] Overdoses with combined β-adrenergic antagonist and calcium channel blocker preparations such as Logimax (felodipine and metoprolol) or Nif-Ten (atenolol and nifedipine) have not been reported, but these combinations would be expected to be quite dangerous in overdose.

DIAGNOSTIC TESTING

All patients with an intentional overdose of a β-adrenergic antagonist should have a 12 lead ECG and continuous cardiac monitoring performed. Serum glucose concentration should be measured regardless of the patient's mental status because β-adrenergic antagonists may cause hypoglycemia. A chest radiograph and measurement of oxygen saturation should be obtained if the patient is at risk for or experiencing symptoms of congestive heart failure. For patients with bradycardia of uncertain etiology, measurement of thyroid function, serum K^+ concentration, renal function, cardiac enzymes, and digoxin concentration may prove helpful. Serum concentrations of β-adrenergic antagonists are not readily available for routine clinical use but may prove helpful in making a retrospective diagnosis in selected cases.

MANAGEMENT

The airway and ventilation should be maintained with endotracheal intubation if necessary. Because laryngoscopy may induce a vagal response, it is reasonable to give atropine before intubation of patients with bradycardia. This is particularly true for children, who are more susceptible to this complication. The initial treatment of bradycardia and hypotension consists of atropine and fluids. These measures will likely be insufficient in patients with severe toxicity but may suffice in patients with mild poisoning or other causes of bradycardia.

Gastrointestinal (GI) decontamination is warranted for all persons who have ingested significant amounts of a β-adrenergic antagonist. Induction of emesis is contraindicated because of the potential for catastrophic deterioration of mental status and vital signs in these patients and because vomiting increases vagal stimulation and may worsen bradycardia.[143] Orogastric lavage is recommended for patients with significant symptoms such as seizures, hypotension, or bradycardia if the drug is still expected to be in the stomach. Orogastric lavage is also recommended for all patients who present shortly after ingestion of large (gram amount) ingestions of propranolol or one of the other more toxic β-adrenergic antagonists (ie, acebutolol, betaxolol, metoprolol, oxprenolol, sotalol). Orogastric lavage causes vagal stimulation and carries the risk of worsening bradycardia, so it is reasonable to pretreat patients with standard doses of atropine. We recommend activated charcoal alone for persons with minor symptoms after an overdose with one of the more water-soluble β-adrenergic antagonists who present later than 1 hour after ingestion. Whole-bowel irrigation with polyethylene glycol should be considered in patients who have ingested sustained-release preparations (see Antidotes in Depth: Whole Bowel Irrigation).

Seizures or coma associated with cardiovascular collapse are treated by attempting to restore circulation. Seizures in a patient with relatively normal vital signs should be treated with benzodiazepines followed by propofol if benzodiazepines fail. Refractory seizures are rare in β-adrenergic antagonist overdose.

Patients who fail to respond to atropine and fluids require management with the inotropes discussed below (Fig. 61–4). When time permits, it is preferable to introduce new medications sequentially so that the effects of each may be assessed. We recommend glucagon followed by calcium, high-dose insulin euglycemia therapy, a catecholamine pressor, and if this fails, phosphodiesterase inhibitors. In critically ill patients, there may not be enough time for this approach, and multiple treatments may be started simultaneously. Advanced hemodynamic monitoring, when available, is advisable to guide therapy for all patients receiving catecholamine pressors or phosphodiesterase inhibitors. Intravenous fat emulsion should be considered for patients
FIGURE 61–4. Positive inotropes improve cardiac function by a number of mechanisms, which usually result in increased intracellular calcium. 1. Xenobiotics that increase cyclic adenosine monophosphate (cAMP): Glucagon receptors and β-adrenergic receptors are coupled to G_s proteins; receptor binding increases cAMP by activation of adenyl cyclase. Phosphodiesterase inhibitors (PDEI) increase cAMP by inhibiting its breakdown. 2. Calcium salts increase calcium influx through the L-type voltage dependent calcium channel (Ca_v-L) during cell depolarization and result in higher intracellular calcium stores. 3. Xenobiotics that inhibit extrusion of calcium via the sodium-calcium exchange pump (NCX), including xenobiotics that increase intracellular sodium, such as cardioactive steroids and sodium channel agonists (eg, aconitine). 4. Xenobiotics that increase the sensitivity of the contractile elements to calcium: Angiotensin II and endothelin do this by inducing an intracellular alkalosis. The calcium sensitizers levosimendan and pimobendan (not shown) can be used to treat heart failure.

who fail this therapy. Mechanical life support with intra-aortic ballon pump or extracorporeal circulation may be lifesaving when medical management fails.

◼ GLUCAGON

Cardiac glucagon receptors, similar to β-adrenergic receptors, are coupled to G_s proteins. Glucagon binding increases adenyl cyclase activity independent of β-adrenergic receptor binding.[171] The inotropic effect of glucagon is enhanced by its ability to inhibit phosphodiesterase and thereby prevent cAMP breakdown.[103]

No controlled trials of glucagon in human cases of β-adrenergic antagonist poisoning have been conducted.[9,19] Nevertheless, with more than 30 years of clinical use,[70,161] glucagon is still recognized as a useful treatment of choice for severe β-adrenergic antagonist toxicity.[63,113,151,164] This is supported by animal models[41,69,90] and a case series suggesting that glucagon is also effective in correcting symptomatic bradycardia and hypotension secondary to therapeutic β-adrenergic antagonist use.[92] Glucagon is a vasodilator, and in animal models of propranolol poisoning, it is more effective in restoring contractility, cardiac output, and heart rate than in restoring blood pressure.[9,90]

The initial adult dose of glucagon for β-adrenergic antagonist toxicity is 3 to 5 mg given slowly over 1 to 2 minutes. The initial pediatric dose is 50 μg/kg. If there is no response to the initial dose, higher doses up to a total of 10 mg may be used. When a response occurs, a glucagon infusion is started. Most authors recommend using an infusion of 2 to 5 mg/h, although many authorities recommend glucagon infusions as high as 10 mg/h. We suggest that the glucagon infusion be started at the "response dose" per hour. Thus, for example, if the patient receives 7 mg of glucagon before a response occurs, the glucagon infusion should be started at 7 mg/h. When a full dose of glucagon fails to restore blood pressure and heart rate and the diagnosis of β-adrenergic antagonist toxicity is probable, we would still recommend starting an infusion of glucagon at 10 mg/h because glucagon will have synergistic effects with subsequent therapies. Glucagon may cause vomiting with a risk of aspiration. Other side effects of glucagon in this setting include hyperglycemia and mild hypocalcemia,[60] and these should be treated appropriately if they develop. Patients also develop rapid tachyphylaxis to glucagon, and the need for increasing doses and additional therapies should be expected, even when patients initially respond (see Antidotes in Depth A19: Glucagon).

CALCIUM

Calcium salts effectively treat hypotension but not heart rate in animal models of β-adrenergic antagonist toxicity.[75,86] Calcium chloride successfully reverses hypotension in patients with β-adrenergic antagonist overdose[22,112] and in combined calcium channel blocker and β-adrenergic antagonist toxicity.[52] The adult starting dose of calcium gluconate is 3 g of the 10% solution given intravenously (IV). We recommend using up to 9 g of calcium gluconate if needed. The initial dose of calcium gluconate in children is 60 mg/kg up to 3 g. This may be repeated up to a total of 180 mg/kg (see Antidotes in Depth A30: Calcium).

INSULIN AND GLUCOSE

High-dose insulin, euglycemia therapy improves cardiac function after cardiac surgery[43] and survival after myocardial infarction.[34,96-98] There is evidence that high-dose insulin combined with sufficient glucose to maintain euglycemia is beneficial in patients with β-adrenergic antagonist poisoning. In a canine model of propranolol toxicity, all six animals treated with insulin and glucose survived compared with 4 of six in the glucagon group, one of six in the epinephrine group, and no survivors in the sham treatment group.[65] Insulin plus glucose was markedly more effective than vasopressin plus epinephrine in a porcine model of propranolol toxicity. In that experiment, all five animals in the insulin group survived the 4-hour protocol, and all five in the vasopressin plus epinephrine group died within 90 minutes.[58] A patient who ingested atenolol and amlodipine had a beneficial response to high-dose insulin.[173] High-dose insulin is simple to use, safe (with appropriate monitoring of glucose and potassium), and does not require invasive monitoring. For these reasons and despite limited clinical experience, we recommend using high-dose insulin and glucose infusions for patients with β-adrenergic antagonist toxicity who have not responded to fluids, atropine, and glucagon. Although the dose of insulin is not definitively established, therapy typically begins with a bolus of 1 Unit/kg of regular human insulin along with 0.5 g/kg of dextrose. If blood glucose is greater than 400 mg/dL (22.2 mmol/L), the dextrose bolus is not necessary. An infusion of regular insulin should follow the bolus starting at 0.5 Unit/kg/h titrated up to 2 Unit/kg/h if there is no improvement after 30 minutes. A continuous dextrose infusion beginning at 0.5 g/kg/h should also be started. Glucose should be monitored every half hour for the first 4 hours and titrated to maintain euglycemia. The response to insulin is typically delayed for 15 to 60 minutes, so

it is usually necessary to start a catecholamine infusion before the full effects of insulin are apparent. It is important to continue monitoring glucose and electrolytes for several hours after insulin is discontinued (see Antidotes in Depth A18: Insulin-Euglycemia Therapy).

CATECHOLAMINES

Patients who do not respond to the preceding therapies usually require a catecholamine infusion. The choice of catecholamine is somewhat controversial. Theoretically, the pure β-adrenergic agonist isoproterenol would seem to be ideal because it can overcome β-adrenergic blockade without causing any α-adrenergic effects. Unfortunately, this therapy has several potential drawbacks that limit its efficacy. In the presence of β-adrenergic antagonism, extraordinarily high doses of isoproterenol and other catecholamines are frequently required.[25,115,120,151,158] Individual case reports document isoproterenol infusions as high as 800 μg/min.[116] At these high doses, the $β_2$-adrenergic effects of isoproterenol cause peripheral vasodilation and may actually lower blood pressure.[120] Nevertheless, in some animal models, isoproterenol is the most effective catecholamine and is even more effective than glucagon in reversing β-adrenergic antagonist toxicity.[149,162] Clinical experience, however, has not shown this to be the case.

In a review of reported cases, glucagon increased heart rate 67% of the time and blood pressure 50% of the time. In contrast, isoproterenol was effective in increasing heart rate only 11% of the time and blood pressure only 22% of the time. Epinephrine was more effective than isoproterenol.[164] The selective $β_1$-adrenergic agonist prenalterol may avoid some of the problems associated with isoproterenol and was used successfully to treat patients with β-adrenergic antagonist overdose.[36,72] However, prenalterol is not FDA approved, and its relatively long half life (~2 hours) makes titration difficult.[123] Dobutamine is a $β_1$-adrenergic agonist with relatively little effect on vascular resistance that may be useful in this setting. However, experience is limited, and dobutamine is not always effective in patients with β-adrenergic antagonist overdose.[115,141] In the setting of β-adrenergic antagonism, catecholamines with substantial α-adrenergic agonist properties may increase peripheral vascular resistance without improving contractility, resulting in acute cardiac failure.

Severe hypertension caused by a lack of $β_2$-adrenergic–mediated vasodilation is another potential adverse reaction from this so called "unopposed α" adrenergic effect.[39] Because of these potential problems, we recommend that catecholamine use be guided by hemodynamic monitoring using clinical criteria, noninvasive techniques such as bioimpedance or echocardiographic monitoring, or direct invasive measures of determining cardiac performance. Catecholamine infusions should be started at the usual rates and then increased rapidly until a clinical effect is obtained. If advanced monitoring is impossible and the diagnosis of β-adrenergic antagonist overdose is fairly certain, it is reasonable to begin an isoproterenol or epinephrine infusion with careful monitoring of the patient's blood pressure and clinical status. The infusion should be stopped immediately if the patient becomes more hypotensive or develops congestive heart failure.

PHOSPHODIESTERASE INHIBITORS

The phosphodiesterase inhibitors inamrinone, milrinone, and enoximone are theoretically beneficial in β-adrenergic antagonist overdose because they inhibit the breakdown of cAMP by phosphodiesterase and hence increase cAMP independently of β-adrenergic receptor stimulation. Phosphodiesterase inhibitors increase inotropy in the presence of β-adrenergic antagonism in both animal models[78] and in humans.[156] Although these therapies appear to be as effective as glucagon in

animal models of β-adrenergic antagonist toxicity,[90,134] controlled dog models were unable to demonstrate an additional benefit of over glucagon.[89,135] Phosphodiesterase inhibitors might be useful in selected patients who fail glucagon therapy and have been used clinically to treat β-adrenergic antagonist–poisoned patients.[67,132,133] Therapy with phosphodiesterase inhibitors is often limited by hypotension secondary to peripheral vasodilation. Furthermore, these medications are difficult to titrate because of relatively long half-lives (ie, 30 to 60 minutes for milrinone, 2 to 4 hours for inamrinone, and approximately 2 hours for enoximone).[106] For these reasons, the phosphodiesterase inhibitors should generally only be considered for patients who have arterial or pulmonary artery pressure monitoring.

■ VENTRICULAR PACING

Ventricular pacing is not a particularly useful intervention in patients with β-adrenergic antagonist toxicity, but it increases the heart rate in some patients.[62] Unfortunately, there will frequently be failure to capture or pacing may increase the heart rate with no increase in cardiac output or blood pressure.[4,72,151] In fact, some authors have noticed that ventricular pacing occasionally decreases blood pressure perhaps secondary to loss of organized atrial contraction or because of impaired ventricular relaxation.[151]

■ EXTRACORPOREAL REMOVAL

Extracorporeal removal is ineffective for the lipid-soluble β-adrenergic antagonists because of their large volumes of distribution. Hemodialysis may remove water-soluble, renally eliminated β-adrenergic antagonists such as atenolol[129] and acebutolol.[124] Because hemodialysis is often technically difficult in poisoned patients because of hypotension and bradycardia, it is rarely used in patients with β-adrenergic antagonist overdose but may be considered in selected cases.

■ MECHANICAL LIFE SUPPORT

It is important to remember that patients with severe hypotension from an acute overdose typically recover without sequelae if ventilation and circulation can be maintained until the xenobiotic is eliminated. When the preceding medical treatment fails, it is appropriate to consider the use of an intra-aortic balloon pump or extracorporeal circulation. Several case reports describe remarkable recoveries after the use of these therapies for refractory β-adrenergic antagonist toxicity[16,102] or combined β-adrenergic antagonist and calcium channel blocker overdose.[66,128,168] A case series documents experience with extracorporeal membrane oxygenation (ECMO) for patients with cardiac arrest caused by cardiovascular drug poisoning. In this series of six patients, two deaths were attributed to the delay to institution of ECMO. The other four patients survived without sequelae.[8]

■ EXPERIMENTAL TREATMENT

Intravenous fat emulsion (IFE) is a promising new antidote that may have a role in selected cases of severe β-adrenergic antagonist overdose. IV administration of lipid emulsion is hypothesized to reduce the toxicity of lipid-soluble agents by lowering free serum concentrations of these xenobiotics as they partition into the lipemic component of blood and improve the bioenergetics of the heart. Although clinical experience is lacking, it is reasonable based on animal models to consider the use of IV fat emulsion in patients with toxicity from a lipid-soluble β-adrenergic antagonist that does not respond to usual therapy.[24,49] The optimal dose and formulation of intravenous fat emulsion for this purpose is unknown. One protocol for the use of lipid emulsion for severe local anesthetic toxicity calls for a 1.5 mL/kg of 20% IFE followed

by an infusion of 0.25 mL/kg/min. The bolus can be repeated in 3 to 5 minutes if necessary. The total dose should be less than 8 mL/kg[163] (see Antidotes in Depth A21: Intravenous Fat Emulsion).

Aminophylline increases the heart rate and contractility by several mechanisms, including catecholamine release, adenosine antagonism, and at supratherapeutic doses, phosphodiesterase inhibition. Aminophylline has been used in cases of refractory bradycardia[160] and was effective in a dog model of propranolol poisoning.[168] Aminophylline was used with good effect in a mixed overdose involving atenolol, quinapril, and fluvoxamine.[120] Because aminophylline has a narrow therapeutic index and other therapies are generally effective, we cannot currently recommend its use unless all other treatment options have failed.

Vasopressin is a hypothalamic hormone that acts at G-protein–coupled receptors to mediate vasoconstriction (at V_1 receptors), water retention (at V_2 receptors), and corticotropin secretion (at V_3 receptors) and may also increase the response to catecholamines. Vasopressin analogues have been used as vasopressors clinically in shock states and for patients in cardiopulmonary arrest.[10,157] Even though vasopressin is a weak or even negative inotrope,[59] it was as effective as glucagon in a porcine model of propranolol toxicity.[58] There have been no reports of vasopressin use for human β-adrenergic antagonist toxicity.

The calcium sensitizers levosimendan and pimobendan interact with the contractile proteins to improve cardiac function and are used clinically to treat patients with heart failure. Levosimendan is both a positive inotrope and a vasodilator and has a better safety profile than pimobendan. It is approved in Europe for use in heart failure patients and is as effective as dobutamine in increasing contractility. Levosimendan infusions allow up-titration of β-adrenergic antagonists in patients with severe heart failure. Calcium sensitizers may prove to have a role in managing patients poisoned with β-adrenergic antagonists.[7,79,80,110]

Pyruvate has been shown to be an effective and apparently safe inotrope when given via the coronary arteries to patients with heart failure.[53,54] Pyruvate acts alone or in synergy with catecholamines to improve both systolic and diastolic function of the heart.[95] The action of pyruvate is poorly understood but likely involves improved cardiac energy delivery. Unfortunately, pyruvate is taken up rapidly in tissues, and some researchers have concluded that intracoronary infusions are required to attain sufficient delivery of pyruvate to the heart.[53,54] However, other researchers have shown that IV pyruvate infusions improve ventricular contractility in intact dogs[172] and in a canine model of cardiac arrest.[140] IV or intracoronary pyruvate infusions may have a place in the management of patients with severe β-adrenergic antagonist poisoning.

SPECIAL CIRCUMSTANCES

The preceding discussion applies to the generic management of β-adrenergic antagonists. Certain β-adrenergic antagonists have unique properties that modify their toxicity. The management considerations for these unique agents are discussed below.

■ SOTALOL

Sotalol toxicity may result in a prolonged QT interval and ventricular dysrhythmias, including torsades de pointes in addition to bradycardia and hypotension. Sotalol-induced bradycardia and hypotension should be managed as with other β-adrenergic antagonists. Specific management of patients with sotalol overdose includes correction of hypokalemia and hypomagnesemia. Overdrive pacing, magnesium infusion, or lidocaine may be effective for sotalol-induced torsade de pointes. In the future, potassium channel openers such as the cardioprotective drug nicorandil may prove effective for sotalol-induced torsade de pointes.[152]

PERIPHERAL VASODILATION

Treatment of patients who have overdosed with one of the vasodilating β-adrenergic antagonists is similar to that for patients who ingest other β-adrenergic antagonists. Decisions about the need for vasopressors should be guided by clinical findings. If vasodilation is a prominent feature, then high doses of pressors with α-adrenergic agonist properties (eg, norepinephrine or phenylephrine) may be required. Conversely, if β-adrenergic antagonism is prominent, then xenobiotics that act to increase intracellular cAMP, such as glucagon, may be needed.[50,67]

MEMBRANE-STABILIZING EFFECTS

It might be expected that hypertonic sodium bicarbonate would be beneficial in treating the ventricular dysrhythmias that occur with these xenobiotics. Unfortunately, there is limited experience with the use of hypertonic sodium bicarbonate in this situation, and the experimental data are mixed. Bicarbonate was not beneficial in a canine model of propranolol toxicity, although there was a trend toward QRS interval narrowing in the hypertonic sodium bicarbonate group.[88] In models with propranolol-poisoned isolated rat hearts, however, hypertonic sodium proved beneficial.[64,65] Perhaps most compelling is the fact that hypertonic sodium bicarbonate appeared to reverse ventricular tachycardia in a human case of acebutolol poisoning.[30] Because hypertonic sodium bicarbonate is a relatively safe and simple intervention, we recommend that it be used in addition to standard therapy for β-adrenergic antagonist–poisoned patients with QRS widening, ventricular dysrhythmias, or severe hypotension. Hypertonic sodium bicarbonate would not be expected to be beneficial in sotalol-induced ventricular dysrhythmias and, by causing hypokalemia, may actually increase the risk of torsade de pointes. The usual dose of hypertonic sodium bicarbonate is 1 to 2 mEq/kg given as an IV bolus. This may be followed by an infusion or repeated boluses may be given as needed. Care should be taken to avoid severe alkalosis or hypokalemia (see Antidotes in Depth: Bicarbonate).

OBSERVATION

All patients who have bradycardia, hypotension, abnormal ECGs, or CNS toxicity after a β-adrenergic antagonist overdose should be observed in a intensive care unit (ICU) until these findings resolve. Toxicity from regular-release β-adrenergic antagonist poisoning other than with sotalol almost always occurs within the first 6 hours.[85,88,117] Therefore, patients without any findings of toxicity after an overdose of a regular-release β-adrenergic antagonist other than sotalol may be discharged from medical care after an observation time of 6 to 8 hours if they remain asymptomatic with normal vital signs and a normal ECG and have had GI decontamination with activated charcoal. Ingestion of extended-release preparations may cause delayed toxicity, and these patients should be observed for 24 hours in an ICU. Patients who may have delayed absorption because of a mixed overdose or underlying GI disease may also require longer observation. Sotalol toxicity may also be delayed with ventricular dysrhythmias first occurring as late as 9 hours after ingestion.[107] We recommend that all patients with sotalol overdose be monitored for at least 12 hours. Patients who remain stable without QT prolongation may then be discharged from a monitored setting.

SUMMARY

β-adrenergic antagonists are commonly used to treat hypertension, angina, tachydysrhythmias, tremor, migraine, and panic attacks. Overdoses of β-adrenergic antagonists are relatively uncommon but

continue to cause deaths worldwide. Patients who develop symptoms after ingesting regular release β-adrenergic antagonists do so within the first 6 hours. Patients with sotalol ingestions are an exception to this and may cause delayed and prolonged toxicity. Extended-release formulations may also result in delayed toxicity and patients who overdose require 24 hours of observation. Patients with β-adrenergic antagonist overdose, when symptomatic, typically develop bradycardia and hypotension. Propranolol and other β-adrenergic antagonists with membrane-stabilizing properties and high lipid solubility are the most toxic in overdose. These drugs cause prolongation of the QRS interval, severe hypotension, coma, seizures, and apnea. Hypoglycemia is rare in adults after β-adrenergic antagonist ingestions but may complicate overdose in children. Bronchospasm may occur in acute β-adrenergic antagonist toxicity in susceptible persons. Sotalol is unique in its ability to prolong the QT interval, and sotalol toxicity often results in refractory ventricular dysrhythmias, which may respond to overdrive pacing or to magnesium infusions. In addition to supportive care, the most important therapy for β-adrenergic antagonist toxicity is glucagon. High doses of insulin together with glucose provide another important early treatment modality. Catecholamine infusions may also be helpful but should be closely monitored, and large doses are typically required. Patients who fail treatment with glucagon, insulin, and catecholamines are critically ill and may respond to phosphodiesterase inhibitors, intravenous fat emulsion, or mechanical support of circulation. Fortunately, most patients respond to simpler measures, and this aggressive therapy is rarely required.

GLUCAGON

Mary Ann Howland

Glucagon is a polypeptide counterregulatory hormone with a molecular weight of 3500 daltons, secreted by the α-cells of the pancreas. Glucagon was discovered in 1923, just 2 years after the discovery of insulin.[9] Previously animal derived, and possibly contaminated with insulin, the current Food and Drug Administration (FDA)-approved form has been synthesized by recombinant DNA technology since 1998.[29] Its traditional role was to reverse life-threatening hypoglycemia in diabetic patients who were unable to ingest dextrose in the outpatient setting. In medical toxicology, however, glucagon is used in the management of β-adrenergic antagonist and calcium channel blocker toxicity.

PHARMACOKINETICS AND PHARMACODYNAMICS

The volume of distribution of glucagon is 0.25 L/kg.[19] The plasma, liver, and kidney extensively metabolize glucagon with an elimination half-life of 8 to 18 minutes.[19] In human volunteers following a single intravenous (IV) bolus, the cardiac effects of glucagon begin within 1 to 3 minutes, are maximal within 5 to 7 minutes, and persist for 10 to 15 minutes.[50] The time to maximal glucose concentration is 5 to 20 minutes, with a duration of action of 60 to 90 minutes.[20] Smooth muscle relaxation begins within 1 minute and lasts 10 to 20 minutes.[20] The onset of action following intramuscular and subcutaneous administration occurs in about 10 minutes, with a peak at about 30 minutes.[19]

Tachyphylaxis or desensitization of receptors may occur with repetitive dosing. Experimental heart preparations exposed to glucagon for varying lengths of time demonstrated a decrease in the amount of cyclic adenosine monophosphate (cAMP) generated.[28,74] Possible explanations for tachyphylaxis include uncoupling from the glucagon receptor and/or increased phosphodiesterase (PDE) hydrolysis of cAMP.[28,70,74,77] Other experiments demonstrated a transient effect of glucagon on contractility and hyperglycemia, also suggesting tachyphylaxis.[24,30]

MECHANISM OF ACTION

Glucagon receptors are demonstrated in animal and human hearts and brains as well as the pancreas, and binding is closely correlated with activation of cardiac adenylate cyclase.[26,37,68] A large number of glucagon binding sites are demonstrated, and as little as 10% occupancy produces near maximal stimulation of adenylate cyclase. The binding of glucagon to its receptor results in coupling with two isoforms of the G_s protein, catalyzing the exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) on the α subunit of the G_s protein.[25,56,73] One isoform is coupled to β agonists, while both isoforms are coupled to glucagon.[73] The GTP-G_s units stimulate adenylate cyclase to convert adenosine triphosphate (ATP) to cAMP.[36,44] In frog, mouse, and guinea pig hearts, glucagon also inhibits the cyclic guanosine monophosphate (cGMP)-inhibited, milrinone-sensitive phosphodiesterase, PDE-3.[4,47] Selective inhibition of PDE-4 potentiated the cAMP response to glucagon in adult rat ventricular myocytes.[55] Glucagon, along with $β_2$ agonists, histamine, and serotonin (but not $β_1$ agonists), also activates G_i, which inhibits cAMP formation in human atrial heart tissue.[31]

Stimulation of glucagon receptors in the liver and adipose tissue increases cAMP synthesis, resulting in glycogenolysis, gluconeogenesis, and ketogenesis.[36] Other properties of glucagon include relaxation of smooth muscle in the lower esophageal sphincter, stomach, small and large intestines, common bile duct, and ureters.[22,25,34]

CARDIOVASCULAR EFFECTS

Investigations of the mechanism of action of glucagon on the heart have been performed on cardiac tissue obtained from patients during surgical procedures and in a variety of in vivo and ex vivo animal studies. The results are often species specific and are affected by the presence or absence of congestive heart failure. The inotropic action of glucagon appears to be related to an increase in cardiac cAMP concentrations.[14,36,44] Both the positive inotropic[2,18,42,50] and chronotropic[2,14,18,32,34,42,44,50,71] actions of glucagon are very similar to those of the β-adrenergic agonists, except that they are not blocked by β-adrenergic antagonists.[73] Although in some canine experiments glucagon was associated with ventricular tachycardia, glucagon was not found to be dysrhythmogenic in studies in patients with severe chronic congestive heart failure or myocardial infarction–related acute congestive heart failure, or in postoperative patients with myocardial depression.[30,38,43,46] The effects of glucagon are also markedly diminished as the severity and chronicity of congestive heart failure increases.[50]

Evidence now suggests an additional mechanism of action for glucagon, independent of cAMP, and dependent on arachidonic acid.[61] Cardiac tissue metabolizes glucagon, liberating mini-glucagon, an apparently active smaller terminal fragment.[61,70] Mini-glucagon stimulates phospholipase A_2, releasing arachidonic acid. Arachidonic acid acts to increase cardiac contractility through an effect on calcium. The effect of arachidonic acid, and therefore of mini-glucagon, is synergistic with the effect of glucagon and cAMP.[62]

VOLUNTEER STUDIES

Cardiovascular effects were extensively studied in 21 patients with heart failure who were given varied doses and durations of glucagon therapy.[51] Eleven patients who received 3 to 5 mg via IV bolus had increases in the force of contraction, as measured by maximum dP/dT (upstroke pattern on apex cardiogram), heart rate, cardiac index, blood pressure, and stroke work. There was no change in systemic vascular resistance, left ventricular end-diastolic pressure (LVEDP), or stroke index. Additionally, glucose concentrations increased by 50% and the potassium concentrations fell. A study of nine patients demonstrated a 30% increase in coronary blood flow following a 50 µg/kg IV dose.[46] Patients who received 1 mg via IV bolus also had an increase in cardiac index, but systemic vascular resistance fell, probably secondary to splanchnic and hepatic vascular smooth muscle relaxation.[51] Patients who received

an infusion of 2 to 3 mg/min for 10 to 15 minutes responded similarly to those who received the 3-5 mg IV boluses, but patients receiving boluses experienced significant dose-limiting nausea and vomiting.[51]

ROLE IN THE MANAGEMENT OF OVERDOSES WITH β-ADRENERGIC ANTAGONISTS

Overdoses with β-adrenergic antagonists are particularly dangerous and are manifested by hypotension, bradycardia, prolonged atrioventricular conduction times, depressed cardiac output, and cardiac failure. Other noncardiovascular effects include alterations in consciousness, seizures and, rarely, hypoglycemia.[1,12,15,17,23,69] Management is often complicated and many therapies, including atropine, isoproterenol, epinephrine, norepinephrine, dopamine, dobutamine, and various combinations, are used with variable success.[16,17] Recently high-dose insulin with glucose, and in the event of a cardiac arrest, intravenous fat emulsion, have been added to the armamentarium. Animal studies document the ability of glucagon to increase contractility, restore the sinus node function after sinus node arrest, increase atrioventricular (AV) conduction, and improve survival.[40,50,59] Glucagon has successfully reversed bradydysrhythmias and hypotension in patients unresponsive to the aforementioned traditional xenobiotics, and should be administered early in the management of patients with severe overdoses.[10,12,15,32,58,67] By increasing myocardial cAMP concentrations independent of the β receptor,[36,44] glucagon is able to increase inotropy[2,18,42,50] and chronotropy.[2,18,32,42,50,71]

Glucagon successfully reversed the bradycardia, low-output heart failure, and hypotension that developed in a premature newborn, presumably as a result of an inappropriately large prenatal dose of labetalol given to the mother. This neonate, delivered at 32 weeks gestation and weighing 1.8 kg, received 0.3 mg/kg glucagon intravenously initially and five additional doses of 0.3 to 0.6 mg/kg over the next 5 hours, with improvement in heart rate, blood pressure, and perfusion. Epinephrine and diuretics were also used.[63]

COMBINED EFFECTS WITH PHOSPHODIESTERASE INHIBITORS AND CALCIUM

Strategies for enhancing the effects of glucagon have involved combining it with the PDE-3 inhibitor amrinone (inamrinone) and its derivative milrinone and most recently rolipram PDE-4 inhibitor. In a canine model of propranolol toxicity, both amrinone (inamrinone) and milrinone alone were comparable to glucagon,[40,60] but the combination of amrinone and glucagon resulted in a decrease in mean arterial pressure.[39] A tachycardia occurred when milrinone was used with glucagon.[59] In an ex vivo model using strips of rat ventricular heart, rolipram enhanced the inotropic effect of glucagon and limited glucagon tachyphylaxis.[28]

The relationship between calcium and the chronotropic effects of glucagon was demonstrated in rats.[7] Maximal chronotropic effects of glucagon are dependent on a normal circulating ionized calcium. Both hypocalcemia and hypercalcemia blunt the maximal chronotropic response.[6,7]

ROLE IN CALCIUM CHANNEL BLOCKER OVERDOSE

Calcium channel blocker overdoses produce a constellation of clinical findings similar to those recognized with β-adrenergic antagonist overdoses, including hypotension, bradycardia, heart block, and myocardial depression. Animal studies[27,57,64,65,75,76] demonstrate the ability of glucagon to reverse the myocardial depression produced by nifedipine, diltiazem, and verapamil. Human case reports demonstrate similar benefit.[11,13,45,48,49,66] Some authors suggest that the addition of amrinone to glucagon therapy is beneficial.[72]

REVERSAL OF HYPOGLYCEMIA

Glucagon was once proposed as part of the initial treatment for all comatose patients.[54] Glucagon stimulates glycogenolysis in the liver. The theoretical rationale for this approach is only partially sound in that hypoglycemic patients may present in coma or with an altered mental status and hypoglycemia can be present concomitantly with a drug overdose. Immediately restoring the patient's blood glucose concentration may be life-saving; however, glucagon requires time to act and may be ineffective in a patient with depleted glycogen stores. Patients with type 2 diabetes are more likely to respond than are patients with type 1 diabetes. The IV administration of 0.5 to 1.0 g/kg of 50% dextrose in adults rapidly reverses hypoglycemia and does not rely on glycogen stores for its effect. IV dextrose, therefore, is preferred over glucagon as the initial substrate to be given to all patients with an altered mental status presumed to be related to hypoglycemia (see Antidotes in Depth A10: Dextrose). Glucagon retains a role as a temporizing measure, until medical help can be obtained, in settings such as in the home where IV dextrose is not an option.

In patients with insulinoma, after an initial hyperglycemic response glucagon may actually worsen hypoglycemia, as the result of a feedback rise in insulin.

ADVERSE EFFECTS AND SAFETY ISSUES

Side effects associated with glucagon include dose-dependent nausea, vomiting,[43] hyperglycemia, hypoglycemia, and hypokalemia; relaxation of the smooth muscle of the stomach, duodenum, small bowel, and colon; and, rarely, urticaria, respiratory distress, and hypotension.[19] The hyperglycemia is followed by an immediate rise in insulin, which causes an intracellular shift in potassium, resulting in hypokalemia.[24,43,50] It is unclear whether stimulation of the Na^+-K^+-adenosine triphosphatase (ATPase) in skeletal muscle also contributes to the hypokalemia as occurs with β-adrenergic agonists.[33,53]

Glucagon can also increase the release of catecholamines in a patient with a pheochromocytoma, resulting in a hypertensive crisis,[24] which can be treated with phentolamine.[19] Continuous prolonged treatment with glucagon might lead to a dilated cardiomyopathy, as was reported in a patient with a glucagonoma.[5] Glucagon is a pregnancy category B drug.

DOSING

An initial IV bolus of 50 μg/kg, infused over 1 to 2 minutes, is recommended (3-5 mg in a 70-kg person).[17] If clinically acceptable, a longer duration of infusion may be used to limit vomiting. Higher doses may be necessary if the initial bolus is ineffective, and up to 10 mg can be used in an adult.[26] Using too small a dose can potentially decrease systemic vascular resistance.[51] In many cases, the bolus dose has been followed by a continuous infusion of 2-5 mg/h (up to 10 mg/h) in 5% dextrose in water, which can be tapered as the patient improves.[1,25,26,52,58,69] This dosing regimen has never been studied and is based on case reports. Experimental heart preparations clearly demonstrate tachyphylaxis with continuous administration. Whether this occurs in humans is unclear, but might plead for repeated bolus

infusions over 1 to 5 minutes rather than continuous infusion.[28,74] In addition, the smooth muscle relaxation associated with a continuous infusion would be assumed to impede attempts at gastrointestinal decontamination with multiple-dose activated charcoal (MDAC) or whole-bowel irrigation (WBI).

AVAILABILITY

Glucagon (rDNA origin) by Eli Lilly and Company is available as a 1 mg (1-Unit) lyophilized powder for injection, with an accompanying 1 mL of diluent in a disposable syringe.[19] The diluent contains 12 mg/mL of glycerin, water for injection, and hydrochloric acid, if needed, for pH adjustment. Phenol is not longer used in the diluent.[3,21] Glucagon (rDNA origin) as GlucaGen by Novo Nordisk A/S is available as a 1-mg (1-Unit) lyophilized powder for injection. It should be reconstituted with 1 mL of sterile water for injection.[20] Concentrations greater than 1 mg/mL should not be used. An adequate supply of glucagon in the emergency department is at least 20 1 mg vials, with assurance of another 30 mg in the pharmacy.[8,41]

SUMMARY

Glucagon can produce positive inotropic and chronotropic effects despite β-adrenergic antagonism and calcium channel blockade. Glucagon is often beneficial in the treatment of patients with severe overdoses of β-adrenergic antagonists and calcium channel blockers. The effects of glucagon may not persist and other therapies, such as insulin and dextrose, should also be considered (Chaps. 60 and 61). The relatively benign character of an IV bolus of glucagon in the patient with a serious overdose of a β-adrenergic antagonist or calcium channel blocker should lead the clinician to use glucagon early in patient management.

CHAPTER 62
OTHER ANTIHYPERTENSIVES

Francis Jerome DeRoos

Hypertension is one of the most common chronic medical problems and one of the most readily amenable to pharmacotherapy. Beginning in the 1960s, when asymptomatic hypertension was linked to significant adverse effects such as stroke and sudden death, antihypertensive pharmacotherapeutics began being used. The first generation included centrally acting, sympatholytics, direct vasodilators, sodium nitroprusside, and diuretics. Unfortunately, these often had significant side effects, leading to the development of not only β-adrenergic antagonists and calcium channel blockers (CCBs) and more recently, angiotensin-converting enzyme inhibitors (ACEIs), and angiotensin receptor blockers (ARBs). This chapter reviews the first-generation antihypertensives, as well ACEIs and ARBs. In general, the majority of antihypertensives manifest clinical signs and symptoms in terms of the degree of hypotension produced. Particular attention will be placed on mechanisms of action and unique toxicologic considerations for each of these xenobiotics.

CLONIDINE AND OTHER CENTRALLY ACTING ANTIHYPERTENSIVES

Clonidine is an imidazoline compound that was synthesized in the early 1960s. Because of its potent peripheral α_2-adrenergic agonist effects, it was initially studied as a potential topical nasal decongestant. However, hypotension was a common side effect, which redirected its consideration for other therapeutic applications.[95] Clonidine is the best understood and the most commonly used of all the centrally acting antihypertensives, a group that includes methyldopa, guanfacine, and guanabenz. Although these drugs differ chemically and structurally, they all decrease blood pressure in a similar manner—by reducing the sympathetic outflow from the central nervous system (CNS). The imidazoline compounds oxymetazoline and tetrahydrozoline, which are used as ocular topical vasoconstrictors and nasal decongestants, produce similar systemic effects when ingested[95] (see Chap. 50).

Since 1985, the increased efficacy and improved side effect profiles of the newer antihypertensives have diminished the use of the α_2-adrenergic agonists in routine hypertension management. However, clonidine use is increasing as a result of a wide variety of applications, including attention-deficit hyperactivity disorder (ADHD); peripheral nerve and spinal anesthesia; and as an adjunct in the management of opioid, ethanol, and nicotine withdrawal.[110,116,120,202] In addition, abuse of clonidine may be a growing problem in opioid-dependent patients, and it has been used in criminal acts of chemical submission.[17,134]

Although centrally acting α_2-adrenergic agonist exposure is relatively uncommon, it may cause significant toxicity, particularly in children. One report from two large pediatric hospitals identified 47 children requiring hospitalization for unintentional clonidine ingestions over a 5-year period.[241] Significant clonidine poisoning has also resulted from formulation and dosing errors in children.[189,219] Imidazolines used as ocular vasoconstrictors have resulted in significant systemic toxicity as well.[95,138,126,180]

■ PHARMACOLOGY

Clonidine and the other centrally acting antihypertensives exert their hypotensive effects primarily via stimulation of presynaptic α_2-adrenergic receptors in the brain.[174,196,233] This central α_2-adrenergic receptor agonism enhances the activity of inhibitory neurons in the vasoregulatory regions of the CNS, notably the nucleus tractus solitarius in the medulla, resulting in decreased norepinephrine release. This results in decreased sympathetic outflow from the intermediolateral cell columns of the thoracolumbar spinal tracts into the periphery[1,232] and reduces the heart rate; vascular tone; and ultimately, arterial blood pressure.[175,245] This centrally mediated sympatholytic effect is modulated by nitric oxide and γ-aminobutyric acid (GABA), which may explain some of the clinical variability that occurs among patients who have overdosed with clonidine.[32,76,212,237]

■ PHARMACOKINETICS

Clonidine is well absorbed from the gastrointestinal (GI) tract (~75%) with an onset of action within 30 to 60 minutes. The peak serum concentration occurs at 2 to 3 hours and lasts as long as 8 hours.[53] Clonidine has 20% to 40% protein binding and an apparent volume of distribution of 3.2 to 5.6 L/kg.[132] The majority of clonidine is eliminated unchanged via the kidneys.[132]

Guanabenz and guanfacine are structurally and pharmacologically very similar to each other. They are well absorbed orally, achieving peak concentrations within 3 to 5 hours, and both have large volumes of distribution (4-6 L/kg for guanfacine; 7-17 L/kg for guanabenz).[100,214] Whereas guanabenz is metabolized predominantly in the liver and undergoes extensive first-pass effect, guanfacine is eliminated equally by the liver and kidney.[100,214] The metabolism of neither drug results in the production of significant active metabolites.

Whereas clonidine, guanabenz, and guanfacine are all active drugs with direct α_2-adrenergic agonist effects, methyldopa is a prodrug. It enters the CNS, probably by an active transport mechanism, before it is converted into its pharmacologically active degradation products.[19] α-Methylnorepinephrine is the most significant of its metabolites, although α-methyldopamine and α-methylepinephrine may also be important.[66,91,188] These metabolites are direct α_2-adrenergic agonists and impart their hypotensive effect as do the other centrally acting antihypertensives. Approximately 50% of an oral dose of methyldopa is absorbed, and peak serum concentrations are achieved in 2 to 3 hours.[156] However, because methyldopa requires metabolism into its active form, these concentrations have little correlation with its clinical effects. Methyldopa has a small volume of distribution (0.24 L/kg) and little protein binding (15%).[156] It is eliminated in the urine, both as parent compound and after hepatic sulfation.[163]

Clonidine is available in both oral and patch form. The patch, referred to as the clonidine transdermal therapeutic system, allows slow, continuous delivery of drug over a prolonged period of time, typically 1 week. This formulation, however, offers unique clinical challenges. Each patch contains significantly more drug than is typically delivered during the prescribed duration of use. For example, whereas a patch that delivers 0.1 mg/day of clonidine contains 2.5 mg total, the product that delivers 0.3 mg/day contains 7.5 mg.[31] Even after 1 week of use, between 35% and 50% and, in some instances, as much as 70%, of the drug remains in the patch.[31,88] Puncturing the outer membrane layer or backing opens the drug reservoir and allows a significant amount of the drug to be released rapidly. In addition, patients do not perceive this delivery system as a medication, and they may not exercise appropriate precautions. For example, discarding a used patch in an open wastebasket provides toddlers, who often are fascinated with stickers and other adhesive objects, an opportunity to remove the

patch and apply, taste, or ingest it. Numerous reports of toxicity in both adults and children have resulted from dermal exposure, mouthing, or ingesting one clonidine patch, emphasizing this concern.[31,88,92,113,182,183]

■ PATHOPHYSIOLOGY

In therapeutic oral dosing, clonidine and the other centrally acting antihypertensives have little effect on the peripheral α_2 receptors, the peripheral sympathetic nervous system, or the normal circulatory responses that occur with exercise or the Valsalva maneuver.[155,167] However, when serum concentrations increase above 2 ng/mL, as in the setting of intravenous (IV) administration or oral overdose, peripheral postsynaptic α_2-adrenergic stimulation may occur, causing increased norepinephrine release and producing vasoconstriction and hypertension.[39,47,158,221] This hypertension is short-lived, however, because the potent centrally mediated sympathetic inhibition becomes the predominant effect, and hypotension ensues.[3,142,200]

Imidazoline-specific binding sites are identified both in the ventrolateral medulla of the brain and in other tissues and may be important in the clinical effects of these xenobiotics.[200,226] Direct stimulation of these receptors appears to lower blood pressure independent of central α_2-adrenergic effects.[21] Therefore, although their precise physiologic relationship has not been clearly elucidated, more evidence supports the concept that both imidazoline and α_2-adrenergic receptors modulate the ability of clonidine, and presumably other centrally acting antihypertensives, to inhibit central norepinephrine release and the cardiovascular effects.[22,89,151]

■ CLINICAL MANIFESTATIONS

Although the majority of the published cases involve clonidine, the signs and symptoms of poisoning with any centrally acting antihypertensive are similar. The CNS and cardiovascular toxicity reflect an exaggeration of their pharmacologic action. Common signs include CNS depression, bradycardia, hypotension, and (occasionally) hypothermia.[5,172,205,229] Most patients who ingest clonidine or the other similarly acting drugs manifest symptoms rapidly, typically within 30 to 90 minutes.[241] The exception may be methyldopa, which requires metabolism to be activated, possibly delaying toxicity for hours.[205,245]

CNS depression is the most frequent clinical finding and may vary from mild lethargy to coma.[137,142,166,181] In addition, severely obtunded patients may experience decreased ventilatory effort and hypoxia.[3] Respirations may be slow and shallow, with intermittent deep, sighing breaths. Various other terms are used to describe this phenomenon, including *gasping*, *Cheyne-Stokes respirations*, and *periodic apnea*.[5,9,113,142] This hypoventilation is typically responsive to tactile stimuli alone, although mechanical ventilation may be required in severe cases.[3,5,93,113] The associated CNS depression typically resolves over 12 to 36 hours.[9,166] Other manifestations of this CNS depression include hypotonia, hyporeflexia, and irritability.[39,142,217] The cranial nerve examination often demonstrates miotic pupils that may remain reactive to light.[3,5,223] Two unusual case reports describe seizures in the setting of clonidine poisoning,[39,135] the mechanism of which is unclear.

Hypothermia is associated with overdoses involving centrally acting antihypertensives.[5,142,172] This is thought to be a consequence of α-adrenergic effects within the thermoregulatory center, although other authors suggest that these drugs activate central serotonergic pathways that alter normal thermoregulation.[127,149] Although this phenomenon may last several hours, it rarely requires treatment and responds well to passive rewarming.[39,172]

Sinus bradycardia may occur in up to 50% of patients who ingest clonidine.[217,241] Although usually associated with hypotension, it may be an isolated finding. Plausible explanations for this bradycardia

include an exaggerated centrally mediated sympatholytic effect, a centrally mediated increase in vagal tone, or a direct stimulation of α_2-adrenergic receptors on the myocardium.[49,122,232,242]

Other conduction abnormalities, including first-degree heart block, Mobite Type I and II atrioventricular block, and complete heart block, have been described both in overdose and after therapeutic dosing.[112,166,196,199,230,242] It appears that very young patients and patients who have underlying sinus node dysfunction, concurrent sympatholytic drug therapy, or renal insufficiency are at greatest risk of developing bradydysrhythmias after central antihypertensive agent ingestion.[26,217,225]

Hypotension is the major cardiovascular manifestation of central antihypertensive toxicity.[5,31,166,217,241] This typically occurs within the first few hours after exposure.[62] Paradoxically, severe hypertension may be noted early in dosing, particularly during IV administration, or in massive overdoses.[3,47,52,142,221] This is the result of peripheral α_2-adrenergic agonism. Typically, as the central sympatholytic effects become predominant, the hypertensive effect is short lived.[93] However, in patients with massive ingestions, hypertension may be protracted and require pharmacologic intervention.[3,52,142,217]

A recent study suggested a dose–response relationship between the history of the quantity of the centrally acting antihypertensive ingested and the severity of the clinical manifestations in children.[15] Others suggest that the age of the patient exposed may be a critical variable as well.[215] Although these observations seem intuitive, it is always important to remember that clonidine ingestions as small as 0.2 mg have resulted in clinically severe poisoning, so it is necessary to assess each exposure individually; the presence of any symptoms should prompt immediate medical evaluation.[166] Fatalities from any of these xenobiotics are rare, with few published reports from the American Association of Poison Control Centers (AAPCC) database[205] (see Chap. 135). This may be because these xenobiotics effectively block all sympathetic outflow from the CNS, and this physiologic effect is not essential for life. The CNS depression resulting in hypoventilation, hypoxia, and poor airway protection may be more pronounced in fatalities.

As a result of Food and Drug Administration (FDA) postmarketing surveillance and a case report that identified four deaths of children who received clonidine, a question was raised about whether there was an association between patients with ADHD who were being treated with combination clonidine–methylphenidate therapy and sudden death.[30,63] However, close scrutiny of these cases revealed significant confounders, and an investigation by the FDA concluded that there was inadequate evidence to confirm this association.[63,178,220,241]

■ WITHDRAWAL

Abrupt cessation of central antihypertensive therapy may result in withdrawal that is characterized by excessive sympathetic activity. Symptoms include agitation, insomnia, tremor, palpitations, and hypertension that begins between 16 and 48 hours after cessation of therapy.[85,184] Ventricular tachycardia and myocardial infarction may occur in patients with clonidine withdrawal.[16,157,173] The frequency and severity of symptoms appear to be greater in patients treated with higher doses for several months and in those with the most severe pretreatment hypertension.[184] However, cases occur even when the dosing is gradually reduced.[27,234] Although this phenomenon is associated with all centrally acting α_2-agonists, it appears to be more prominent with shorter-acting drugs such as clonidine and guanbenz.[25,72,179,244] The mechanism for this hyperadrenergic phenomenon appears to involve an increase in CNS noradrenergic activity in the setting of decreased α_2-receptor sensitivity.[58] Reasonable treatment strategies include administering clonidine or benzodiazepines, via either the oral or IV route followed by a closely monitored tapering of the dosing

over several weeks. Animal and human data suggest that β-adrenergic antagonists, including labetalol, are harmful in the setting of clonidine withdrawal, and their use is contraindicated.[8,107]

DIAGNOSTIC TESTING

Clonidine and other centrally acting antihypertensives are not routinely included in serum or urine toxicologic assays. Consequently, management decisions should be based on clinical parameters. No electrolyte or hematologic abnormalities are associated with this exposure. Because of the potential for bradydysrhythmias and hypoventilation, a 12-lead electrocardiogram (ECG) and continuous cardiac and pulse oximetry monitoring are strongly recommended during the assessment.

MANAGEMENT

Appropriate therapy begins with particular focus on the patient's respiratory and hemodynamic status. Administration of activated charcoal (AC) is the primary mode of GI decontamination in most ingestions. However, in patients manifesting significant toxicity, the risks of placing a nasogastric tube and instilling AC may not exceed the potential benefits. Induction of emesis is contraindicated because of the possibility of rapid deterioration in mental status. Orogastric lavage has limited utility because these drugs are rapidly absorbed. Patients often present after the onset of symptoms rather than immediately after ingestion, and patients respond well to supportive care. In cases involving clonidine patch ingestions, whole-bowel irrigation appears to be an effective intervention.[92]

All patients with CNS depression should be evaluated for hypoxia and hypoglycemia. Those with respiratory compromise, including apnea, often respond well to simple auditory or tactile stimulation.[3,5,93,113] Significant arousal during preparation for intubation often precludes the need for mechanical ventilation.[3] Endotracheal intubation may be required, however, for the most severely poisoned patients.

Patients with isolated hypotension should initially be treated with standard doses of IV boluses of crystalloid. Bradycardia is typically mild and usually does not require any therapy if adequate peripheral perfusion exists. If the bradycardia is severe, however, atropine is often effective, but redosing may be required.[3,5,137,217] Dopamine may be beneficial in patients with recalcitrant bradycardia or hypotension.[3,5,31,77,137]

Naloxone was probably first used in patients with clonidine poisoning because of the similarity of its clinical findings to those of opioid toxicity, namely CNS and respiratory depression and miosis. Several clonidine-poisoned patients have had significant arousal after naloxone administration, as well as increased respiratory effort, heart rate, and blood pressure.[9,118,223] However, the exact reason for this physiologic response remains unclear. Animal models suggest that endogenous CNS opioids may modulate sympathetic outflow.[62,106,200]

This concept is supported by a clinical study in which clonidine administration to hypertensive patients for 3 days resulted in a significant decrease in blood pressure. Subsequent administration of 0.4 mg of naloxone parenterally reversed the decrease in blood pressure and heart rate in almost 60% of the patients.[61] Because of the short duration of effects of naloxone (20–60 minutes), redosing or continuous infusion may be required. As with some synthetic opioids, such as propoxyphene and fentanyl, clinical improvement may occur only after high doses (4–10 mg) of naloxone,[113,140] and some patients have no response regardless of dosing.[10,137,241] If, in fact, naloxone acts as a nonspecific sympatholytic agent, it may also be beneficial in poisoning involving other α-adrenergic agents; however, there is a paucity of published clinical experience. In one adult with severe guanabenz poisoning, 7 mg of naloxone failed to improve her clinical status.[172]

Rarely, naloxone administration in the setting of clonidine overdose may precipitate significant hypertension, so continuous hemodynamic monitoring is indicated.[113,241]

The use of α-adrenergic antagonists such as tolazoline and yohimbine as specific antidotes for patients with α$_2$-adrenergic agonist overdoses is controversial. Although some patients have had significant clinical improvement,[166,197] tolazoline was ineffective in others.[3,217] The adult dose of tolazoline is 5 to 10 mg IV infusion every 15 minutes, up to a total maximum of 40 mg.[39] Given that tolazoline treatment is variably successful and that most physicians are unfamiliar with it, it cannot be recommended in the primary management strategy for centrally acting antihypertensive poisoning.

Early-onset hypertension is typically self-limited, and therapy should be cautiously undertaken, with the expectation that the hypertension will be self-limited. If hypertension is severe or prolonged, treatment with an infusion of sodium nitroprusside is appropriate.[142] Other short-acting antihypertensives, such as esmolol, may exacerbate this paradoxical hypertension in a manner similar to that which occurs when these xenobiotics are used in cocaine toxicity by inducing unopposed α$_1$-receptor stimulation (see Chap. 76). Although oral nifedipine has been used,[52] its lack of titratability and its unpredictable efficacy make its use inappropriate as well.

OTHER SYMPATHOLYTIC ANTIHYPERTENSIVES

Several other xenobiotics also exert their antihypertensive effect by decreasing the effects of the sympathetic nervous system. Often termed *sympatholytics*, they can be classified as ganglionic blockers, presynaptic adrenergic blockers, or α$_1$-adrenergic antagonists, depending on their mechanism of action. These drugs are rarely used clinically, and little is known about their effects in overdose.

GANGLIONIC BLOCKERS

Ganglionic blockers, such as trimethaphan, inhibit impulse transmission down both the postganglionic sympathetic and parasympathetic nerves, decreasing vascular tone, cardiac output, and blood pressure. These xenobiotics were used more frequently in the 1950s and 1960s in Europe, but because of their significant side effects, they were quickly replaced. Side effects stem from the unpredictable degree of sympathetic, as well as additional parasympathetic, blockade and include paralytic ileus, constipation, urinary retention, impotence, dry mouth, and blurred vision.[163] Trimethaphan is the only ganglionic blocker available in the United States, and it is administered IV. Although there have been no reported cases of intentional overdose, there have been cases of cardiopulmonary arrest associated with administration of continuous doses and with a 10-fold dosing error in a child while treating a hypertensive crisis.[46,84] In overdose, the exaggerated hypotensive response should respond well to IV crystalloid boluses and, if needed, a direct-acting vasopressor such as norepinephrine.

PRESYNAPTIC ADRENERGIC ANTAGONISTS
Guanethidine

These xenobiotics exert their sympatholytic action by decreasing norepinephrine release from presynaptic nerve terminals. Whereas guanethidine and guanadrel interfere with the action potential that triggers norepinephrine release,[202] reserpine depletes norepinephrine and other catecholamines from the presynaptic nerve terminals, probably by direct binding and inactivation of catecholamine storage vesicles.[73] Adverse effects limit their clinical usefulness. These effects include a high incidence of orthostatic and exercise-induced hypotension, diarrhea, increased gastric secretions, and impotence.[163] In addition, this hypotensive effect may be prolonged for as long as 1 week.[109,203] Because of its ability to cross the blood–brain barrier, reserpine may also deplete central catecholamines and produce drowsiness, extrapyramidal symptoms, hallucinations, or depression.[131] In overdose, an extension of their pharmacologic effects is expected. Patients with severe orthostatic hypotension should be anticipated and treated with IV crystalloid boluses and a direct-acting vasopressor. If reserpine is involved, significant CNS depression should also be anticipated.[131]

■ PERIPHERAL α_1-ADRENERGIC ANTAGONISTS

The selective α_1-adrenergic antagonists include prazosin, terazosin, and doxazosin. The α_1 receptor is a postsynaptic receptor primarily located on vascular smooth muscle, although they are also found in the eye and in the GI and genitourinary tracts.[43] In fact, these xenobiotics provide first-line pharmacologic therapy for patients with urinary dysfunction secondary to benign prostatic hyperplasia. They produce arterial smooth muscle relaxation, vasodilation, and a reduction of the blood pressure. Although better tolerated than ganglionic blockers and peripheral adrenergic neuron blockers, they may still produce significant symptoms of postural hypotension, including lightheadedness, syncope, or palpitations, particularly after the first dose or if the dosing is rapidly increased.[14] Hypotension and CNS depression ranging from lethargy to coma have been reported in overdose.[125,129,194] In addition, priapism may occur.[129,186] Treatment with supportive care, including IV fluid boluses and a vasopressor such as dopamine, was effective in the few overdose cases reported.[125,129,144]

■ DIRECT VASODILATORS

Nitroprusside
Hydralazine, Minoxidil, and Diazoxide These xenobiotics produce vascular smooth muscle relaxation independent of innervation or known pharmacologic receptors.[54,108,115] This vasodilatory effect has been attributed to stimulation of nitric oxide release from vascular endothelial cells. The nitric oxide then diffuses into the underlying smooth muscle cells, stimulating guanylyl cyclase to produce cyclic guanosine monophosphate (cGMP). This second messenger indirectly inhibits calcium entry into the smooth muscle cells, producing vasodilation.[193] Minoxidil, however, also has direct potassium channel activation effects.[123,161] It has been proposed that the opening of these adenosine triphosphate–linked potassium channels results in potassium influx and cell depolarization, thereby reducing calcium influx and ultimately relaxing vascular smooth muscle.[28]

As this vasodilation occurs, the baroreceptor reflexes, which remain intact, produce an increased sympathetic outflow to the myocardium, resulting in an increase in heart rate and contractile force. Typically,

these xenobiotics are used therapeutically in patients with severe, refractory hypertension and in conjunction with a β-adrenergic antagonist to diminish reflex tachycardia. Hydralazine, minoxidil, and diazoxide are effective orally, but sodium nitroprusside is only used IV. Minoxidil is also used topically in a 2% solution to promote hair growth, and significant poisoning has occurred in suicidal adults who have ingested this formulation.[148] Diazoxide, although previously used to rapidly reduce blood pressure in hypertensive emergencies, is rarely used for this indication now as a consequence of its poor titratability and its variable, and occasionally profound, hypotensive effect.[114]

Adverse effects associated with daily hydralazine use include several immunologic phenomenon such as hemolytic anemia; vasculitis; acute glomerulonephritis; and most notably, a lupuslike syndrome.[176] Minoxidil may cause ECG changes, both in therapeutic doses and in overdose. Sinus tachycardia, ST segment depression, and T-wave inversion have all been reported.[83,177,210] There also appears to be an association with supratherapeutic doses of minoxidil and left ventricular multifocal, subacute necrosis, and subsequent fibrosis.[86,87] The significance of either of these changes is unknown; they typically resolve with either continued therapy or as other toxic manifestations resolve.[83,87,210]

The common toxic manifestations of these xenobiotics in overdose are an extension of their pharmacologic action. Symptoms may include lightheadedness, syncope, palpitations, and nausea.[2,136] Signs may be isolated to tachycardia alone,[177,210] flushing, or alterations in mental status, which is related to the degree of hypotension.[148] Based on AAPCC annual poison data, it appears that in recent years, the majority of reported exposures to this class of drugs involve the topical formulation of minoxidil[60] (see Chap. 135).

After appropriate GI decontamination, routine supportive care should be performed, with special consideration to maintaining adequate mean arterial pressure. If IV crystalloid boluses are insufficient, a peripherally acting α-adrenergic agonist, such as norepinephrine or phenylephrine, is an appropriate next therapy. Dopamine and epinephrine should be avoided to prevent an exaggerated myocardial response and tachycardia from β-adrenergic stimulation.

Nitroprusside Sodium nitroprusside is effectively a prodrug, exerting its vasodilatory effects only after its breakdown and the release of nitric oxide. The nitroprusside molecule also contains five cyanide radicals that, although gradually released, occasionally produce cyanide or thiocyanate toxicity.[162,198] Physiologic methemoglobin can bind the liberated cyanide. The binding capacity of physiologic methemoglobin is about 175 µg/kg of cyanide, corresponding to a little less than 500 µg/kg of infused sodium nitroprusside. These cyanide moieties are rapidly cleared, both by interacting with various sulfhydryl groups in the surrounding tissues and blood and enzymatically in the liver by rhodanese, which couples them to thiosulfate-producing thiocyanate.[67] This cyanide detoxification process in healthy adults occurs at a rate of about 1 µg/kg/min, which corresponds to a sodium nitroprusside infusion rate of 2 µg/kg/min.[44,198] It is limited by the sulfur donor availability, so factors that reduce these stores, such as poor nutrition in infants and toddlers, critical illness, surgery, and diuretic use, place patients at risk for developing cyanide toxicity.[35,44] The hemolysis associated with cardiopulmonary bypass may place the patient at particular risk because the elevated free hemoglobin may accelerate the release of cyanide from the sodium nitroprusside moiety.[35] Therefore, depending on the balance of cyanide release (eg, the rate of sodium nitroprusside infusion) and the rate of cyanide detoxification (eg, the sulfur donor stores), cyanide toxicity may develop within hours. Infusion of nitroprusside at a rate of more than 1.5 mg/kg administered over a few hours or more than 4 µg/kg/min for more than 12 hours may overwhelm the capacity of rhodanese for detoxifying cyanide.[185] Signs and symptoms

of cyanide toxicity include alteration in mental status; anion gap metabolic acidosis; and in late stages, hemodynamic instability (see Chap. 126). Hydroxycobalamin is rapidly becoming the drug of choice for known cyanide poisonings.

One method of preventing cyanide toxicity from sodium nitroprusside is to expand the thiosulfate pool available for detoxification by the concomitant administration of sodium thiosulfate.[44,81,198] Dosing of 1 g sodium thiosulfate for every 100 mg of nitroprusside is typically sufficient to prevent cyanide accumulation[185] infusing 500 mg sodium thiosulfate (A standard 50-mL bottle of 25% sodium thiosulfate found in the Cyanide Antidote kit contains 12.5 gm).[185] Unfortunately, the thiocyanate that is formed may accumulate, particularly in patients with renal insufficiency, and may produce thiocyanate toxicity.[67,198]

Thiocyanate is almost exclusively renally eliminated, with an elimination half-life of 3 to 7 days. It is postulated that a continuous sodium nitroprusside infusion of 2.5 μg/kg/min in patients with normal renal function could produce thiocyanate toxicity within 7 to 14 days, although it may be as short as 3 to 6 days or as little as 1 μg/kg/min in patients with chronic renal insufficiency who are not receiving hemodialysis.[198] The symptoms of thiocyanate toxicity begin to appear at serum concentrations of 60 μg/mL (1 mmol/L); are very nonspecific; and may include nausea, vomiting, fatigue, dizziness, confusion, delirium, and seizures.[67] Thiocyanate toxicity may produce life-threatening effects, such as hemodynamic and intracranial pressure elevation, when serum concentrations are above 200 μg/mL.[44,67,81,227] Anion gap metabolic acidosis and hemodynamic instability do not occur with thiocyanate toxicity. Although cyanide or thiocyanate concentrations are not typically useful in the management of patients with cyanide toxicity, they may be beneficial for monitoring critically ill patients who are at risk of thiocyanate poisoning. Hemodialysis clears thiocyanate from the serum and should be strongly considered in patients with severe clinical manifestations of thiocyanate toxicity.[57,141,160]

Another therapeutic used to prevent cyanide toxicity from sodium nitroprusside is a simultaneous infusion of hydroxocobalamin. Although only available in the United States since 2007, hydroxocobalamin has been studied and successfully used in Europe to prevent cyanide poisoning from sodium nitroprusside infusions.[42,96,117,246] Similar to thiosulfate, when simultaneously infused, hydroxocobalamine does not interfere with the vasodilatory effects of sodium nitroprusside.[94] Dosing of 25 mg/h has successfully reduced cyanide poisoning in humans.[42,246] Because of the relative cost, and interactions with some laboratory tests of hydroxocobalamin, however, thiosulfate should remain the mainstay of prophylaxis against sodium nitroprusside-induced cyanide toxicity (see Antidotes in Depth A39 and A40: Hydroxocobalamin and Sodium Thiosulfate).

■ DIURETICS

Diuretics can be divided into three main groups: (1) the thiazides and related compounds, including hydrochlorothiazide and chlorthalidone; (2) the loop diuretics, including furosemide, bumetanide, and ethacrynic acid; and (3) the potassium-sparing diuretics, including amiloride, triamterene, and spironolactone. Two other groups of diuretics—the carbonic anhydrase inhibitors, such as acetazolamide, and osmotic diuretics, such as mannitol—are not used as antihypertensive agents.

The thiazides produce their diuretic effect by inhibition of sodium and chloride reabsorption in the distal convoluted tubule. Loop diuretics, in contrast, inhibit the coupled transport of sodium, potassium, and chloride in the thick ascending limb of the loop of Henle. Although their exact antihypertensive mechanism is unclear, an increased urinary excretion of sodium, potassium, and magnesium results from the use of loop diuretics. Potassium-sparing diuretics act either as aldosterone antagonists, such as spironolactone, or as renal epithelial sodium channel antagonists, such as triamterene, in the late distal tubule and collecting duct.[104]

The majority of toxicity associated with diuretics is metabolic and occurs during chronic therapy or overuse.[240] Hyponatremia develops within the first 2 weeks of initiation of therapy in more than 67% of susceptible patients.[213] Patients who are elderly, female, malnourished, or taking thiazides are at greatest risk.[7] With severe hyponatremia (<120 mEq/L), symptoms may include headache, nausea, vomiting, confusion, seizures, or coma. The osmotic demyelination syndrome has been reported during rapid correction of severe hyponatremia secondary to diuretic abuse[40] (see Chap. 16).

Other electrolyte abnormalities associated with diuretic use include hypokalemia and hypomagnesemia, which may precipitate ventricular dysrhythmias and sudden death. This is an extremely controversial topic, with several excellent studies providing conflicting results.[18,68,169,206,208] Although it is unclear how great a risk, if any, diuretic use may be, it remains prudent to monitor and correct the patient's potassium concentration.[99,206,239] This is particularly important in elderly patients and for those patients who concomitantly use digoxin, in which setting hypokalemia is clearly associated with dysrhythmias (see Chap. 64).[24,218] Potassium-sparing diuretics may cause hyperkalemia, particularly in the setting of renal insufficiency or when combined with other hyperkalemia-producing drugs such as ACEIs.[108]

Thiazide diuretics are associated with inducing hyperglycemia, particularly in patients with diabetes mellitus. This is a result of depletion of total-body potassium stores. Because insulin secretion is dependent on transmembrane potassium fluxes, this decrease in potassium concentration reduces the amount of insulin secreted.[133] This effect is dose dependent and reversible either by potassium supplementation or discontinuation of the thiazide diuretic.[34,90] This association has lead to significant work and discussion about the routine use of thiazide diuretics as first-line antihypertensives in the treatment of uncomplicated patients.[45,79,153]

Thiazide diuretics are also associated with inducing hyperuricemia, uric acid, renal calculi, and gout. Uric acid is the end product of purine metabolism, and its renal elimination is significantly dependent on intravascular and urinary volume. Diuretic-induced volume depletion decreases uric acid filtration and increases its reabsorption in the proximal tubule.[204,216] Several studies support the association with hyperuricemia and the development of gout.[29,82] One study found a link between thiazide diuretic use and the likelihood of the need for subsequent antigout therapy.[80]

Several unusual reactions are associated with thiazide diuretic use, including pancreatitis; cholecystitis; and hematologic abnormalities such as hypercoagulability, thrombocytopenia, and hemolytic anemia.[55,56,190,192,228,238]

Despite the widespread use of these xenobiotics, acute overdoses are distinctly rare.[128] Major signs and symptoms include GI distress, brisk diuresis, possible hypovolemia and electrolyte abnormalities, and altered mental status.[128] Typically, the diuresis is short lived because of the limited duration of effect and the rapid clearance of the majority of diuretics. Assessment should focus on fluid and electrolyte status, which should be corrected as needed. If hyperkalemia is unexpectedly discovered, either the ingestion of a potassium-sparing xenobiotic or, more likely, an overdose of potassium supplements, which are frequently prescribed in conjunction with thiazide and loop diuretics, should be considered.[101,102] Altered mental status, including coma, may result from diuretic overdose without evidence of any fluid or electrolyte abnormalities.[15,128,191] Postulated mechanisms include a direct drug effect and induction of transient cerebral ischemia.[164]

■ ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACEIs are among the most widely prescribed antihypertensive drugs. At the time of this writing, there are 10 ACEIs approved by the US FDA

TABLE 62–1. Classification of Antihypertensives Available in the United States

β-Adrenergic antagonists (see Chap. 61)

Calcium channel blockers (see Chap. 60)

Sympatholytics

    Central α$_2$-adrenergic agonists

        Clonidine, guanabenz, guanfacine, methyldopa

    Ganglionic blockers

        Trimethaphan

    Peripheral adrenergic neuron antagonists

        Guanethidine, guanadrel, metyrosine, reserpine

    Peripheral α$_1$-adrenergic antagonists

        Prazosin, terazosin, doxazosin

Diuretics

    Thiazides

        Bendroflumethiazide, chlorthalidone, chlorothiazide, hydrochlorothiazide, hydroflumethiazide, indapamide, methyclothiazide, metolazone, polythiazide, trichlormethiazide

    Loop diuretics

        Bumetanide, ethacrynic acid, furosemide, torsemide

    Potassium-sparing diuretics

        Amiloride, eplerenone, spironolactone, triamterene

Vasodilators

    Hydralazine, minoxidil, diazoxide, nitroprusside

Angiotensin-converting enzyme inhibitors

    Benazepril, captopril, enalapril, fosinopril, lisinopril, moexipril, perindopril, quinapril, ramipril, spirapril, trandolapril

Angiotensin II receptor blockers

    Candesartan, cilexetil, eprosartan, irbesartan, losartan, telmisartan, valsartan, olmesartan

---

ACEI-Induced Angioedema Angioedema is an inflammatory reaction in which there is increased capillary blood flow and permeability, resulting in an increase in interstitial fluid. If this process is confined to the superficial dermis, urticaria develops; if the deeper layers of the dermis or subcutaneous tissue are involved, angioedema results. Angioedema most commonly involves the periorbital, perioral, or oropharyngeal tissues.[187] This swelling may progress rapidly over minutes and result in complete airway obstruction and death.[70,74,201] The pathogenesis of acquired angioedema involves multiple vasoactive substances, including histamine, prostaglandin D$_2$, leukotrienes, and bradykinin. Because ACE also inactivates bradykinin and substance P, ACE inhibition results in elevations in bradykinin concentrations that appear to be the primary cause of both ACEI-induced angioedema and cough (Fig. 62–1).[4,103] There is no evidence that the ACEI-induced angioedema phenomenon is IgE mediated.[4]

Although the literature is replete with reports of ACEI-induced angioedema, the overall incidence is only approximately 0.1%, and it is idiosyncratic.[64,103,105,209] One-third of these reactions occur within hours of the first dose, and another third occur within the first week.[139,209] It is important to remember that the remaining third of cases may occur at any time during therapy, even after years.[36] Women, African Americans, and patients with a history of idiopathic angioedema appear to be at greater risk.[139,168]

Treatment varies depending on the severity and rapidity of the swelling. Because of its propensity to involve the tongue, face, and oropharynx, the airway must remain the primary focus of management. A nasopharygeal airway is often helpful. If there is any potential for or suggestion of airway compromise, endotracheal intubation should be performed. Severe tongue and oropharyngeal swelling may make orotracheal or nasotracheal intubation extremely difficult, if not impossible. If this is a concern, fiberoptic nasal intubation may be an attractive option, provided that the resources are available. Other techniques, including retrograde intubation over a guidewire that was passed through the cricothyroid membrane and emergent cricothyrotomy, should also be considered.[187] The most important aspect of airway management in patients experiencing ACEI-induced angioedema, however, is early risk assessment for airway obstruction and rapid intervention before the development of severe and obstructive swelling.

for the treatment of hypertension (Table 62–1). In general, these drugs are well absorbed from the GI tract, reaching peak serum concentrations within 1 to 4 hours. Enalapril and ramipril are prodrugs and require hepatic metabolism to produce their active forms. These drugs are primarily eliminated via the kidneys.

All ACEIs have a common core structure of a 2-methylpropanolol-L-proline moiety.[71] This structure binds directly to the active site of ACE, which is found in the lung and vascular endothelium, preventing the conversion of angiotension I to angiotensin II. Because angiotensin II is a potent vasoconstrictor and stimulant of aldosterone secretion, vasodilation; decreased peripheral vascular resistance; decreased blood pressure; increased cardiac output; and a relative increase in renal, cerebral, and coronary blood flow occur.[71] This hypotensive response may be severe in select patients after their initial dose, resulting in syncope and cardiac ischemia.[37,97] Patients with renovascular-induced hypertension and patients who are hypovolemic from concomitant diuretic use appear to be at greatest risk.[97] Overall, however, these drugs are well tolerated and have a very low incidence of side effects. Some reported adverse effects include rash, dysgeusia, neutropenia, hyperkalemia, chronic cough, and angioedema.[51,71,224] Because of their interference with the renin–angiotensin system, ACEIs are potential teratogens and should never be used by pregnant women or women who intend to become pregnant.[12]

FIGURE 62–1. An overview of the normal function of angiotensin II and the mechanisms of action of angiotensin-converting enzyme inhibitors (ACEI) and the angiotensin II receptor blockers (ARB). PVR, peripheral vascular resistance. ACEIs are often implicated in angioedema and cough.

Because ACEI-induced angioedema is not an IgE-mediated phenomenon pharmacologic therapy targeting an allergic cascade, such as epinephrine, diphenhydramine, and steroids, should not be expected to be effective. However, when the history is unclear, these medications should not be withheld for fear of withholding life-saving therapy from someone having a severe IgE-mediated allergic reaction.

All patients with mild or quickly resolving angioedema should be observed for several hours to ensure that the swelling does not progress or return. Outpatient therapy with a short course of oral antihistamines and corticosteroids is appropriate. Such patients should be instructed to discontinue ACEI therapy permanently and to consult their primary care physicians about other antihypertensive options. Because this is a mechanistic and not allergic adverse effect, the use of any other ACEIs is contraindicated.

Angiotensin-Converting Enzyme Inhibitor Overdose The toxicity of ACEIs in overdose appears to be limited.[38,130] Although several reports of overdoses involving ACEIs have been published, the majority of the cases reported manifested toxicity of a coingestant.[48,78,239] Hypotension may occur in select patients,[12,117] but deaths are rarely reported in isolated ACEI ingestions.[170,236] Other patients may remain asymptomatic despite high serum drug concentrations.[124]

Treatment should focus on supportive care and on identifying any coingestants that may be more toxic, particularly other antihypertensives such as β-adrenergic antagonists and CCBs. In most cases, AC alone is sufficient GI decontamination. IV crystalloid boluses are often effective in correcting hypotension, although in rare cases, catecholamines may be required.[6]

Naloxone may also be effective in reversing the hypotensive effects of ACEIs. ACEIs may inhibit the metabolism of enkephalins and potentiate their opioid effects, which include lowering blood pressure.[50,154] In a controlled human volunteer study, continuous naloxone infusion effectively blunted the hypotensive response of captopril.[1] In one case report, naloxone appeared to be effective in reversing symptomatic hypotension secondary to a captopril overdose.[235] In another published case, naloxone was ineffective.[11] Although its role in the setting of ACEI overdose remains unclear, naloxone may obviate the need for large quantities of crystalloid or vasopressors and should therefore be considered.

■ ANGIOTENSIN II RECEPTOR BLOCKERS

ARBs were first introduced in 1995, and currently, six members of this class are marketed in the United States. These drugs are rapidly absorbed from the GI tract, reaching peak serum concentrations in 1 to 4 hours, and then are either eliminated unchanged in the feces or after undergoing hepatic metabolism via the mixed function oxidase system eliminated in the bile.[143,145-147,165]

Although these drugs are similar to ACEIs in that they decrease the effects of angiotensin II rather than decrease the formation of angiotensin II, they act by antagonizing angiotensin II at the type 1 angiotensin (AT-1) receptor (see Fig. 62–1).[111] This allows the drugs to inhibit the vasoconstrictive- and aldosterone-promoting effects of angiotensin II and reduce blood pressor by blunting both the sympathetic as well as the rennin–angiotensin systems.[143] In addition, they do not interfere with bradykinin degradation, thus reducing the risk of adverse effects, such as cough or angioedema, when compared to ACEI therapy.[119,139,171,222] However, cases of angioedema associated with ARB therapy have been reported.[33,139,231]

Similar to ACEIs, ARBs should never be used by pregnant patients because of their teratogenic potential.[12,207] In addition, when starting the drug, up to 1% develop of patients first-dose orthostatic hypotension.[75]

There have been few published reports of overdoses involving these drugs. Adverse signs and symptoms reflect orthostatic or absolute hypotension and include palpitations, diaphoresis, dizziness, lethargy, or confusion.[65,150,211] In mildly poisoned patients, this hypotension may be treated with IV crystalloid alone. However, in the most severe cases, hypotension may require pressor therapy.[150,211] Patients who are chronically taking ARBs have exhibited significant hypotension during induction of general anesthesia that is often refractory to traditional vasoconstrictor therapy, such as norepinephrine, ephedrine, and phenylephrine, but appear to respond rapidly to vasopressin.[20,23,59]

SUMMARY

Numerous xenobiotics are currently marketed for the treatment of chronic hypertension, including centrally acting drugs, other sympatholytics, direct vasodilators, diuretics, ACEIs, and ARBs. Although these xenobiotics are not typically associated with severe poisonings, either because of limited use, as with many of the sympatholytics and direct vasodilators, or because of limited toxicity, as with diuretics, ACEIs, and ARBs, severe poisonings may occur. Although centrally acting antihypertensives, such as clonidine, may produce significant CNS depression and bradycardia, as well as hypotension and the signs and symptoms associated with the degree of the hypoperfusion. Management of ingestions involving these antihypertensives should focus on appropriate GI decontamination, typically oral AC, and hemodynamic monitoring and support with IV crystalloids and catecholamines. Naloxone may be used in clonidine- or ACEI-poisoned patients, but its efficacy is variable. Sodium nitroprusside use may result in cyanide toxicity if the infusion rate exceeds the body's thiosulfate stores. Although cyanide toxicity may be prevented with concomitant infusion of sodium thiosulfate, thiocyanate toxicity may develop, particularly in patients with renal dysfunction.

CHAPTER 63
ANTIDYSRHYTHMICS

Lewis S. Nelson and Neal A. Lewin

The term *dysrhythmia* encompasses an array of abnormal cardiac rhythms that range in clinical significance from merely annoying to instantly life threatening. Antidysrhythmics include all xenobiotics that are used to treat any of these various dysrhythmias. The importance of dysrhythmia management in the modern practice of medicine cannot be overstated because dysrhythmias are among the most common causes of preventable sudden cardiac death.[30,53] Despite an incomplete understanding of the underlying mechanisms of dysrhythmia formation, an abundance of antidysrhythmics have been developed, each attempting to alter specific electrophysiologic components of the cardiac impulse generating or conducting system. In addition to the predictable, mechanism-based adverse effect of each xenobiotic, unique and often unanticipated effects also occur.[96] Experience with overdose of many of these xenobiotics is limited, and management is generally based on the underlying pharmacologic principles, existing case reports, and the experimental literature.

HISTORY AND EPIDEMIOLOGY

For a long time, antidysrhythmics were considered among the most rational of the available cardiac medications. This well-earned reputation was related to their high efficacy at reducing the incidence of malignant dysrhythmias. Similarly, they are effective at controlling nuisance rhythm disorders. However, this approach changed dramatically after publication of the Cardiac Arrhythmia Suppression Trials (CAST and CAST II)[1,3,29] and, more recently, with the rise of mechanical interventions, such as ablation therapy and implantable defibrillators. CAST assessed the ability of three antidysrhythmics to suppress asymptomatic ventricular dysrhythmias known to be harbingers of sudden death. The original CAST study was discontinued in 1989 before completion, when encainide and flecainide not only failed to prevent sudden death but actually increased overall mortality. The CAST II trial noted similar problems with moricizine.[1] It has since become clear that the enhanced mortality associated with many antidysrhythmics is a result of their dysrhythmogenic effects and that virtually all xenobiotics of this group carry such a risk.[95] More recently, it has been demonstrated that for patients with atrial fibrillation, there is no benefit to rhythm conversion compared with controlling the ventricular response rate.[99]

This chapter focuses on the xenobiotics that serve primarily as antidysrhythmics that, with the exception of lidocaine, have few other medicinal indications. Chapters 22 and 23 provide a more detailed description of the electrophysiology of dysrhythmias and a discussion of their genesis. In addition, the toxicities from calcium channel blockers and β-adrenergic antagonists, which have indications in addition to dysrhythmia control, are discussed separately in Chapters 60 and 61.

CLASSIFICATION OF ANTIDYSRHYTHMICS

Antidysrhythmics modify impulse generation and conduction by interacting with various membrane sodium, potassium, and calcium ion channels. Generally, antidysrhythmics affect electrophysiologic effects

either through alteration of the channel pore or, more commonly, by modification of its gating mechanism (Fig. 63–1).[56] Unfortunately, given their exceedingly complex mechanisms of action, the descriptive terms used to explain their molecular actions are not always completely accurate. For example, the description of an antidysrhythmic as a specific "channel blocker," although representative of the conceptual action of that drug, is inaccurate because in most cases, the molecule does not actually block the channel but rather prevents the channel from opening properly. Furthermore, many of these drugs are active nonspecifically at other channels or on other cells, resulting in divergent clinical actions of similarly classified drugs.

The Vaughan-Williams classification of antidysrhythmics by electrophysiologic properties emphasizes the connection between the basic electrophysiologic actions and the antidysrhythmic effects.[115] Although initially proposed as a descriptive model for electrophysiologic actions and not for clinical effects, the Vaughan-Williams classification is commonly invoked as a user-friendly guide to clinical therapy. In 1991, a competing system known as "the Sicilian Gambit" was constructed by a task force of European cardiologists based on the mechanisms by which antidysrhythmics modify dysrhythmogenic mechanisms.[2] Although perhaps more contemporary in theory, this latter classification system is complex and is therefore not widely implemented. An even more rational classification would match the electrophysiologic effects of the antidysrhythmics with their molecular interactions on different regions of the various ion channels, such as channel gating and pore conductance.[56]

This discussion of antidysrhythmics uses the Vaughan-Williams classification, recognizing the shortcomings delineated above.[113] The pharmacokinetic properties of the various drugs are summarized in Table 63–1.

■ CLASS I ANTIDYSRHYTHMICS

All antidysrhythmics in Vaughan-Williams class I (A, B, and C) alter Na^+ conductance through cardiac voltage-gated, fast inward Na^+ channels (see Table 63–1). These drugs bind to the Na^+ channels and slow their recovery from the open or inactivated state to the resting, or closed, state (see Fig. 63–1). This conversion must occur before the channel can reopen and participate in another depolarization. Consequently, as the proportion of drug-bound Na^+ channels increases, fewer of these channels are capable of reactivation on the arrival of the next depolarizing impulse. As a result, by reducing the excitability of the myocardium, abnormal rhythms are both prevented and terminated.

Blockade of these sodium channels slows the rise of phase 0 of the cellular action potential, which correlates with a reduction in the rate of depolarization of the myocardial cell (or V_{max}). Similarly, conduction through the myocardium is slowed, producing a measurable prolongation of the QRS complex on the surface electrocardiogram (ECG). Correspondingly, slowed intramyocardial conduction is associated with reduced contractility, manifesting as negative inotropy. Myocardial depression also results from effects of reduced intracellular Na^+ on Na^+-Ca^{2+} exchange.[76] This in turn reduces the intracellular Ca^{2+} concentration, normal concentrations of which are required for adequate contractility.

The differences among class I drugs are directly related to their pharmacologic relationships with the Na^+ channel. However, it is noteworthy that the original subdivision of class I drugs was based on clinical observations, not current pharmacologic awareness, accounting for the somewhat illogical ordering of the class I subdivisions.[113] Type IB drugs have their highest affinity for inactivated Na^+ channels. This occurs at the end of depolarization, during early repolarization, and during periods of myocardial ischemia, all situations in which
FIGURE 63–1. Sodium channel blockade. On appropriate signal, sodium channel activation occurs, at which time the sodium channel converts from the resting (III) state to the open state (I). This allows sodium ion influx to initiate phase 0 of the action potential, or cellular depolarization. The sodium channels subsequently assume the inactivated state by closure of an inactivation gate; this is a voltage-dependent phenomena and occurs concomitantly with, although more slowly than, channel activation. Cellular depolarization is maintained for a period of time by other ion channels that form the plateau of the action potential. Before reactivating, sodium channels must convert back to the resting state, which also occurs in a voltage-dependent fashion. Many antidysrhythmics stabilize the inactivated state of the channel and, by slowing conversion to the resting state, prevent its reopening, reducing the excitability of the cell. Because this is a population phenomena, there are dose-dependent effects on channel blockade; thus, more drug interferes with more channels. Interestingly, certain xenobiotics, such as ciguatoxin and aconitine, stabilize the open state of the sodium channel and produce persistent depolarization.

the myocardium is partially depolarized. These drugs also have rapid "on–off" binding kinetics (rapid $\tau_{recovery}$) and are thus bound only briefly, during late electrical systole, the period during which the Na+ channels are predominantly in the inactivated form. They are almost exclusively unbound during electrical diastole, which is the major portion of the cardiac cycle at normal heart rates. However, the degree of binding increases as the heart rate accelerates because the duration of diastole decreases and the relative proportion of time spent in systole increases; this is termed *use dependence*. Because all IB drugs do not bind to activated sodium channels, in therapeutic doses, they do not affect the rate of rise of phase 0 of the action potential, or V_{max}, and have no effect on the ECG.[114] Alternatively, the class IC drugs either act preferentially on activated Na+ channels or they release from the Na+ channels very slowly (slow $\tau_{recovery}$) and thus are still bound during the next cardiac cycle. This prolonged channel blockade and reduced channel reactivation results in both greater pharmacologic effects and toxicity, even at slow heart rates. These drugs reduce V_{max} and prolong the QRS complex. Class IA drugs fall between the other two subclasses.

Although in the Vaughan-Williams classification, class I drugs are considered primarily sodium channel blockers, many, particularly those in class IA, have important effects on cardiac potassium channels. These channels are critical to maintenance of the cardiac action potential and repolarization of the myocardial cell. Slowing of potassium efflux prolongs the duration of the action potential and accounts for the persistence of refractoriness, or the time during which the cell

is incapable of re-depolarization. This effect produces QT prolongation on the surface ECG, and predisposes to the triggering of polymorphic ventricular tachycardia.[94] Because class IB drugs have no effect on myocardial potassium channels, they do not alter refractoriness or the QT interval. In fact, class IB drugs often reduce the action potential duration, shortening refractoriness. Further discussion of potassium channel blockade is found in Chapter 22 and below in the discussion of class III antidysrhythmics.

■ CLASS IA ANTIDYSRHYTHMICS: PROCAINAMIDE, QUINIDINE, AND DISOPYRAMIDE

Procainamide Procainamide (Fig. 63–2) can be used to suppress either atrial or ventricular tachydysrhythmias. Importantly, procainamide undergoes hepatic biotransformation by acetylation to *N*-acetylprocainamide (NAPA), the rate of which is genetically determined.[79] Although NAPA lacks the Na+ channel-blocking activity of procainamide, it prolongs the action potential duration through blockade of the K+ rectifier currents, and for this reason, it is available as the class III antidysrhythmic acecainide.[47]

Rapid intravenous (IV) dosing of procainamide is potentially dangerous because its initial volume of distribution is smaller than its final volume of distribution. Because this initial compartment includes the heart, adverse myocardial effects may be unexpectedly pronounced. Thus, to prevent toxicity during drug infusion, the IV loading dose is generally administered by slow infusion with ECG monitoring. Both procainamide and NAPA are renally eliminated and may accumulate in patients with renal insufficiency.[28,69]

Although the chronic use of procainamide may be accompanied by the development of antinuclear antibodies or drug-induced systemic lupus erythematosis,[50] this syndrome is not associated with acute poisoning. Furthermore, NAPA has less propensity than procainamide to produce this syndrome.[47] Other reported adverse effects include seizures and antimuscarinic effects with acute overdose and myopathic pain, thrombocytopenia, and agranulocytosis after long-term use.

Serum concentrations of both procainamide and NAPA should be determined as part of therapeutic drug monitoring (therapeutic dose, 5–20 μg/mL) and in patients with procainamide overdose. Because the elimination half-life of procainamide is 3 to 4 hours, which is substantially shorter than that of NAPA (6–10 hours), chronic overdosing typically results in NAPA toxicity.[7] In this situation, the QT interval, a reflection of K+ channel blockade, correlates directly—and blood pressure correlates inversely—with the degree of poisoning. Severe effects usually do not occur until total (procainamide plus NAPA) serum concentrations are greater than 60 μg/mL.[8] Because of its structural similarity with amphetamine, patients with procainamide overdose may have a false-positive urine enzyme-multiplied immunoassay test (EMIT) result for amphetamines.[116]

Quinidine Quinidine (see Fig. 63–2), the *d*-isomer of quinine, is derived from the bark of the cinchona tree. Because it is a weak base, it is typically formulated as the sulfate or gluconate salt. Quinidine undergoes hydroxylation by the liver, and both active and inactive metabolites are renally eliminated.

Quinidine was once widely used for the management of patients with atrial or ventricular dysrhythmias but has largely fallen out of favor because of its adverse effects. Quinidine has substantial cardiotoxicity that includes intraventricular conduction abnormalities and an increased QT interval. Many of the ECG changes mimic those of hypokalemia. "Quinidine syncope," in which patients on therapeutic doses of quinidine experience paroxysmal, transient loss of consciousness, is most frequently a result of torsade de pointes.[54]

TABLE 63–1. Antidysrhythmics: Pharmacology, Pharmacokinetics, and Adverse Effects

Drug	Route	Primary Route of Elimination	Elimination Half-Life	Channel Blockade	Volume Distribution (L/kg)	Protein Binding (%)	Adverse Effects and Complicating Factors	Other
Class IA								
Disopyramide	PO	Liver, kidney	4-10 h	Na^+, ($\tau = 9$ s), K^+, Ca^{2+}	0.59 ± 0.15	35–95 depending on serum concentration	CHF, negative inotropic effects, anticholinergic, torsades de pointes, heart block, hypoglycemia	
Procainamide (PA)	IV, PO	50%–60% unchanged in kidney; active hepatic metabolite (NAPA)	PA: 3–4 h ↑ renal disease NAPA: 6–10 h ↑ renal disease	Na^+ ($\tau = 1.8$ s), K^+	1.9 ± 0.3	16 ± 9	Hypotension (ganglionic blockade), QRS widening, fever, SLE-like syndrome, torsades de pointes	NAPA: active metabolite, renally eliminated, K^+ channel blocker; half-life: 6–10 h; a sustained-release PA preparation is available
Quinidine	PO	Liver, kidney, 10%–20% unchanged	6–8 hours ↑ liver disease (to >50 hours) and renal failure (to 9–12 h).	Na^+ ($\tau = 3$ s), K^+, Ca^{2+}	2.7 ± 1.2	87 ± 3	Heart block, sinus node dysfunction, prolonged QT, hypotension, hypoglycemia, torsades de pointes, thrombocytopenia, ↑ digoxin concentrations	
Class IB								
Lidocaine	SC, IV, PO	Liver, active metabolite (MEGX CYP3A4) (30% BA)	8 min after bolus 2 h terminal	Na^+ ($\tau = 0.1$ s)	1.1 ± 0.4	70 ± 5	Fatigue, agitation, paresthesias, seizures, hallucinations, rarely bundle branch block	Metabolites: GX and MEGX, are less potent as Na^+ channel blockers than lidocaine
Mexiletine	IV, PO	Liver (CYP 2D6)	6-17 h	Na^+ ($\tau = 0.3$ s)	4.9 ± 0.5	63 ± 3	See lidocaine

FIGURE 63–2. Structures of class IA antidysrhythmics and quinine.

Because quinidine shares many pharmacologic properties with quinine (see Chap. 58), patients may occasionally experience cinchonism after either chronic or acute quinidine overdose. This syndrome includes abdominal symptoms, tinnitus, and altered mental status. Quinidine also produces both peripheral and cardiac antimuscarinic effects, which enhances conduction via the atrioventricular (AV) node. Furthermore, as with quinine, quinidine-induced blockade of K^+ channels in pancreatic islet cells may cause uncontrolled insulin release, leading to hypoglycemia.[86]

Serum quinidine concentrations greater than 14 μg/mL are associated with cardiotoxicity,[61] as evidenced by a 50% increase in either the QRS or QT interval.

Disopyramide Disopyramide (see Fig. 63–2) is more likely than other class IA antidysrhythmics to produce negative inotropy and congestive heart failure. This effect may be noted both in patients receiving therapeutic dosing[108] and in those who overdose, and may be related to the blockade of myocardial calcium channels caused by disopyramide.[51] The mono-*N*-dealkylated metabolite of disopyramide produces the most pronounced anticholinergic effects of the class,[88,100] accounting for the occasional use of disopyramide to treat patients with neurocardiogenic syncope. Lethargy, confusion, or hallucinations may be prominent in overdose.

Electrophysiologic abnormalities similar to those associated with poisoning from other class IA drugs can occur, including intraventricular conduction abnormalities, torsades de pointes, and other ventricular dysrhythmias. Disopyramide frequently causes hyperinsulinemic hypoglycemia through its antagonism of K^+ channels in the pancreatic islet cells.[48]

Management of Class IA Antidysrhythmic Toxicity Management centers on assessment and correction of cardiovascular dysfunction. Following airway evaluation and IV line placement, 12-lead ECG and continuous ECG monitoring are of paramount importance. Appropriate gastrointestinal decontamination is recommended when the patient is sufficiently stabilized and should include whole-bowel irrigation if a sustained-release preparation is involved.

For patients who have widening of the QRS complex duration, bolus administration of IV hypertonic sodium bicarbonate is indicated. [see Antidotes In Depth A5, Sodium Bicarbonate] Depolarization is accelerated and the QRS complex duration is reduced, by enhancing rapid sodium ion influx through the myocardial sodium channels.[14] However, hypokalemia from the use of sodium bicarbonate may further prolong the QT interval, requiring careful monitoring of the serum K^+ concentration and ECG. Class IA antidysrhythmic-induced hypotension is treated primarily with rapid infusion of 0.9% NaCl, in order to expand the patient's intravascular volume and to simultaneously increase myocardial contractility (i.e., enhanced Starling force). Hypotension in the setting of QRS complex duration prolongation may respond favorably to hypertonic sodium bicarbonate, which enhances inotropy by both accelerating depolarization and raising intravascular volume. Dopamine, dobutamine, isoproterenol, norepinephrine, and intraaortic balloon pump insertion may also be required, but their use has not been systematically evaluated. Because disopyramide also blocks calcium channels, calcium administration is reportedly beneficial,[4] although evidence to support this antidotal effect is lacking. Glucagon effectively reversed myocardial depression in canine models, but it has not been evaluated in humans.[78]

Patients with stable ventricular dysrhythmias occurring in the setting of class IA antidysrhythmic poisoning are usually treated with hypertonic sodium bicarbonate or lidocaine. Although it may seem counterintuitive to administer another class I antidysrhythmic to a patient already poisoned by a class I antidysrhythmic, there is sound theoretical and experimental literature to support the use of lidocaine in this setting.[118] Because lidocaine is a class IB drug with rapid on-off receptor kinetics, it may displace the "slower" class IA drug from the binding site on the sodium channel, effectively reducing channel blockade. Sodium bicarbonate enhances conduction through the myocardium, promoting spontaneous termination of the ventricular dysrhythmia. Magnesium sulfate and overdrive pacing may be helpful in treating torsades de pointes. Xenobiotics that must be avoided in treating patients with dysrhythmias associated with class IA poisoning include other class IA and IC antidysrhythmics, as well as the β-adrenergic antagonists and calcium channel blockers, all of which may exacerbate conduction abnormalities or produce hypotension.

The roles of activated charcoal hemoperfusion, hemofiltration, and continuous arteriovenous hemodiafiltration are inadequately defined, but may be most beneficial for removing NAPA.[8,16,69] There is no clinical evidence to support the use of hemodialysis or hemoperfusion for quinidine or disopyramide poisoning.[55]

■ CLASS IB ANTIDYSRHYTHMICS: LIDOCAINE, TOCAINIDE, MEXILETINE, AND MORICIZINE

Lidocaine Lidocaine (Fig. 63–3) is an aminoacyl amide that is a synthetic derivative of cocaine. Its predominant clinical uses are as a local anesthetic and, for mechanistically similar reasons, to control ventricular dysrhythmias. The high frequency of lidocaine-related medication errors relates in part to its wide use as well as the availability of multiple diverse "amps" of lidocaine designed for varying indications including resuscitation, preparation of infusions, and local anesthesia.[57] Lidocaine may prevent myocardial reentry by preferentially suppressing conduction in compromised tissue.[109] Following an IV bolus, lidocaine rapidly enters the central nervous system but quickly redistributes into the peripheral tissue with a distribution half-life of approximately 8 minutes.[15, 71] Lidocaine is 95% dealkylated by hepatic CYP 3A4 to an active metabolite, monoethylglycylxylidide (MEGX) and, subsequently, to the inactive glycine xylidide (GX). GX is further metabolized to monoethylglycine and xylidide. MEGX, although less
FIGURE 63–3. Structures of the class IB antidysrhythmics lidocaine (and metabolite [MEGX]), tocainide, mexiletine, and moricizine.

potent as a Na^+ channel blocker than the parent drug, may bioaccumulate because of its substantially longer half-life.[12]

Patients with lidocaine toxicity develop both central nervous system and cardiovascular effects, generally in that order. Because of its rapid entry into the brain, acute lidocaine poisoning typically produces central nervous system dysfunction, particularly seizures, as its initial manifestation.[34,93,103] Concomitant respiratory arrest generally occurs. Shortly following the central nervous system effects, depression in the intrinsic cardiac pacemakers leads to sinus arrest, AV block, intraventricular conduction delay, hypotension, and/or cardiac arrest.[23] If the patient is supported through this period, the drug rapidly distributes away from the heart, and spontaneous cardiac function returns.

Acute lidocaine toxicity from nonmassive amounts is generally related to excessive or inappropriate therapeutic dosing. Common settings include inadvertent IV administration instead of the intended route and excessive subcutaneous administration during laceration repair. Acute lidocaine toxicity may occur also with topical tracheal application of lidocaine used for bronchoscopy,[120] during cirumcision,[93] as well as intraureteral application during ureteroscopic stone extraction.[83] The typical CNS manifestations of nonmassive acute lidocaine poisoning include drowsiness, weakness, a sensation of "drifting away," euphoria, diplopia, decreased hearing, paresthesias, muscle fasciculations, and seizures. The more severe of these effects develop when serum lidocaine concentrations exceed 5 μg/mL and are often preceded by paresthesias or somnolence. Any of these symptoms should, therefore, prompt the clinician to examine the patient's medication administration history or drug-infusion rate. Apnea and seizures, as well as hypotonia in neonates, are reported to result from nonmassive acute lidocaine toxicity.[92]

A related form of toxicity and death results from subcutaneous and adipose administration of lidocaine during tumescent liposuction.[90] In this technique, a large volume of dilute lidocaine is used to distend subcutaneous fat prior to liposuction. Although in some reports the cause of death was controversial,[87] postmortem lidocaine concentrations were commonly elevated, and it is likely that lidocaine metabolites were also involved in the adverse events.[58,90] Interestingly, proponents of this procedure suggest that lidocaine doses up to a maximum of 55 mg/kg are safe,[81] whereas the conventional recommended limit for subcutaneous lidocaine with epinephrine is only 5–7 mg/kg. Of significant concern is that the recommended doses used for liposuction procedures do not consider the ability of lidocaine to saturate the CYP3A4 enzymes. When saturation occurs, elimination lags behind absorption and lidocaine toxicity may result.

Numerous publications unequivocally demonstrate the toxicity associated with orally administered lidocaine despite its poor bioavailability.[23,121] Some of the toxicity may be due to MEGX. Because of the relatively high concentration of viscous lidocaine (typically 4%), this preparation is overrepresented in reports of oral lidocaine poisoning.[49] As little as 15 mL of 2% viscous lidocaine in a 3-year-old child (estimate, 300 mg or 21.4 mg/kg/dose) may cause seizures.

Chronic lidocaine toxicity most commonly occurs as a result of therapeutic misadventure in patients receiving lidocaine infusions, generally in a critical care unit. Toxicity following appropriate dosing is most likely to occur in patients with reduced hepatic blood flow (e.g., congestive heart failure), liver disease, or concomitant therapy with CYP3A4 and CYP1A2 inhibitors (see Chap. 12 Appendix).[80,111] Adverse reactions to lidocaine also increase with advancing age, decreasing body weight, and increasing infusion rate. Chronic lidocaine toxicity occurs in 6–15% of patients receiving infusions at 3 mg/min for several days.[101] Partly for this reason, lidocaine is no longer routinely used to prevent dysrhythmias in the immediate postmyocardial infarction period. The clearance of lidocaine falls after approximately 24 hours of the start of an infusion, and this effect may be due to competition for hepatic metabolism between lidocaine and its metabolites.

Tocainide Tocainide is indicated for the oral treatment of ventricular dysrhythmias; it is no longer available in the US. Although a lidocaine analog, it does not undergo first-pass metabolism and is therefore almost 100% orally bioavailable.[65] Both renal failure and congestive heart failure prolong its half-life considerably. The few overdoses reported with tocainide are associated with CNS and cardiovascular complications similar to those that occur with lidocaine overdose.[10,107] Therapeutic dosing is associated with rash, hepatotoxicity and blood dyscrasias, which, although rare, have limited its widespread use.

Mexiletine Mexiletine, originally developed as an anorectic agent, was found to have antidysrhythmic, local anesthetic, and anticonvulsant activity.[20] It is currently available in oral form for the management of ventricular dysrhythmias. Its chemical structure and electrophysiologic properties are similar to those of lidocaine. Mexiletine, a base, is absorbed in the small intestine; therefore, its absorption is increased when the gastric contents are alkalinized. Congestive heart failure and cirrhosis, as well as therapy with cimetidine or disulfiram, decrease the clearance of mexiletine.[64] Its metabolism, predominantly through CYP2D6, is accelerated by concomitant use of phenobarbital, rifampin, and phenytoin.[64]

Adverse therapeutic effects are primarily neurologic and are similar to those that occur with lidocaine. The few reported cases of mexiletine

overdose describe prominent cardiovascular effects such as complete heart block, torsade de pointes, and asystole.[26,38] Neurotoxicity resulting from overdose includes self-limited seizures, generally in the setting of cardiotoxicity. Moreover, a single case report described a patient with mexiletine poisoning who experienced status epilepticus without any hemodynamic or electrocardiographic abnormalities.[77] Mexiletine may produce a false-positive result on the amphetamine immunoassay of the urine.[26,62]

Moricizine Moricizine possesses the general qualities of class I drugs but is difficult to specifically subclassify because it has properties that place the drug in either classes IB or IC.[25] Historically, it has been discussed as a class IB drug, as it is here. The parent drug undergoes extensive and rapid metabolism. Dose-related lengthening of PR and QRS intervals are expected, as are hemiblocks, bundle blocks, and sustained ventricular tachydysrhythmias. Experience with moricizine during the CAST II trial in the setting of myocardial infarction suggests that it is a prodysrhythmic.[1] Clinical experience with overdose is limited, but it is expected to be similar to that of other class I antidysrhythmics.

Management of Class IB Antidysrhythmic Toxicity The focus of the initial management for IV lidocaine-induced cardiac arrest is continuous cardiopulmonary resuscitation to allow lidocaine to redistribute away from the heart. Apart from this setting, management of hemodynamic compromise includes fluid replacement and other conventional strategies. Resistant hypotension may require dopamine or norepinephrine administration, insertion of an intraaortic balloon assist pump, or bypass.[40] Cardiopulmonary bypass, which does not directly enhance elimination, maintains hepatic perfusion, thereby allowing the lidocaine to be metabolized.[40] Bradydysrhythmias typically do not respond to atropine, requiring the administration of a chronotrope such as dopamine, norepinephrine, or isoproterenol. External pacing or insertion of a transvenous pacemaker may be useful, but the myocardium is often refractory to electrical capture. Lidocaine-induced seizures and those related to lidocaine analogs are generally brief in nature and do not require specific therapy. For patients requiring treatment, an IV benzodiazepine generally suffices; rarely, a barbiturate is required. Similarly, although IV lipid emulsion is often described as useful for the resuscitation of patients with life-threatening local anesthetic overdose, its use for lidocaine-poisoned patients is unstudied and likely unnecessary given the rapid time course of recovery (see Antidotes in Depth: A21: Intravenous Fat Emulsion). Enhanced elimination techniques are limited after IV poisoning because of the rapid time course of poisoning.

After oral poisoning by a class IB drug, activated charcoal should be administered as appropriate. Hemoperfusion or hemodialysis may increase the clearance of tocainide, but its indications remain unclear, and its benefit is likely very limited.[117] The extensive distribution and rapid metabolism of mexiletine make it a poor candidate for extracorporeal drug removal.

◼ CLASS IC ANTIDYSRHYTHMICS: FLECAINIDE AND PROPAFENONE

Flecainide Flecainide, a derivative of procainamide, is orally administered to maintain sinus rhythm in patients with structurally normal hearts who have atrial fibrillation or supraventricular tachycardia.[11] Renal insufficiency, drug interactions, and congestive heart failure all decrease the clearance of flecainide and its active metabolite. Additionally, alkaluria reduces its clearance, presumably by enhanced tubular reuptake of nonionized drug. Patients using therapeutic doses may develop left ventricular dysfunction with worsening congestive heart failure. This is presumably a result of the negative inotropic effect of flecainide, which itself may relate to its antagonistic effects on

calcium channels. Furthermore, sudden dysrhythmic death may occur, particularly in patients with underlying ischemic heart disease.[89]

A 50% increase in QRS duration, a 30% prolongation of the PR interval, or a 15% prolongation of the QT interval occurs with flecainide toxicity, a combined complex that may mimic Brugada syndrome.[45,52] The expected consequences of these electrophysiologic disturbances include bradycardia, premature ventricular contractions, and ventricular fibrillation. The combination of marked QRS and PR interval changes, associated with minimal QT interval prolongation, is characteristic of flecainide toxicity and contrasts with those described with other antidysrhythmic agents.[24]

Propafenone Propafenone bears a structural resemblance to propranolol,[36] as well as similar qualitative, but not quantitative, electrophysiologic properties.[73] Propafenone blocks fast inward sodium channels, is a weak β-adrenergic antagonist, and is an L-type calcium channel blocker.[33,104] Its long half-life allows the accumulation of parent compound, particularly in patients with the slow metabolizer pharmacogenetic variant of CYP2D6, which may cause excessive β-adrenergic antagonism.[66] Propafenone overdose produces sinus bradycardia, as well as ventricular dysrhythmias and negative inotropy.[36]

Acute overdose of propafenone typically produces wide complex tachycardia, right bundle-branch block, first-degree AV block, and prolongation of the QT interval, as well as generalized seizures.[59] Massive overdose in a young adult may be related to the subsequent development of a mild cardiomyopathy and a left bundle-branch block.[59]

Management of Class IC Antidysrhythmic Toxicity Initial stabilization should include standard management strategies for hypotension and seizures. Additionally, therapy for hypotension and the electrocardiographic manifestations of class IC poisoning includes IV hypertonic sodium bicarbonate to overcome the Na⁺ channel blockade.[60] An animal study documented the beneficial effects of hypertonic sodium bicarbonate on flecainide-induced ventricular dysrhythmias, and three reports of human overdose verify QRS complex narrowing in response to hypertonic sodium bicarbonate administration.[17,42,68] Although sodium loading with hypertonic saline may be similarly effective, it remains unproven. The renal elimination of flecainide is reduced by urinary alkalinization, suggesting that sodium chloride, in equimolar doses, may ultimately prove superior to sodium bicarbonate.[74] The administration of other class IC or IA antidysrhythmics is contraindicated because of their additive blockade of the Na⁺ channel. Similarly, the administration of phenytoin to a child with propafenone poisoning was associated with a prolongation of the QRS interval, which initially responded to sodium bicarbonate, but the patient subsequently developed a bradyasystolic arrest.[72] However, amiodarone has been successful in the setting of flecainide-induced ventricular fibrillation refractory to other therapy.[105] The efficacy of an external or internal pacemaker may be limited because of the drug-induced increased electrical pacing threshold of the ventricle.[31] Successful therapy with cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO) has been reported and should be considered if available.[9,27]

Extracorporeal removal is not expected to be beneficial for patients with flecainide poisoning. Although hemodialysis was successful in removing propafenone after overdose, additional studies are needed to determine its clinical benefit.[18]

◼ CLASS III ANTIDYSRHYTHMICS: AMIODARONE, DOFETILIDE, AND IBUTILIDE

The class III antidysrhythmics prevent and terminate reentrant dysrhythmias by prolonging the action potential duration and effective refractory period without slowing conduction velocity during
FIGURE 63–4. Structures of amiodarone (**A**) compared with triiodothyronine (T$_3$) (**B**). Amiodarone is nearly 40% iodine (I) by weight.

phase 0 or 1 of the action potential. This drug-induced effect on the action potential is generally caused by blockade of the rapidly activating component of the delayed rectifier potassium current, which is responsible for repolarization.

The class III antidysrhythmics in use today prolong repolarization of both the atria and the ventricles. Thus, common electrocardiographic effects at therapeutic doses include prolongation of the PR and QT intervals and abnormal T and U waves. Chapters 22 and 23 contain a detailed discussion of the pharmacologic mechanisms of class III antidysrhythmics. Also, Chapters 23 and 61 discuss sotalol.

Amiodarone Amiodarone (Fig. 63–4) is an iodinated benzofuran derivative that is structurally similar to both thyroxine and procainamide. Forty percent of its molecular weight is iodine. The 2005 revision of the Advanced Cardiac Life Support (ACLS) guidelines placed tremendous emphasis on the early IV administration of amiodarone. This, along with the ability of amiodarone to terminate or prevent atrial fibrillation, has lead to the increased use of this drug despite its association with potentially severe adverse effects.[112]

Although amiodarone has multiple pharmacologic effects, its efficacy as an antidysrhythmic agent is primarily the result of its class III antidysrhythmic effects. It also has weak α- and β-adrenergic antagonist activity and can block both L-type calcium channels and inactivated sodium channels. Amiodarone is slowly absorbed by the oral route and concentrates in the liver, lung, and adipose tissue. Steady-state pharmacokinetics may not occur until after 1 month of use.

The ECG effects of amiodarone differ based on the route of drug administration. Therapeutic oral doses prolong PR and QT intervals but not the QRS complex. IV dosing may produce a prolongation of the PR interval but has few other ECG manifestations. Ventricular dysrhythmias and sinus bradycardia are the most serious cardiac complications of therapeutic doses of amiodarone.[119] Monomorphic and polymorphic ventricular tachycardias may be resistant to cardioversion and pharmacologic interventions[13,35] but are surprisingly uncommon, given the frequency and extent to which the QT interval prolongation occurs. The ability of amiodarone to compete for P-glycoprotein is responsible for several consequential drug effects, including elevated digoxin and cyclosporin concentrations and an enhanced anticoagulation effectiveness of warfarin[63,122] (see Chap. 8 and 12).

The diverse complications associated with long-term therapy do not occur after short-term IV use. Chronic therapy with oral amiodarone is associated with substantial pulmonary, thyroid, corneal, hepatic, and cutaneous toxicity because of bioaccumulation in these organs. Many of these effects appear to be dose related, but because of the wide range of

bioavailabilities and metabolic patterns among different patients, as well as the overlap between therapeutic and toxic serum concentrations, therapeutic drug monitoring is of limited benefit.[43] Pneumonitis, the most consequential extracardiac adverse effect, affects up to 5% of patients taking amiodarone therapeutically. Amiodarone pneumonitis may develop within days of initiating therapy but typically occurs only after years of therapy. Its occurrence may be dose related: a daily dose of more than 400 mg is a risk factor, and pneumonitis is rare in those taking less than 200 mg daily. The recent focus on using the minimal effective dose has reduced the incidence of pneumonitis.[32,82] Oxygen supplementation may speed the development of pneumonitis, which may explain the initial belief that patients with chronic lung disease are at increased risk for amiodarone pneumonitis. Manifestations of pneumonitis include dyspnea, cough, hemoptysis, crackles, hypoxia, and radiographic changes.[21] Computed tomography scanning is the most helpful initial diagnostic test for pneumonitis, but is not useful for monitoring purposes (monitoring is often done with diffusing capacity of CO).[43] Bronchoalveolar lavage typically reveals interstitial pneumonitis with many macrophages and a characteristic finely vacuolated foamy cytoplasm, but confirmation of the diagnosis requires open lung biopsy.

Thyroid dysfunction, either amiodarone-induced thyrotoxicosis (AIT) or amiodarone-induced hypothyroidism (AIH), occurs in approximately 4% of patients.[22] AIH is more common than AIT when iodine intake is sufficient.[43] AIH is likely caused by an exaggerated Wolff-Chaikoff effect, in which iodine, in this case from amiodarone, inhibits the organification and release of thyroid hormone. AIT appears to exist in two distinct forms: type I AIT, which occurs in patients with abnormal thyroid glands and iodine-induced excessive thyroid hormone synthesis and release, and type II AIT, in which destructive thyroiditis leads to release of thyroid hormone from the damaged follicular cells. The relative prevalence of the two forms of AIT is unknown, but it may depend on the ambient iodine intake. Amiodarone may also reduce the effect of thyroid hormone on peripheral tissue.[37] The diagnosis is confirmed with standard thyroid function testing[110] (see Chap. 49).

Corneal microdeposits are extremely common during chronic therapy and may lead to vision loss.[70] Abnormal elevation of hepatic enzymes occurs in more than 30% of those on long-term therapy, and hepatotoxicity may be associated with progression to cirrhosis. Periodic monitoring of aminotransferases is typically recommended.[43] Hepatotoxicity may occur after initial loading of amiodarone.[91] Slate gray or bluish discoloration of the skin is common, particularly in sun-exposed portions of the body.[97]

Dofetilide Dofetilide is approved for conversion of atrial fibrillation or atrial flutter to a normal sinus rhythm. Dofetilide increases the effective refractory period more substantially in atrial tissue than in ventricular fibers, accounting for this clinical indication.[98] Unlike many of the other antidysrhythmics, it may reduce the morbidity of atrial fibrillation in patients with congestive heart failure, and it is still used despite the emphasis on rate control instead of rhythm control in treating atrial fibrillation. Dofetilide has no known effect on calcium or sodium channels, nor does it result in β-adrenergic antagonism. Dofetilide increases the QT interval but does not change either the PR interval or the QRS complex in humans. Heart rate and blood pressure are also not appreciably affected.

Although limited data are available, the expected and reported adverse cardiac events include ventricular tachycardia, particularly torsade de pointes.[119] The approximate incidence of torsade de pointes in patients receiving high therapeutic doses of the drug is 3%.[5] For this reason, the Food and Drug Administration has in place strict requirements for the use of dofetilide, such as an individualized dose initiation algorithm and mandatory hospitalization for initial therapy.[6,85]

Overdose data reported by the manufacturer include two cases. Whereas one patient reportedly ingested 28 capsules and experienced no events, a second patient inadvertently received two supratherapeutic doses 1 hour apart and experienced fatal ventricular fibrillation after the second dose.[85] A 33-year-old man ingested 5 mg (20 capsules) and developed QT prolongation within 1 hour of ingestion but had no dysrhythmia during his 4-day hospital stay.

Ibutilide Ibutilide is an antidysrhythmic with predominant class III activity used for the rapid conversion of atrial fibrillation and flutter to normal sinus rhythm. Because of its extensive first-pass metabolism, ibutilide can only be administered parenterally. Its metabolic pathways are not well understood but do not involve the isoenzymes CYP3A4 or CYP2D6. Pharmacokinetic data thus far do not indicate that age, gender, hepatic, or renal dysfunction necessitates adjustment of recommended dosage of ibutilide. In addition to its effects on the delayed rectifier current, ibutilide activates a slow inward sodium current.[75]

Ibutilide may increase the QT interval and cause torsades de pointes, especially in patients with congenital long-QT syndrome and in women.[44] Although ibutilide may enhance the efficacy of transthoracic cardioversion for atrial fibrillation, its use in patients with ejection fractions below 20% is associated with an increased incidence of sustained polymorphic ventricular tachycardia. Acute renal failure, including biopsy-identified crystals, has been reported in association with ibutilide cardioversion, but a causal relationship is not yet definitive.[39] Acute overdose information, only available in limited form (four patients) through the manufacturer, suggests that ventricular dysrhythmias and high-degree AV conduction abnormalities should be expected.[84]

Management of Class III Antidysrhythmic Toxicity Treatment experience with class III drug overdose is limited. Isoproterenol and overdrive pacing have been used successfully to treat patients with amiodarone-induced torsades de pointes.[102] Administration of class IB antidysrhythmics or propranolol for the control of monomorphic ventricular tachycardia cannot be recommended on theoretical grounds. Paradoxically, amiodarone may reduce the "torsadogenic" effects of the other class III antidysrhythmics.[106] This effect is likely mediated by the beneficial effects of amiodarone on the dispersion of myocardial repolarization and its calcium channel–blocking activity.

Multiple-dose activated charcoal may be helpful if used shortly after overdose. Hemodialysis is not expected to be beneficial in general, either because of extensive protein binding or because of large volumes of distribution (see Table 63–1). A neonate survived cardiovascular collapse with the use of ECMO after an iatrogenic IV amiodarone overdose.[46]

■ UNCLASSIFIED: ADENOSINE

Adenosine, a nucleoside found in all cells, is released from myocardial cells under physiologic and pathophysiologic conditions. It is administered as a rapid IV bolus to terminate reentrant supraventricular tachycardia. The effects of adenosine are mediated by its interaction with specific G protein–coupled adenosine (A_1) receptors that activate acetylcholine-sensitive outward K^+ current in the atrium, sinus nodes, and AV nodes. The resultant hyperpolarization reduces the rate of cellular firing. Adenosine also reduces the Ca^{2+} currents, and its antidysrhythmic activity results from its effect in increasing AV nodal refractoriness and from inhibiting delayed afterdepolarizations elicited by sympathetic stimulation.[67]

The adverse effects of adenosine administration are very common and include transient asystole, dyspnea, chest tightness, flushing, hypotension, and atrial fibrillation. Although bronchospasm occurs after intrapulmonary administration, it has not been reported after IV use. Dyspnea, and probably chest tightness, is related to adenosine stimulation of the pulmonary vagal C fibers.[19] Fortunately, most of the adverse effects of adenosine are transient because of its rapid metabolism to inosine by both extracellular and intracellular deaminases. The clinical effects are potentiated by dipyridamole, an adenosine uptake inhibitor,[41] and by denervation hypersensitivity in cardiac transplant recipients. Methylxanthines may produce adenosine receptor blockade (see Chap. 65). In this setting, larger-than-usual doses of adenosine are required to produce an antidysrhythmic effect. Overdose of adenosine has not been reported. Treatment is supportive because of the rapid elimination of the drug.

SUMMARY

Many antidysrhythmics are currently available for clinical use. In the overdose setting, the class IA, B, and C drugs are all associated with sodium channel blockade, which may cause profound cardiac dysrhythmias and morbidity if not treated judiciously. The class IC drugs are considerably more toxic than the other class I drugs, although even the class IB drugs may be lethal in overdose. The class III antidysrhythmics in overdose may cause malignant dysrhythmias, particularly torsades de pointes. Amiodarone has many noncardiac effects, particularly pneumonitis and thyroid effects, that limit its therapeutic usefulness. Clinical effects after overdose are poorly described for class III drugs but will likely manifest as exaggerations of therapeutic pharmacologic effects. Proper management of both adverse effects and overdose can be accomplished only by understanding the pharmacokinetics and toxicokinetics of these drugs.

CHAPTER 64
CARDIOACTIVE STEROIDS

Jason B. Hack

Digoxin
MW: = 780 daltons

Unsaturated lactone ring

Digitoxoses

Steroid nucleus
(cyclopentanoperhydrophenanthrene)

Aglycone, Genin
(Basic cardenolide structure)
Cardioactive steroids (CAS) remain in wide use throughout the world, although their benefits have become more and more restricted. Some of the most remarkable poisonings occur with exposures to plants such as *Digitalis purpurea* and *Nerium oleander* containing CAS, which are used by herbalists for varied disorders. Recent abuse of dried toad secretions from *Bufo* spp has lead to deaths with typical CAS morbidity and very high mortality. Rapid recognition of the CAS toxidrome and appropriate use of digoxin-specific antibody fragments can prove lifesaving.

HISTORY AND EPIDEMIOLOGY

There is evidence in the *Ebers Papyrus* (Papyrus Smith) that the Egyptians used plants containing CAS at least 3000 years ago. However, it was not until 1785, when William Withering wrote the first systemic account about the effects of the foxglove plant, that the use of CAS was more widely accepted into the Western apothecary. Foxglove was initially used as a diuretic and for the treatment of "dropsy" (edema), and Withering eloquently described its "power over the motion of the heart, to a degree yet unobserved in any other medicine."[124]

Subsequently, CAS became the mainstay of treatment for congestive heart failure and to control the ventricular response rate in atrial tachydysrhythmias. Because of their narrow therapeutic index and widespread use, both acute and chronic toxicity remain important problems.[84] According to the American Association of Poison Control Centers data, between the years 2002 and 2006, there were approximately 8000 exposures to CAS-containing plants with no attributable deaths and about 14,000 exposures to CAS-containing xenobiotics resulting in 100 deaths (see Chap. 135).

Toxicity is typically encountered in very young and very old individuals. In children, most acute overdoses are unintentional, resulting from dosing errors (this is particularly pertinent with the use of digoxin because the submilligram doses make dose calculations subject to

10-fold [decimal point] errors), or mistakenly ingesting an adult's medication. Older adults are at particular risk for toxicity, either from interactions of the CAS with other medications in their chronic regimen or indirectly as a consequence of an alteration in the absorption or elimination kinetics. Drug–drug interactions from an adult's polypharmacy or from additional acute care xenobiotics that change CAS clearance in the liver or kidney, may alter protein binding and may result in increased bioavailability.

The most commonly prescribed CAS in the United States is digoxin; other internationally available but much less commonly used preparations are digitoxin, ouabain, lanatoside C, deslanoside, and gitalin. CAS toxicity may also result from exposure to certain plants or animals. Documented plant sources of CAS include oleander (*Nerium oleander*); yellow oleander (*Thevetia peruviana*), which has been implicated in the suicidal deaths of thousands of patients in Southeast Asia[26], foxglove (*Digitalis* spp), lily of the valley (*Convallaria majalis*), dogbane (*Apocynum cannabinum*), and red squill (*Urginea maritima*). CAS poisoning may result from teas containing seeds of these plants and water and herbal products contaminated with plant CAS (see Chap. 43).[16,19,52,79,90,97,116] Toxicity also results from ingestion, instead of the intended topical application, of a purported aphrodisiac derived from the dried secretion of toads from the *Bufo* species, which contains a bufadienolide-class CAS.[10,12,13] Although there have been no reported human exposures, fireflies of the *Photinus* species (*P. ignitus*, *P. marginellus*, and *P. pyralis*) contain the CAS lucibufagin that is structurally a bufadienolides.[30,65]

CHEMISTRY

CAS contain an aglycone or "genin" nucleus structure with a steroid core and an unsaturated lactone ring attached at C-17. Cardiac glycosides contain additional sugar groups attached to C-3. The sugar residues confer increased water solubility and enhance the ability of the molecule to enter cells. Cardenolides are primarily plant-derived aglycones with a five-member unsaturated lactone ring. The bufadienolide and lucibufagin groups of CAS molecules are mainly animal derived (with such notable exceptions as scillaren from red squill) and contain a six-member unsaturated lactone ring. When the aglycone digoxigenin is linked to one or more hydrophilic sugar (digitoxoses) moieties at C-3, it forms digoxin, a cardiac glycoside. The aglycone of digitoxin differs from that of digoxin by the lack of a hydroxyl group on C-12, and ouabain differs from digoxin by both the absence of a hydroxyl group on C-12 and the addition of hydroxyl groups on C-1, -5, -10, and -11. The cardioactive components in toad secretions are genins and lack sugar moieties.

PHARMACOKINETICS

The correlation between clinical effects and serum concentrations is based on steady-state concentrations, which are dependent on many absorption, distribution, and elimination factors (Table 64–1). Although not proven, other CAS likely follow the distribution pattern of digoxin or digitoxin such that obtaining a serum concentration before 6 hours after ingestion (the time at which tissue concentration peak) gives a misleadingly high serum concentration resulting from its bimodal distribution. After therapeutic dosing, the intravascular distribution and elimination of digoxin from the plasma are best described using a two-compartment model that is achieved over approximately 36 to 48 hours in patients with normal renal function. The distribution or α-phase represents the rapid decrease of drug concentration intravascularly and is dependent on whether the method of administration

TABLE 64–1. Pharmacology of Selected Cardioactive Steroids

Pharmacology	Digoxin	Digitoxin
Onset of Action		
PO	1.5–6 h	3–6 h
IV	5–30 min	30 min–2 h
Maximal effect		
PO	4–6 h	6–12 h
IV	1.5–3 h	4–8 h
Intestinal absorption	40%–90% (mean, 75%)	>95%
Plasma protein binding	25%	97%
Volume of distribution	5–7 L/kg (adults)	0.6 L/kg (adults)
	16 L/kg (infants)	
	10 L/kg (neonates)	
	4–5 L/kg (adults with renal failure)	
Elimination half-life	1.6 days	6–7 days
Route of elimination	Renal (60%–80%), with limited hepatic metabolism	Hepatic metabolism (80%)
Enterohepatic circulation	7%	26%.

is intravenous (IV) or oral (PO). An exponential decline occurs as the drug is rapidly distributed from the blood to the peripheral tissues, with a 30-minute distribution half-life. During the distribution phase, most of the intravascular CAS leaves the blood and is found in the tissues, resulting in a large volume of distribution (Vd) (eg, the Vd of digoxin is 5–7 L/kg with therapeutic use). The β or elimination phase with a half-life (for digoxin) of approximately 36 hours represents the drug's total-body clearance, which is achieved primarily by the kidneys (70% in a person with normal renal function).[17,46]

After a massive acute digoxin overdose, the half-life may be shortened to as little as 13 to 15 hours because elevated serum concentrations result in greater renal clearance before distribution to the tissues.[51,111] Even with therapeutic administration of CAS, adjustments to the dosing regimen must be made to avert toxicity caused by the physiologic changes associated with aging, including hypothyroidism, chronic hypoxemia with alkalosis, and decreased creatinine clearance. Physiologic changes in CAS kinetics occur with functional decline of the liver, kidney, and heart and dynamics with electrolyte abnormalities, including hypomagnesemia, hypercalcemia, hypernatremia, and commonly hypokalemia. Therefore, serum concentrations should be monitored to avoid inadvertent toxicity. Hypokalemia resulting from a variety of mechanisms, such as the use of loop diuretics, poor dietary intake, diarrhea, and the administration of potassium-binding resins, enhances the effects of CAS on the myocardium and is associated with dysrhythmias at lower serum CAS concentrations. Chronic hypokalemia reduces the number of Na^+-K^+-adenosine triphosphatase (ATPase) units in skeletal muscle, which may alter drug effects.[63]

Drug interactions between digoxin and quinidine, verapamil, diltiazem, carvedilol, amiodarone, and spironolactone are common.[20,23,45,68,93] These interactions occur because of a reduction in the protein binding of the CAS, increasing availability to the tissues; a reduction in excretion as a consequence of a decrease in renal perfusion; or as a result of interference with secretion by the kidneys and intestines because of inactivation of P-glycoproteins. In approximately 10% to 15% of

patients receiving digoxin, a significant amount of digoxin is inactivated in the gastrointestinal (GI) tract by enteric bacterium, primarily *Eubacterium lentum.* Inhibition of this inactivation by the alteration of the GI flora by many antibiotics, particularly the macrolide antibiotics, may result in increased bioavailability[73] and therefore may produce as much as a twofold increase in serum CAS concentration.[92]

MECHANISMS OF ACTION AND PATHOPHYSIOLOGY

■ ELECTROPHYSIOLOGIC EFFECTS ON INOTROPY

Although incompletely understood, it appears that CAS increase the force of contraction of the heart (positive inotropic effect) by increasing cytosolic Ca^{2+} during systole. Both Na^+ and Ca^{2+} ions enter and exit cardiac muscle cells during each cycle of depolarization and contraction–repolarization and relaxation. Sodium entry heralds the start of the action potential (phase 0) and carries the inward, depolarizing positive charge. Calcium subsequently enters the cardiac myocyte through L-type calcium channels during late phase 0 and the plateau phase of the action potential, and this Ca^{2+} triggers the release of more Ca^{2+} into the cytosol from the sarcoplasmic reticulum. During repolarization and relaxation (diastole), Ca^{2+} is both pumped back into the sarcoplasmic reticulum by a local Ca^{2+}-ATPase and is pumped extracellularly by an Na^+-Ca^{2+} antiporter (Fig. 64–1; see Chap. 23).[78]

CAS inhibit active transport of Na^+ and K^+ across the cell membrane during repolarization by binding to a specific site on the extracellular face of the α-subunit of the membrane Na^+-K^+-ATPase. This inhibits the cellular Na^+ pump activity, which decreases Na^+ extrusion and increases Na^+ in the cytosol, thereby decreasing the transmembrane Na^+ gradient. Because the Na^+-Ca^{2+} antiporter derives its power not from adenosine triphosphate (ATP) but rather from the Na^+ gradient generated by the Na^+-K^+ transport mechanism,[29] the dysfunction of the Na^+-K^+-ATPase pump reduces Ca^{2+} extrusion from the cell. The additional cytoplasmic Ca^{2+} enhances the Ca^{2+}-induced Ca^{2+} release from the sarcoplasmic reticulum during systole and by this mechanism increases the force of contraction of the cardiac muscle. Additional mechanisms of action are being explored and include creation of transmembrane calcium channels by cardioactive glycosides.[1]

■ EFFECTS ON CARDIAC ELECTROPHYSIOLOGY

At therapeutic serum concentrations, CAS increase automaticity and shorten the repolarization intervals of the atria and ventricles (Table 64–2). There is a concurrent decrease in the rate of depolarization and conduction through the sinoatrial (SA) and atrioventricular (AV) nodes, respectively. This is mediated both indirectly via an enhancement in vagally mediated parasympathetic tone and directly by depression of myocardial tissue. These changes in nodal conduction are reflected on the electrocardiogram (ECG) by a decrease in ventricular response rate to suprajunctional rhythms and by PR interval prolongation (the latter is part of digitalis effect). The effects of CAS on ventricular repolarization are related to the elevated intracellular resting potential caused by the enhanced availability of Ca^{2+} and manifest on the ECG as QT interval shortening and ST segment and T-wave forces opposite in direction to the major QRS forces. The last effect results in the characteristic scooping of the ST segments (referred to as the *digitalis effect*) (Fig. 64–2).

Excessive increases in intracellular Ca^{2+} caused by toxic CAS effects result in delayed afterdepolarizations. These are fluxes in membrane potential caused by spontaneous Ca^{2+}-induced Ca^{2+} release, which is caused by the excess intracellular Ca^{2+} and appear on the ECG like
FIGURE 64–1. Pharmacology and toxicology of the cardioactive steroids (CAS). (A) Normal depolarization. Depolarization occurs after the opening of fast Na+ channels; the increase in intracellular potential opens voltage-dependent Ca2+ channels, and the influx of Ca2+ induces the massive release of Ca2+ from the sarcoplasmic reticulum, producing contraction. (B) Normal repolarization. Repolarization begins with active expulsion of Na+ ions in exchange for K+ using an ATPase. This electrogenic (3 Na+ for 2 K+) pump creates an Na+ gradient that is used to expel Ca2+ via an antiporter (NCX). The sarcoplasmic reticulum resequesters its Ca2+ load via a separate ATPase. (C) Pharmacologic CAS. Digitalis inhibition of the Na+-K+-ATPase raises the intracellular Na+ content, preventing the antiporter from expelling Ca2+ in exchange for Na+. The net result is an elevated intracellular Ca2+, resulting in enhanced inotropy through enhanced SR calcium release. (D) Toxic CAS. Excessive elevation of the intracellular Ca2+ elevates the resting potential, producing myocardial sensitization, and predisposing to dysrhythmias. The addition of exogenous Ca2+ may overwhelm the capacity of the sarcoplasmic reticulum to sequester this ion, resulting in dysrhythmia or myocardial dysfunction.

U waves. Occasionally, these may initiate a cellular depolarization that manifests as a premature ventricular contraction (see Chap. 23).[28,60]

Hypokalemia inhibits Na+-K+-ATPase activity and contributes to the pump inhibition induced by CAS, enhances myocardial automaticity, and increases myocardial susceptibility to CAS-related dysrhythmias.

This may be partly a result of decreased competitive inhibition between the CAS and potassium at the Na+-K+-ATPase exchanger.[95] Severe hypokalemia (<2.5 mEq/L) reduces the rate of sodium-potassium pump function, slowing the pump and exacerbating concomitant sodium-potassium pump inhibition by the CAS.[60]

TABLE 64–2. Electrophysiologic Effects of Cardioactive Steroids on the Myocardium

	Atria and Ventricles	AV Node	Electrocardiogram
Excitability	↑	–	Extrasystoles, tachydysrhythmias
Automaticity	↑	–	Extrasystoles, tachydysrhythmias
Conduction velocity	↓	↓	↑ PR interval, AV block
Refractoriness	↓	↑	↑ PR interval, AV block, decreased QT interval

AV, atrioventricular.

■ EFFECTS OF CARDIOACTIVE STEROIDS ON THE AUTONOMIC NERVOUS SYSTEM

CAS affect the parasympathetic system by increasing the release of acetylcholine from vagal fibers,[75,114] possibly through augmentation of intracellular calcium. CAS affect the sympathetic system by increasing efferent sympathetic discharge,[85,109] which may exacerbate dysrhythmias.

CLINICAL MANIFESTATIONS

Although there are differences in the signs and symptoms of acute and chronic CAS poisoning, adults and children have similar manifestations when poisoned.

■ NONCARDIAC MANIFESTATIONS

Acute Toxicity An asymptomatic period of several minutes to several hours may follow a single administered toxic dose of CAS. The first symptom is typically nausea, vomiting, or abdominal pain. Central nervous system effects of acute toxicity may include lethargy, confusion, and weakness that are not caused by hemodynamic changes.[16] The absence of nausea and vomiting several hours after exposure makes acute CAS poisoning unlikely.

Chronic Toxicity Chronic toxicity is often difficult to diagnose as a result of its insidious development and protean manifestations, including weakness, anhedonia, and loss of appetite. Symptoms may also include those that occur with acute poisonings; however, they are often less obvious. GI findings include nausea, vomiting, abdominal pain, and weight loss. Neuropsychiatric disorders include delirium, confusion, drowsiness, headache, hallucinations, and (rarely) seizures.[16,38,40] Visual disturbances include transient amblyopia, photophobia, blurring, scotomata, photopsia, decreased visual activity, and aberrations of color vision (chromatopsia), such as yellow halos (xanthopsia) around lights.[69,70]

Electrolyte Abnormalities Elevated serum potassium concentrations frequently occur in patients with acute CAS poisoning.[60,63] Hyperkalemia has important prognostic implications because the serum potassium concentration is a better predictor of lethality than either the initial ECG changes or the serum CAS concentration.[5,6] In a study of 91 acutely digitoxin poisoned patients conducted before digoxin-specific Fab was available, approximately 50% of the patients with serum potassium concentrations of 5.0 to 5.5 mEq/L died. Although a serum potassium concentration lower than 5.0 mEq/L was associated with no deaths, all of the 10 patients with serum potassium concentration above 5.5 mEq/L died.[5] Elevation of the serum potassium concentration after administration of CAS is a result of CAS inhibition of the Na^+-K^+-ATPase pump, which results in the inhibition of potassium uptake in exchange for Na^+ by skeletal muscle (the largest potassium reservoir). Hyperkalemia probably causes further hyperpolarization of myocardial conduction tissue, increasing AV nodal block, thereby exacerbating CAS-induced bradydysrhythmias and conduction delays.[60] However, correction of the hyperkalemia alone does not increase patient survival;[5] it is a marker for, but not the cause of, the morbidity and mortality associated with CAS poisoning. The interrelationships between intracellular and extracellular potassium and CAS therapy are complex and incompletely understood.

■ CARDIAC MANIFESTATIONS

General The alterations in cardiac rate and rhythm occurring with CAS poisoning may result in nearly any dysrhythmia. The exception is that a rapidly conducted supraventricular tachydysrhythmia is not likely attributable to the prominent depressive effect of CAS on the AV node. In 10% to 15% of cases, the first sign of toxicity is the appearance of an ectopic ventricular rhythm.[94] Although no single dysrhythmia is pathognomonic of CAS toxicity, toxicity should be suspected when there is evidence of increased automaticity in combination with impaired conduction through the SA and AV nodes.[60] Bidirectional ventricular tachycardia is nearly diagnostic, although it may also occur with poisoning by aconitine and other uncommon xenobiotics[105] (see Fig. 22–19). Dysrhythmias result from the complex electrophysiologic influences on both the myocardium and conduction system of the heart resulting from direct, vagotonic, and other autonomic actions of the CAS.

The effects of digoxin vary with dose and differ depending on the type of cardiac tissue involved. The atrial and ventricular myocardial tissues exhibit increased automaticity and excitability, resulting in extrasystoles and tachydysrhythmias. Conduction velocity is reduced in both the atrial conducting system and nodal tissue, resulting in an increased PR interval and AV nodal block. Indeed, AV junctional blocks of varying degrees associated with increased ventricular automaticity are the most common cardiac manifestations, occurring in 30% to 40%, of patients with CAS toxicity.[76] AV dissociation may result from suppression of the dominant pacemaker with escape of a secondary pacemaker or from inappropriate acceleration of a ventricular pacemaker. Hypotension, shock, and cardiovascular collapse may ensue. Table 64–3 summarizes these phenomena.

Acute Toxicity Many cardiac dysrhythmias are associated with CAS toxicity. These dysrhythmias are unified by a sensitized myocardium and a depressed AV node (see Table 64–3). The initial bradydysrhythmia results from increased vagal tone at the SA and AV nodes and is often responsive to atropine.

TABLE 64–3. Cardiac Dysrhythmias Associated with Cardioactive Steroid Poisoning

Myocardial irritability causing dysrhythmias

Atrial flutter and atrial fibrillation with atrioventricular (AV) block

Bidirectional ventricular tachycardia

Delayed after no space depolarizations

Nonparoxysmal atrial tachydysrhythmias with AV block

Nonsustained ventricular tachycardia

Premature and sustained ventricular contractions

Ventricular bigeminy

Ventricular fibrillation

Primary conduction system dysfunction causing dysrhythmias

AV dissociation

Exit blocks

High-degree AV block

His-Purkinje dysfunction

Junctional tachycardia

Sinoatrial (SA) nodal arrest

Sinus bradycardia.

Chronic Toxicity Bradydysrhythmias that appear later in acute poisonings and with chronic CAS toxicity occur by direct actions on the heart and often are minimally responsive to atropine, if at all. Ventricular tachydysrhythmias are more common in patients with chronic or late acute poisoning.

DIAGNOSTIC TESTING

Properly obtained and interpreted serum digoxin concentrations aid significantly in the management of patients with suspected digoxin toxicity, as well as in the management of patients poisoned by several other CAS. Although most institutions report a therapeutic range for serum digoxin concentration from 0.5 to 2.0 ng/mL (SI units, 1.0-2.6 nmol/mL), current research suggests lowering the upper limit to 1.0 ng/mL maintains benefit while decreasing the risk of toxicity.[98,107] In addition to determining a serum CAS concentration, care must be taken to interpret the concentration as a correlate with the clinical condition of the patient; the interval between the last dose and the time the blood sample was taken; and the presence of other metabolic abnormalities, including hypokalemia, hypomagnesemia, hypercalcemia, hypernatremia, alkalosis, hypothyroidism, and hypoxemia and the use of xenobiotics such as amiodarone, calcium channel blockers, catecholamines, quinidine, and diuretics.

Although CAS poisoning is multifactorial and it is inappropriate to use the upper limit of the therapeutic range of digoxin as the sole indicator of toxicity,[101] there is a significant correlation between a patient's clinical condition and their serum concentration. In general, patients with pharmaceutical CAS toxicity have mean serum concentrations above 2 ng/mL for digoxin and above 40 ng/mL for digitoxin measured 6 hours after the last dose.[59] The significance of a serum concentration depends on when the value is obtained in relation to an acute ingestion and the distribution phase of the drug; a value of 15 ng/mL of digoxin is more ominous 6 hours after

an ingestion than 1 hour after an ingestion. Additionally, there is often an overlap in serum digoxin concentrations between toxic and nontoxic patients.

In most hospitals, "digoxin levels" are the only estimation available to physicians in the acute setting when evaluating a patient for presumed non-digoxin CAS poisoning. The polyclonal assays typically used in most institutions frequently, but unpredictably, cross-react with other plant- or animal-derived CAS. Although a monoclonal digoxin immunoassay accurately quantifies serum digoxin, an elevated digoxin concentration in the correct clinical setting may qualitatively assist in making a presumptive diagnosis of non-digoxin CAS exposure (see Chaps. 43 and 118).[14,88] For example, using various techniques, including high-performance liquid chromatography (HPLC) and monoclonal and polyclonal antibody analysis, "digoxin" concentrations are recorded from serum to which has been added oleandrin and oleandrigenin from *Nerium oleander* or from patients exposed to *Thevetia peruviana* (yellow oleander) or toad-secreted bufadienolides.[10,26,54] With the use of more specific analytic technology, patients with CAS poisoning from plant- or animal-derived CAS may have low or nonexistent digoxin concentrations (see Chaps. 43 and 118).

Serum concentrations of digoxin are measured in one of two ways: free digoxin and total digoxin. The most common method of quantifying total digoxin in the serum is by fluorescence polarization immunoassay (FPIA). Under normal circumstances, measuring total digoxin in the serum is sufficient because serum concentrations are predictive of cardiac concentrations.[24] However, after the use of digoxin-specific Fab (which remains almost entirely within the intravascular space [Vd, 0.40 L/kg]), there is a large elevation in total CAS concentrations because the CAS is drawn from the tissues and complexes with the antibody fragment, thus trapping the CAS in the intravascular space. When this bulk movement is achieved by binding with Fab fragments, a tremendous increase, often approaching an order of magnitude, in total serum digoxin concentrations occurs. In this situation, laboratory manipulation methods to detect only the unbound digoxin and allow the quantification of free digoxin in the serum include ultrafiltration and equilibrium dialysis.[36] Paradoxically, excess digoxin antibody may cause a false elevation in digoxin concentration (see Chap. 6).

■ ENDOGENOUS DIGOXIN-LIKE IMMUNOREACTIVE SUBSTANCE

Some patients who are not receiving a CAS may nevertheless have a positive digoxin assay result as a result of an endogenous substance that is structurally and functionally similar to the prescribed CAS.[45] This finding is described in patients with increased inotropic need or reduced renal clearance, including neonates[117]; patients with renal insufficiency,[11,41,53] liver disease,[81] subarachnoid hemorrhage,[123] congestive heart failure,[39,102] insulin-dependent diabetes,[35] stress,[40,118] acromegaly,[26] or hypothermia[117]; after strenuous exercise[118]; and in pregnancy.[32,42,50] An endogenous Na+-K+-ATPase inhibiting dihydropyrone-substituted bufadienolide CAS has been isolated from human placenta.[33] It differs from the toad bufadienolides solely by a single double-bond pyrone ring. Because bufadienolides are not normally found in either healthy humans or edible plants, a synthetic pathway to produce dihydropyrone-substituted steroids in humans may be responsible for this endogenous digoxin-like immunoreactive substance (EDLIS). Further research is necessary to confirm this pathway.[50] The clinician suspecting this problem should consult the clinical laboratory.[34] Clinical observations indicate that the serum digoxin concentration contributed by EDLIS is usually less than 2 ng/mL. Other endogenous substances, such as bilirubin,[81] and exogenous substances, such as spironolactone,[103] may also cross-react with the digoxin assay and cause a false-positive result.

THERAPY

ACUTE MANAGEMENT OVERVIEW

Initial treatment of a patient with acute CAS poisoning includes providing general care, (eg, GI decontamination, monitoring for dysrhythmias, measuring electrolyte and digoxin concentrations) and definitive care (eg, administering digoxin-specific antibody fragments). Secondary care includes treating complications such as dysrhythmias and electrolyte abnormalities.

GASTROINTESTINAL DECONTAMINATION

The initial treatment should be directed toward prevention of further GI absorption. Only rarely should emesis or lavage may be considered because efficacy is limited secondary to rapid absorption from the gut and to the emetic effects of the drug itself. Patients with chronic ingestion also do not usually benefit from these GI decontamination techniques because of the limited availability of drug in the GI tract for removal. Because many CAS, such as digitoxin and digoxin, are recirculated enterohepatically and enteroenterically, both late and repeated activated charcoal administration (1 g/kg of body weight every 2–4 hours for up to four doses) may be beneficial in reducing serum concentrations.[17,21,67,71,86,121] Similar to activated charcoal, steroid-binding resins, such as cholestyramine and colestipol,[49,91] may prevent reabsorption of CAS from the GI tract and reduce the serum half-life by interrupting both enteroenteric and enterohepatic circulation, and they may be used when digoxin-specific Fab is not immediately available or when renal function is inadequate.[21,49]

ADVANCED MANAGEMENT

Digoxin-Specific Antibody Fragments The definitive therapy for patients with life-threatening CAS toxicity is to administer digoxin-specific antibody fragments.[2,34,36,87,90,97,106,112,125] Purified digoxin-specific Fab causes a sharp decrease in free serum digoxin concentrations; a concomitant but clinically unimportant, massive increase in total serum digoxin; an increase in renal clearance of CAS; and a decrease in the serum potassium concentration.[2] In addition, the administration of digoxin-specific Fab is pharmacoeconomically advantageous.[22] Although the xenobiotic itself is relatively expensive, its expense is far outweighed by obviating the need, risk, and expense of long-term intensive care unit stays and of repetitive evaluation of potassium and digoxin concentrations. Table 64–4 lists the indications for administering digoxin-specific Fab. Extensive discussion is found in Antidotes in Depth A20: Digoxin-Specific Antibody Fragments (Fab).

Other Cardiac Therapeutics Secondary xenobiotics used in patients with symptomatic CAS exposures include the use of atropine for supraventricular bradydysrhythmias or high degrees of AV block. Atropine dosing is 0.5 mg administered IV to an adult or 0.02 mg/kg with a minimum of 0.1 mg to a child. Atropine should be titrated to block the vagotonic effects of the CAS. The dose may be repeated at 5-minute intervals if necessary. Therapeutic success is unpredictable because the depressant actions of CAS are mediated only partly through the vagus nerve.

Phenytoin and lidocaine are other drug therapies that are rarely used (secondary to Fab fragments obviating their utility) for the management of CAS-induced ventricular tachydysrhythmias and ventricular irritability. These xenobiotics depress the enhanced ventricular automaticity without significantly slowing, and perhaps enhancing, AV nodal conduction.[96] In fact, phenytoin may reverse digitalis-induced prolongation of AV nodal conduction while suppressing digitalis-induced ectopic tachydysrhythmia without diminishing myocardial contractile forces.[48] In addition, phenytoin may terminate supraventricular dysrhythmias
